In the spirit of "what is measured improves," most states require public reporting of health care–associated infection. Thirty-six states require health care facilities in their jurisdictions to report to CDC's National Healthcare Safety Network (NHSN) (*https://www.cdc.gov/nhsn/index.html*) reporting system, which provides uniform definitions and facilitates transmission of data. Beginning in 2011, CMS required hospitals to report health care–associated infection data to NHSN to qualify for their full annual payment update. In subsequent years, CMS included health care–associated infection reporting requirements to NHSN as part of the Hospital Value Based Purchasing Program and Hospital Acquired Conditions Reduction Program. Increasing reliance on NHSN led to participation by >24,000 facilities (~5500 of the ~5700 acute-care hospitals in the United States, ~620 LTACHs, ~432 inpatient rehabilitation facilities, ~8150 outpatient dialysis facilities, ~5600 ambulatory surgery centers, and ~3800 skilled nursing facilities). This level of participation provides a nationwide view of health care–associated infections and antimicrobial resistance and potential access to national rates of antimicrobial use.

Results of surveillance are expressed as rates, qualified when possible by duration of risk, site of infection, patient population, and exposure to risk factors. To account for some of these variables, the CDC now uses a standardized infection ratio (SIR; *https://www.cdc.gov/nhsn/pdfs/ps-analysis-resources/nhsn-sir-guide.pdf*) as part of NHSN rate reporting. Denominators often include the number of patients exposed to a specific risk or the number of intervention days (e.g., 1000 patient-days on a ventilator). As use of invasive devices such as indwelling bladder catheters has purposely been decreased, the denominators have become smaller, but patients who still require such devices (potential numerators) often are at intrinsically higher risk—a situation that may paradoxically increase rates when device-days account for the denominator.

Temporal trends in rates should be reviewed, and rates should be compared with regional and national benchmarks that incorporate the SIR. Interhospital comparisons still may be misleading because of the wide range in risk factors and severity of underlying illnesses. Process measures usually do not require risk adjustment but some, such as adherence to hand hygiene, can be difficult to measure, leading to development of a number of innovative electronic monitoring systems that track hand-hygiene adherence. Although this approach is exciting, sustained improvements in rates remain to be seen. Major morbidity and costly outcomes (e.g., cardiac surgery wound infection rates) can identify outlier hospitals (e.g., in the highest deciles of risk) for further evaluation. Most importantly, temporal analysis of a hospital's infection rates—comparison to self over time—can help to determine if control measures are succeeding and where increased efforts should be focused.

EPIDEMIOLOGIC BASIS AND GENERAL MEASURES FOR PREVENTION AND CONTROL

Nosocomial infections follow basic epidemiologic patterns that direct prevention and control measures. Nosocomial pathogens have reservoirs, are transmitted by largely predictable routes, and require

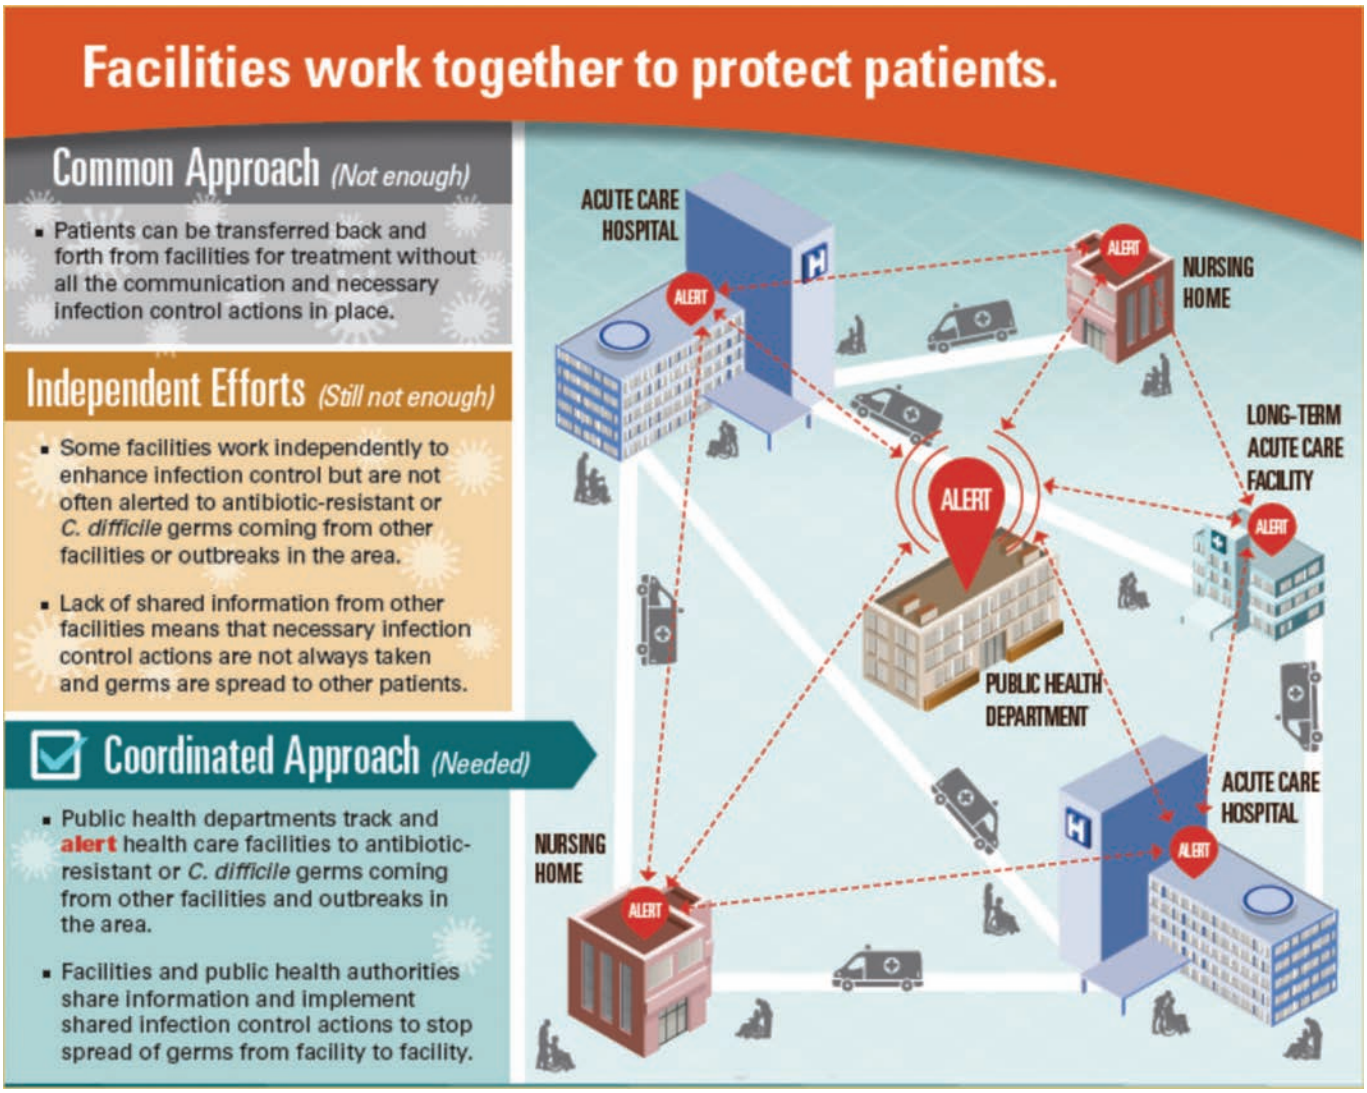

FIGURE 142-1 Regional spread and control of antimicrobial-resistance. *(From www.cdc.gov/vitalsigns/stop-spread.)*

susceptible hosts. Reservoirs and sources exist in the inanimate environment (e.g., antibiotic-resistant bacteria or *Clostridioides difficile* spores on frequently touched surfaces) and in the animate environment (e.g., infected or colonized patients and hospital visitors). The mode of transmission usually is either cross-infection (e.g., indirect spread from one patient to another on the inadequately cleaned hands of hospital personnel) or autoinoculation (e.g., aspiration of oropharyngeal flora); patient hand colonization with problem microbes also may contribute to self, environmental, and health care worker contamination. Occasionally, pathogens (e.g., group A streptococci and many respiratory viruses) are spread from person to person via large infectious droplets released by coughing or sneezing. Much less common—but often devastating in terms of epidemic risk—is true airborne spread of small or droplet nuclei (as in nosocomial chickenpox or measles) or common-source spread (e.g., by contaminated IV fluids). Factors that increase patient susceptibility include diabetes, renal insufficiency, and other comorbidities; extremes of age; abnormalities of innate defense (e.g., due to genetic polymorphisms; see **Chap. 466**); medical–surgical interventions that compromise host defenses; and epidemiologic issues, such as "colonization pressure" created by neighboring patients.

Hospital infection-control programs determine general and specific control measures based on the "causal pathway" of spread **(Fig. 142-2)**. Given the prominence of cross-infection, hand hygiene is cited as the most important preventive measure. Health care worker adherence to hand hygiene is historically low. Reasons cited include inconvenience, time pressures, and skin damage from frequent washing. Sinkless alcohol rubs are quick and highly effective, and their emollients may improve hand condition. Use of alcohol hand rubs between patient contacts is recommended for all health care workers except when hands are visibly soiled or after care of a patient who is part of an outbreak of infection with *C. difficile*, whose spores resist killing by alcohol. In these cases, washing with soap and running water is recommended.

Adequate staffing is essential in acute and long-term settings to allow for attention to hand hygiene and asepsis during patient care and to provide thorough environmental cleaning.

NOSOCOMIAL AND DEVICE-RELATED INFECTIONS

The five major nosocomial infection sites are urinary, lower respiratory, surgical wound, bloodstream, and gastrointestinal (mostly *C. difficile*). The percentage of infections due to invasive devices—25–50%—has fallen in recent years, reflecting marked improvements in the use and design of devices. Intensive education, bundling of evidence-based interventions **(Table 142-1)**, and use of checklists to facilitate adherence have reduced infection rates, largely through improved asepsis in handling and earlier removal of invasive devices. This progress demonstrates both the effectiveness of infection-control programs and the need to focus surveillance and interventions on control of the other 50–75% of health care–associated infections.

URINARY TRACT INFECTIONS

Urinary tract infections (UTIs) due to indwelling bladder catheters affect ~160,000 patients annually, which represents a deceased risk over the past several years, and account for ~10% of nosocomial infections;

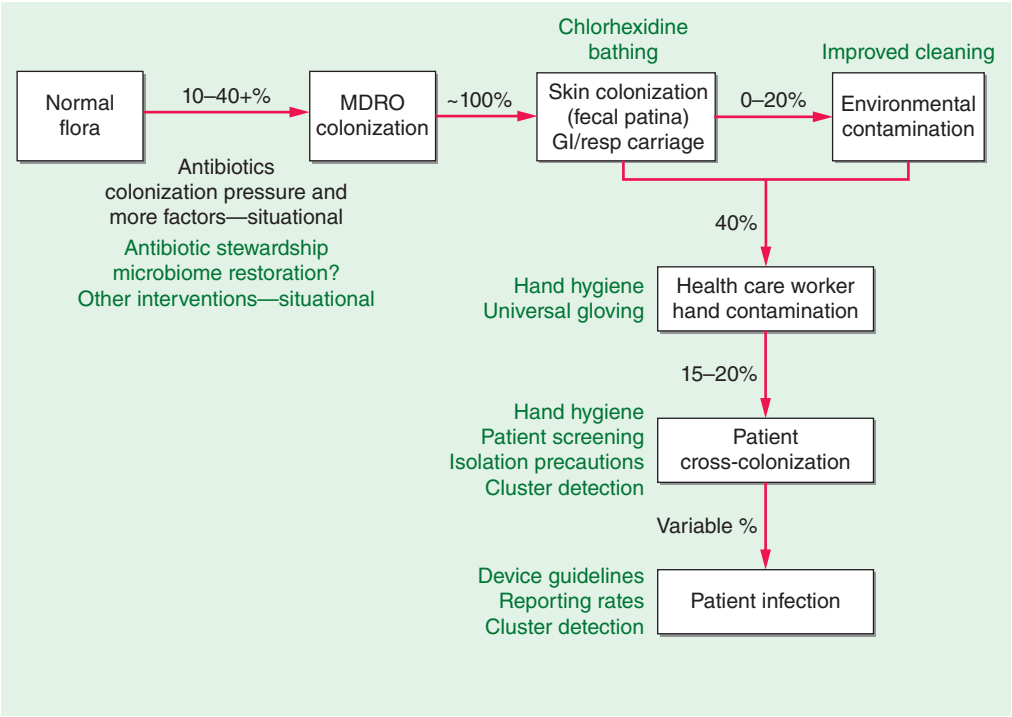

FIGURE 142-2 Basic infection control interventions on the causal pathway of development and spread of multidrug-resistance organisms (MDROs) in hospitals and long-term care facilities. The boxes show the status of patients, healthcare workers, and the environment; the %s are the likelihood of progressing along the pathway; and the recommendations in green are potential interventions to prevent that progression. GI/Resp, gastrointestinal/respiratory.

up to 3% of bacteriuric patients develop bacteremia. Although most UTIs contribute marginally to prolongation of hospital stay or cost, a major concern is the role of infected urine as a key reservoir of antibiotic-resistant bacteria and *Candida*. Most nosocomial UTIs have been associated with preceding instrumentation or indwelling bladder catheters, which create a 3–7% risk of infection each day, although in some recent surveys, a majority of UTIs were not device associated.

UTIs generally are caused by pathogens that spread up the periurethral space from the patient's perineum or gastrointestinal tract—the most common pathogenesis in women—or via intraluminal contamination of urinary catheters, usually due to cross-infection by caregivers who are emptying drainage bags. Pathogens come occasionally from inadequately disinfected equipment and rarely from contaminated supplies. The frequency with which asymptomatic UTIs occur, especially in older women, may inflate infection rates due to erroneous assumptions that the urinary tract is the source of infection in a febrile hospitalized patient.

With organized control programs to monitor key performance measures (Table 142-1), hospitals can reduce rates of catheter use and UTI. In addition, in a multicenter trial, daily chlorhexidine bathing lessened UTI risk in catheterized men. A condom catheter for men without bladder obstruction may be more acceptable than an indwelling catheter and may lessen the risk of UTI if maintained carefully. A new prevention strategy for women is use of flexible external catheters that are positioned between the labia and buttocks to wick away urine via low-pressure suction. Older strategies have included the use of topical meatal antimicrobial agents, drainage bag disinfectants, and anti-infective catheters, none of which is considered routine. The role of suprapubic catheters in preventing infection is not well defined.

Treatment of UTIs is based on the results of quantitative urine cultures **(Chap. 135)**. The most common pathogens are *Escherichia coli*, nosocomial gram-negative bacilli, enterococci, and *Candida*. Recovery of *Staphylococcus aureus* from urine cultures may result from hematogenous seeding and indicate an occult systemic infection. In patients with chronic indwelling bladder catheters, especially those in long-term-care facilities, the catheter microbiome—microorganisms living on encrustations within the catheter lumen—may differ from actual urinary tract pathogens. Thus, for suspected UTI in the setting of chronic catheterization (especially in women), it is useful to replace the bladder catheter and to obtain a freshly voided urine specimen.

PNEUMONIA

Pneumonia accounts for ~28% of nosocomial infections; with improvements in device and patient care—most importantly, lessening patient time on ventilators—ventilator-associated pneumonias (VAPs) have become less frequent and now account for only ~25–35% of all nosocomial lower respiratory tract infections. Most cases of bacterial nosocomial pneumonia are caused by aspiration of endogenous or hospital-acquired oropharyngeal or gastric flora. Nosocomial pneumonias have been associated with more deaths than have infections at any other body site. However, attributable mortality rates suggest that the risk of dying from nosocomial pneumonia is affected greatly by other factors, including comorbidities, inadequate antibiotic treatment, and the involvement of specific pathogens (particularly *Pseudomonas aeruginosa* or *Acinetobacter*). Surveillance and accurate diagnosis of pneumonia have been problematic in hospitals because many patients, especially those in the intensive care unit (ICU), have abnormal chest roentgenographs, fever, and leukocytosis potentially attributable to multiple causes. This diagnostic uncertainty has led to a refocus from VAP to ventilator-associated events (VAEs), conditions, and complications, for which worsening physiologic parameters, such as oxygenation, are key metrics. VAEs occur in as many as 5–10% of patients using mechanical ventilators.

There is increasing interest in health care–associated pneumonia in patients who are on general wards or not receiving mechanical ventilation. Viral pneumonias, which are particularly important in pediatric and immunocompromised patients, are discussed in the virology section and in **Chap. 126**.

Risk factors for nosocomial pneumonia include those events that increase colonization by potential pathogens (e.g., prior antimicrobial therapy, contaminated ventilator equipment, or decreased gastric acidity, which also may increase risk of colonization by antibiotic-resistant bacteria); those that facilitate aspiration of oropharyngeal contents into the lower respiratory tract (e.g., intubation, decreased levels of consciousness, or presence of a nasogastric tube); and those that reduce pulmonary defense mechanisms and permit overgrowth of aspirated

TABLE 142-1 Examples of Selected Components of Evidence-Based Bundled Interventions to Prevent Common Health Care–Associated Infections and Other Adverse Events[a]

Prevention of Central Venous Catheter Infections

Catheter insertion bundle

- Educate personnel about catheter insertion and care.
- Use chlorhexidine to prepare the insertion site.
- Use maximal barrier precautions and asepsis during catheter insertion.
- Consolidate insertion supplies (e.g., in an insertion kit or cart).
- Use a checklist to enhance adherence to the insertion bundle.
- Empower nurses to halt insertion if asepsis is breached.

Catheter maintenance bundle

- Cleanse patients daily with chlorhexidine.
- Maintain clean, dry dressings.
- Enforce hand hygiene among health care workers.
- Use aseptic technique when accessing transducers or vascular ports.

Ask daily: Is the catheter needed? Remove catheter if not needed or used.

Prevention of Ventilator-Associated Events

- Avoid mechanical ventilation whenever possible.
- Elevate head of bed to 30–45° to lessen aspiration risk.
- Decontaminate oropharynx regularly with chlorhexidine (controversial).
- Use aseptic care of all respiratory equipment.
- Consider using endotracheal tubes with channels for subglottic drainage of secretions.
- Give "sedation vacation" and assess readiness to extubate daily, which can shorten duration of intubation and of intensive care unit stays.
- Use deep-vein thrombosis prophylaxis (unless contraindicated).

Prevention of Surgical-Site Infections

- Choose a surgeon wisely.
- Treat *active* infections preoperatively.
- Administer prophylactic antibiotics within 1 h before surgery; discontinue within 24 h.
- Limit any hair removal to the time of surgery; use clippers or do not remove hair at all.
- Prepare surgical site with chlorhexidine-alcohol.
- Enforce operating room asepsis, e.g., minimize movement in-and-out of the room.
- Assess attention to technical surgical issues (e.g., avoiding open or prophylactic wound drains).
- Provide surveillance results to surgeons.

Prevention of Urinary Tract Infections

- Place bladder catheters only when absolutely needed (e.g., to relieve obstruction), not solely for the provider's convenience.
- Use aseptic equipment and technique for catheter insertion and urinary tract instrumentation.
- Minimize manipulation or opening of drainage systems; avoid catheter irrigation.
- Ask daily: Is the bladder catheter needed? Remove catheter if not needed.
- Use bladder scanners to avoid catheterization, e.g., for assessing urinary retention.

Prevention of Pathogen Cross-Transmission

- Cleanse hands with alcohol hand rub before and after all contacts with patients or their environments.

[a]See text for additional interventions to prevent device- and procedure-associated infections; checklists and personnel education have been recommended as management tools for each of the prevention bundles.

Source: Adapted from information presented at the following websites: *www.cdc.gov/hicpac/pubs.html; www.cdc.gov/HAI/index.html; www.ihi.org.*

pathogens (e.g., chronic obstructive pulmonary disease or upper abdominal surgery).

Several control measures can lessen risk for pneumonia (Table 142-1). Although the benefits of selective decontamination of the oropharynx and gut with nonabsorbable antimicrobial agents—a practice usually avoided in the United States because of concerns about antibiotic resistance—have been controversial, a randomized multicenter Dutch trial demonstrated lowered ICU mortality rates among patients on mechanical ventilation who underwent oropharyngeal decontamination. Nevertheless, reducing VAP rates often has not lessened overall ICU mortality, suggesting inadequacies of surveillance and that VAP often may be a marker for patients with an otherwise-heightened risk of death.

The most likely pathogens for nosocomial pneumonia and treatment options are discussed in **Chap. 126**. Of note, early-onset nosocomial pneumonia, which manifests within the first 4 days of hospitalization, is often caused by community-acquired pathogens such as *Streptococcus pneumoniae* and *Haemophilus* species, although some studies have challenged this view. Late-onset pneumonias commonly are due to *S. aureus*, *P. aeruginosa*, *Enterobacter* species, *Klebsiella pneumoniae*, or *Acinetobacter*. Shorter durations of treatment for nosocomial pneumonia can lessen emergence of resistant pathogens, and a negative nasal swab for methicillin-resistant *S. aureus* precludes the need to treat for this pathogen. In febrile patients (particularly those who have tubes inserted through the nares), occult bacterial sinusitis and otitis media should be considered.

SURGICAL-SITE (WOUND) INFECTIONS

Wound infections account for ~17% of nosocomial infections. The average wound infection has an incubation period of 5–7 days—longer than many postoperative stays. For this reason and because many procedures are now performed on an outpatient basis, the incidence of wound infections has become difficult to assess. These infections usually are caused by the patient's endogenous or hospital-acquired skin and mucosal flora and occasionally are due to airborne spread of skin squames that may be shed into the wound from members of the operating-room team or environmental sources. True airborne spread of infection is rare in operating rooms unless there is a disseminator (e.g., of group A streptococci or staphylococci) among the staff or air supply contamination (e.g., with mold). In general, the common risks for postoperative wound infection are related to the surgeon's technical skill, the patient's underlying conditions (e.g., diabetes mellitus, obesity) or advanced age, and inappropriate timing of antibiotic prophylaxis. Additional risks include the presence of drains, prolonged preoperative hospital stays, shaving of operative sites by razor the day before surgery, and prolonged duration of surgery.

The substantial global morbidity and costs associated with these infections have led to international guidelines (*http://www.who.int/gpsc/ssi-guidelines/en/*) in addition to existing national prevention programs and recommendations for bundling of preventive measures (Table 142-1). Preoperative administration of intranasal mupirocin to patients colonized with *S. aureus*, preoperative antiseptic bathing, intra- and postoperative oxygen supplementation, and attention to patients' blood glucose levels and body temperature have been controversial because of conflicting study results, but evidence seems mostly to favor these interventions. Recently debated issues include appropriate garb in operating rooms—less may be more—and the value of negative-pressure wound dressings.

The most common pathogens in postoperative wound infections are *S. aureus*, coagulase-negative staphylococci, and enteric and anaerobic bacteria. In rapidly progressing postoperative infections manifesting within 24–48 h of a surgical procedure, the level of suspicion regarding group A streptococcal or clostridial infection **(Chaps. 148 and 154)** should be high. Diagnosis of infections of prosthetic devices, such as orthopedic implants, may be complicated when pathogens are cloistered in prosthesis-adherent biofilms; cultures of sonicates from explanted prosthetic joints have been more sensitive. Treatment of postoperative wound infections requires adequate source control, i.e., drainage or surgical excision of infected or necrotic material, and antibiotic therapy aimed at the most likely or laboratory-confirmed pathogens.

INFECTIONS RELATED TO VASCULAR ACCESS AND MONITORING

Intravascular device–related bacteremias cause ~10–15% of nosocomial infections; central vascular catheters (CVCs) account for most of

these bloodstream infections, although peripheral catheters are underappreciated as a source of nosocomial bacteremia. National estimates have indicated that ~72,000 primary bloodstream infections occur in the United States each year. CVC infections have had estimated attributable mortality rates of 12–25%, an excess length of hospital stay of 7–15 days, and an estimated cost of $31,000–65,000 per episode; one-third to one-half of these episodes occurred in ICUs. However, infection rates have dropped steadily since the publication of guidelines by the Healthcare Infection Control Practices Advisory Committee (HICPAC) (*www.cdc.gov/hicpac/*). With increasing care of seriously ill patients in the community, vascular catheter–associated bloodstream infections acquired in outpatient settings are becoming more frequent. Broader surveillance for infections—outside ICUs and even outside hospitals—is more routine.

Catheter-related bloodstream infections derive largely from the cutaneous microbiome at the insertion site, with pathogens migrating extraluminally to the catheter tip, usually during the first week after insertion—a risk that has been lessened greatly by use of bundled catheter-insertion guidelines. In addition, contamination of the hubs of CVCs or of the ports of needle-less systems may lead to intraluminal infection over longer periods, particularly with surgically implanted or cuffed catheters. Intrinsic (during the manufacturing process) or extrinsic (on-site in a health care facility) contamination of infusate, although rare, is the most common cause of epidemic device-related bloodstream infection. The most common pathogens isolated from vascular device–associated bacteremias include coagulase-negative staphylococci, *S. aureus* (often resistant to methicillin), enterococci, nosocomial gram-negative bacilli, and *Candida*. Many pathogens, especially staphylococci, produce extracellular polysaccharide biofilms that facilitate attachment to catheters and provide sanctuary from antimicrobial agents.

Evidence-based bundles of control measures (Table 142-1) have been strikingly effective, eliminating almost all CVC-associated infections in some ICUs, and can be effective in low-income and middle-income, as well as in high-income, countries. Additional control measures include use of a chlorhexidine-impregnated patch at the skin-catheter junction; application of semitransparent access-site dressings (for ease of bathing and site inspection and protection of the site from secretions); daily bathing of ICU patients with chlorhexidine; avoidance of the femoral site for catheterization; and rotation of peripheral catheters—an underrecognized cause of staphylococcal bacteremia—to a new site at specified intervals (e.g., every 72–96 h) rather than as clinically indicated (a debatable recommendation that may be facilitated by use of an IV therapy team).

Controversial issues have included the role of gut translocation rather than vascular-access sites as a cause of primary bacteremia in immunocompromised patients and the implications for surveillance definitions; the best frequency for rotation of CVC sites (given that guidewire-assisted catheter changes at the same site do not lessen and can even increase infection risk); the relative risk posed by peripherally inserted central catheters (PICC lines); and the risk–benefit of prophylactic use of vancomycin, alcohol, or other solutions as catheter "locks"—concentrated anti-infective solutions instilled into the catheter lumen—for high-risk patients.

Vascular device–related infection is suspected on the basis of the appearance of the catheter site or the presence of fever or bacteremia without another source in patients with vascular catheters. The diagnosis is confirmed by the recovery of the same species of microorganism from peripheral-blood cultures and from semiquantitative or quantitative cultures of the vascular catheter tip. Cultures drawn from the CVC for diagnostic purposes are convenient but risk false-positive results (e.g., due to catheter hub contamination). When infusion-related sepsis is considered (e.g., because of the abrupt onset of fever or shock temporally related to infusion therapy), a sample of the infusate or blood product should be retained for culture.

Therapy for vascular access–related infection is directed at the pathogen recovered from the blood and/or infected site. Important considerations are the need for an echocardiogram (to evaluate the patient for endocarditis), the duration of therapy, and the need to remove potentially infected catheters. In one report, approximately one-fourth of patients with intravascular catheter–associated *S. aureus* bacteremia who were studied by transesophageal echocardiography had evidence of endocarditis; this test may be useful in determining the appropriate duration of treatment.

Detailed consensus guidelines for the management of intravascular catheter–related infections have been published and recommend catheter removal in most cases of bacteremia or fungemia due to nontunneled CVCs. When attempting to salvage a potentially infected catheter, some clinicians use the "antibiotic lock" technique, which may facilitate penetration of infected biofilms, in addition to systemic antimicrobial therapy (see *www.idsociety.org/Other_Guidelines/*).

ISOLATION TECHNIQUES

Written policies for isolation of infectious patients are a staple for infection-control programs. The CDC has guidelines for all components of health care, including acute-care hospitals and long-term, ambulatory, and home-care settings (see *www.cdc.gov/hicpac/pdf/isolation/Isolation2007.pdf*), as well as recommendations for the control of multidrug-resistant organisms.

Standard precautions are designed for the care of all patients in hospitals and aim to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources. These precautions include gloving and hand cleansing for potential contact with (1) blood; (2) all other body fluids, secretions, and excretions, whether or not they contain visible blood; (3) nonintact skin; and (4) mucous membranes. Depending on exposure risks, standard precautions also include use of masks, eye protection, and gowns.

Precautions for the care of patients with potentially contagious clinical syndromes (e.g., acute diarrhea) or with suspected or diagnosed colonization or infection by transmissible pathogens are based on probable routes of transmission: *airborne*, *droplet*, or *contact*, for which personnel don, at a minimum, N95 respirators, surgical face masks, or glove and gown, respectively. Sets of precautions may be combined for diseases that have more than one route of transmission (e.g., contact and airborne isolation for varicella).

Some prevalent antibiotic-resistant pathogens, particularly those that colonize the gastrointestinal tract (e.g., vancomycin-resistant enterococci [VRE] and even multidrug-resistant gram-negative bacilli such as strains of *K. pneumoniae* and other Enterobacteriaceae that produce carbapenemases [carbapenem-resistant Enterobacteriaceae, or CRE]), may be present on *intact* skin of patients in hospitals (the "fecal patina"). This issue has led some experts to recommend gloving for all contact with patients who are acutely ill and/or in high-risk units, such as ICUs or LTACHs, and daily bathing of all ICU and LTACH patients with chlorhexidine to remove this veneer of antibiotic-resistant bacteria. Wearing gloves does not replace the need for hand hygiene because hands sometimes (in up to 20% of interactions) become contaminated during wearing or removal of gloves.

Further, in response to the frequent spread of resistant pathogens in long-term care facilities, CDC recommends *enhanced barrier precautions*—use of gown and gloves for high-contact resident care activities that have been demonstrated to result in transfer of resistant strains to health care personnel (*https://www.cdc.gov/hai/containment/faqs.html*).

EPIDEMIC AND EMERGING PROBLEMS

Full-blown epidemics probably account for <5% of nosocomial infections, but mini-clusters of a few infections that result from time-limited gaps in asepsis may be more common. The investigation and control of nosocomial epidemics require that infection control personnel (1) develop a case definition, (2) confirm that an outbreak really exists (since apparent epidemics may actually be pseudo-outbreaks due to surveillance or laboratory artifacts), (3) review aseptic practices and disinfectant use, (4) determine the extent of the outbreak, (5) perform an epidemiologic investigation, which may require a case–control study to determine sources and modes of transmission, (6) work closely with microbiology personnel to culture for common sources or personnel carriers as appropriate and to provide molecular typing—by

pulsed-field gel electrophoresis (PFGE) or whole genome sequencing (WGS)—of epidemiologically important isolates, and (7) heighten surveillance to judge the effect of control measures. Control measures generally include reinforcing routine aseptic practices, hand hygiene, and environmental cleaning; surveillance for additional cases and ensuring appropriate isolation (and instituting cohort isolation and nursing if needed); and implementing further controls on the basis of the investigation's findings. Examples of some emerging and potential epidemic problems and control measures follow.

VIRAL RESPIRATORY INFECTIONS: CORONAVIRUS EPIDEMICS AND PANDEMIC INFLUENZA

The world has been plagued with three coronavirus respiratory illness epidemics since 2003. Common features include initial spread as a zoonosis, e.g., from "wet" (live food) markets; suspicion that bats are a key viral reservoir; risk of person-to-person and of nosocomial spread; excess mortality compared to common viral community-acquired infections; extensive use of isolation and quarantine in some affected communities; public fear; and often marked economic impact, e.g., due to temporary stoppages of commerce.

Infections caused by the severe acute respiratory syndrome (SARS)–associated coronavirus challenged health care systems globally in 2003 **(Chap. 199)**. In 2012, Middle East respiratory syndrome coronavirus (MERS-CoV) emerged as a more geographically localized problem **(Chap. 199)**, related initially to exposure to camels. For SARS, basic infection-control measures helped to keep the worldwide case and death counts at ~8000 and ~800, respectively. The epidemiology of SARS—spread largely in households once patients were ill or in hospitals—contrasts markedly with that of influenza **(Chap. 200)**, which is often contagious a day before symptom onset and therefore can spread rapidly in the community among nonimmune persons.

The most recent coronavirus to emerge is SARS-CoV-2 **(Chap. 199)**. The resultant COVID-19 infections are less lethal than SARS was (<2% vs ~10%, respectively) but much more of a global risk because infected patients may be contagious 1–2 days before symptoms appear. COVID-19 was first recognized in Wuhan City, Hubei Province, China in late 2019 and spread rapidly within China, despite aggressive isolation and quarantine programs, and to several continents via plane and cruise ship passengers. Each infected patient appears to lead to two to three secondary cases, mostly via dispersal of large respiratory droplets, but the potential for environmental and opportunistic airborne spread (e.g., during aerosol-generating procedures), as was seen with SARS, is a concern. A larger problem is spread by minimally symptomatic patients, which has created an influenza-like risk of extensive spread in the community. While efforts are underway to develop a vaccine and effective antiviral agents, control of SARS-CoV-2 must rely on prompt case recognition (based on epidemiologic or clinical clues and widened use of polymerase chain reaction [PCR] diagnostic tests), aggressive contact tracing, isolation, quarantine of exposed individuals, and aggressive use of personal protective equipment by health care workers.

Although the three coronavirus outbreaks are dramatic, seasonal influenza, with as many as 30 million cases and 30,000 deaths, remains a daunting *annual* challenge. Control of seasonal influenza has depended on (1) use of annually updated vaccines by children, the general public, and health care workers; (2) prescription of antiviral medications for early treatment and for prophylaxis as part of outbreak control, especially for high-risk patients and in high-risk settings like nursing homes or hospitals; (3) infection control (surveillance and droplet precautions) for symptomatic patients; and (4) general use of universal respiratory hygiene and cough etiquette (basically, "cover your cough") and source containment (e.g., use of face masks and spatial separation) for outpatients with potentially infectious respiratory illnesses. In an outpatient study, health care worker use of high-efficiency N95 respirators (recommended for airborne isolation) versus procedure masks (used for droplet precautions) resulted in no significant difference in the acquisition of laboratory-confirmed influenza.

In the spring of 2009, a novel strain of influenza virus—H1N1 (swine flu) virus—caused the first influenza pandemic in four decades. This pandemic led to reexaminations of the value of nonpharmacologic interventions, such as social distancing (e.g., closing of schools and community venues), that were used in the 1918–1919 influenza pandemic. These interventions became necessary again due to the extensive community spread of COVID-19. Recombinant events that create new strains (e.g., H7N9) to which there is population-wide susceptibility continue to challenge global efforts at infection control and vaccine development **(Chap. 200)**.

OTHER EMERGING VIRAL PATHOGENS

The reemergence of Ebola virus in West Africa has had a global impact on infection-control preparedness and isolation techniques, on guidelines for donning and doffing of—and design refinements for—personal protective equipment, on situational awareness, and on successful development of vaccines and antivirals **(Chap. 210)**. The emergence of epidemic Zika virus disease in Brazil and its spread throughout Latin America to the United States created a major concern for pregnant women and has added to the list yet another potential blood-borne pathogen that requires blood-bank screening **(Chap. 209)**.

NOSOCOMIAL DIARRHEA

Overall rates of *C. difficile*–associated diarrhea **(Chap. 134)** have increased during the past few years, especially among older patients in U.S. hospitals. This increase has been related in part to a new, more virulent strain, NAP1/BI/027, and to use of PCR testing. In 2017, 223,900 cases of *C. difficile* infection occurred and at least 12,800 people died. In a CDC multistate survey, *C. difficile* was the most common nosocomial pathogen, causing 12% of health care–associated infections. Use of WGS is improving our understanding of *C. difficile* epidemiology. For now, control measures include judicious use of all antibiotics, especially fluoroquinolone antibiotics that have been implicated in driving outbreaks; heightened suspicion for atypical presentations (e.g., toxic megacolon or leukemoid reaction without diarrhea); enhanced disinfection of isolation rooms with sporicidal agents, such as bleach; and early diagnosis, treatment, and contact precautions. Preliminary data suggest a role for probiotics in the prevention of diarrhea in patients in whom systemic antibiotic therapy is being initiated. Fecal transplantation has had dramatic results in the treatment of relapsing cases of *C. difficile*–associated diarrhea **(Chap. 134)**.

Outbreaks of norovirus infection **(Chap. 203)** in health care facilities can be challenging. The virus often is introduced by ill visitors or staff. Norovirus should be suspected when nausea and vomiting are prominent aspects of bacterial culture–negative diarrheal syndromes. Contact precautions may need to be augmented by aggressive environmental cleaning (given the persistence of norovirus on inanimate objects), prevention of secondary cases in members of the cleaning staff through an emphasis on the use of personal protective equipment and hand hygiene, and active exclusion of ill staff and visitors.

CHICKENPOX

Infection-control practitioners institute a varicella exposure investigation and control plan whenever health care workers have been exposed to chickenpox **(Chap. 193)** or have worked while having or during the 24 h before developing chickenpox. Fortunately, routine varicella vaccination of children and susceptible health care employees has made nosocomial spread less common.

MYCOBACTERIA

Important measures for the control of pulmonary tuberculosis **(Chap. 178)** include prompt recognition, isolation, and treatment of cases; recognition of atypical presentations (e.g., lower-lobe infiltrates without cavitation); use of negative-pressure, 100% exhaust, private isolation rooms with closed doors, and at least 6–12 air changes per hour; use of N95 respirators by caregivers entering isolation rooms; possible use of high-efficiency particulate air-filter units and/or ultraviolet lights for disinfecting air when other engineering controls are not feasible or reliable; and follow-up testing of susceptible personnel who have been exposed to infectious patients before isolation. The use of serologic

tests, rather than skin tests, in the diagnosis of latent tuberculosis has become common, and health care worker testing is now largely event-directed rather than annual.

An unprecedented multicountry outbreak of postoperative invasive *Mycobacterium chimaera* infections has been traced to contaminated heater–cooler devices used commonly during cardiac surgery.

GROUP A STREPTOCOCCAL INFECTIONS

The potential for an outbreak of group A streptococcal infection **(Chap. 148)** should be considered when even one or two nosocomial cases occur. Most outbreaks involve surgical wounds and are due to the presence of an asymptomatic carrier in the operating room. Investigation can be confounded by carriage at extrapharyngeal sites such as the rectum and vagina.

FUNGAL INFECTIONS

When dusty areas—common sources of fungal spores—are disturbed during hospital repairs or renovation, the spores become airborne. Inhalation of spores by immunosuppressed (especially neutropenic) patients creates a risk of pulmonary and/or paranasal sinus infection and disseminated aspergillosis **(Chap. 217)**. Routine surveillance among neutropenic patients for infections with filamentous fungi, such as *Aspergillus* and *Fusarium*, helps hospitals to assess environmental risks. As a matter of routine, hospitals should inspect and clean air-handling equipment; review all planned renovations with infection-control personnel and construct appropriate barriers; remove immunosuppressed patients from renovation sites; and consider the use of high-efficiency particulate air-intake filters for rooms housing immunosuppressed patients.

A major multistate iatrogenic outbreak of meningitis, localized spinal or paraspinal infection, and arthritis due to *Exserohilum rostratum* was recognized in 2012 and traced to contamination of an injectable preservative-free steroid product produced by a single compounding pharmacy **(Chap. 217)**.

Candida auris **(Chap. 216)**, a pathogen first identified in Japan in 2009, has emerged globally as a cause of invasive health care–associated infections, with several distinct aspects. The appearance on multiple continents occurred over a period of only months, markedly faster than spread of most problem pathogens. Although *C. auris* strains (clades) are similar within a region, they differ genetically between continents; some strains are resistant to multiple antifungals.

Epidemiologic and clinical features of *C. auris* include prolonged colonization of multiple body sites, especially skin and nares; high organism burdens that have facilitated nosocomial spread in acute and, particularly, long-term care hospitals; and high mortality in fungemic patients. Control currently relies on aggressive surveillance and contact precautions for colonized patients, point prevalence surveys in facilities with emerging *C. auris* problems, and cleaning of the often-extensive environmental contamination (including reusable patient care equipment) in rooms of colonized patients. Efforts to decolonize patients have been variably successful. Collaboration of infection control, public health, and laboratory personnel has been essential.

LEGIONELLOSIS

Nosocomial *Legionella* pneumonia **(Chap. 159)** is most often due to contamination of potable water or of water used in decorative fountains. This disease predominantly affects immunosuppressed patients, particularly those receiving glucocorticoid medications. The risk varies greatly geographically, depending on the extent of hospital water contamination and on hospital practices (e.g., the presence of decorative fountains in hospital lobbies or inappropriate use of nonsterile water in respiratory therapy equipment). If nosocomial cases are detected, environmental samples (e.g., tap water) should be cultured. If cultures yield *Legionella* and if typing of clinical and environmental isolates reveals a correlation, eradication measures should be pursued. An alternative approach is to periodically culture tap water in wards housing high-risk patients. If *Legionella* is found, a concerted effort should be made to introduce engineering controls to reduce or eliminate water-borne *Legionella* within the facility.

ANTIBIOTIC-RESISTANT BACTERIA: SURVEILLANCE, CONTROL, AND ANTIBIOTIC AND DIAGNOSTIC STEWARDSHIP

Emerging multidrug-resistant bacteria like CRE are harbingers of a potential postantibiotic era. The CDC's comprehensive 2019 Antibiotic Resistance Threat Report (*https://www.cdc.gov/drugresistance/pdf/threats-report/2019-ar-threats-report-508.pdf*) provides the updated estimate that >2.8 million antibiotic-resistant infections occur in the United States each year, and >35,000 people die as a result. The report ranks and reviews the 18 microbes currently viewed as our biggest threats and also provides a watch list of potential problems **(Table 142-2)**.

Control of resistance depends on early detection of problem pathogens that now can be facilitated by collaboration with the nationwide CDC-supported, state-based Antibiotic Resistance Laboratory Network (*https://www.cdc.gov/drugresistance/solutions-initiative/ar-lab-network.html*); on aggressive reinforcement of routine asepsis; on implementation of barrier precautions for all colonized and/or infected patients; on use of patient surveillance cultures to more fully ascertain the extent of patient colonization; on diagnostic stewardship to avoid overtreatment, e.g., of colonizing germs; on antimicrobial stewardship to lessen ecologic pressures; and on timely initiation of an epidemiologic investigation when rates increase. There is increasing interest in use of "implementation science" to close the gap between discussions of control measures and practice.

Advanced molecular diagnostics (e.g., PFGE and, more recently, WGS) can help differentiate an outbreak due to a single strain (which necessitates an emphasis on hand hygiene and an evaluation of potential common-source exposures) from a polyclonal outbreak (which requires an emphasis on antibiotic prudence and device bundles; Table 142-1), providing a form of "precision infection control." Continuing emergence of multidrug-resistant organisms suggests that control efforts have been insufficient and that heightened interventions and global strategies are needed urgently

TABLE 142-2 Bacteria and Fungi Listed in the CDC 2019 AR Threats Report

Urgent threats
Carbapenem-resistant *Acinetobacter*
Candida auris
Clostridioides difficile
Carbapenem-resistant Enterobacteriaceae
Drug-resistant *Neisseria gonorrhoeae*
Serious Threats
Drug-resistant *Campylobacter*
Drug-resistant *Candida*
ESBL-producing Enterobacteriaceae
Vancomycin-resistant *Enterococci* (VRE)
Multidrug-resistant *Pseudomonas aeruginosa*
Drug-resistant nontyphoidal *Salmonella*
Drug-resistant *Salmonella* serotype Typhi
Drug-resistant *Shigella*
Methicillin-resistant *Staphylococcus aureus* (MRSA)
Drug-resistant *Streptococcus pneumoniae*
Drug-resistant Tuberculosis
Concerning threats
Erythromycin-resistant group A *Streptococcus*
Clindamycin-resistant group B *Streptococcus*
Watch list
Azole-resistant *Aspergillus fumigatus*
Drug-resistant *Mycoplasma genitalium*
Drug-resistant *Bordetella pertussis*

Abbreviations: AR, antibiotic resistance; CDC, Centers for Disease Control and Prevention; ESBL, extended-spectrum beta-lactamase.

Source: Centers for Disease Control and Prevention. *https://www.cdc.gov/drugresistance/pdf/threats-report/2019-ar-threats-report-508.pdf.*

(see *https://www.cdc.gov/drugresistance/biggest-threats.html* and *https://www.cdc.gov/vitalsigns/stop-spread/index.html*); this need is highlighted by the creation of the U.S. Presidential Advisory Council on Combating Antibiotic-Resistant Bacteria and by the U.N. General Assembly's 2016 Declaration (see *https://www.hhs.gov/ash/advisory-committees/paccarb, http://www.un.org/pga/71/2016/09/21/press-release-hl-meeting-on-antimicrobial-resistance/,* and *https://www.gov.uk/government/publications/uk-5-year-antimicrobial-resistance-strategy-2013-to-2018*).

To facilitate tracking of resistance problems, the CDC's innovative, interactive online Antibiotic Resistance Patient Safety Atlas allows users to search state-level resistance data (*https://arpsp.cdc.gov/*). The European Centre for Disease Prevention and Control also has online resistance reporting (*http://ecdc.europa.eu/en/healthtopics/antimicrobial-resistance-and-consumption/antimicrobial_resistance/EARS-Net/Pages/EARS-Net.aspx*).

Several antibiotic resistance problems are pressing global threats. First, *S. aureus* continues to cause significant morbidity and mortality. The emergence of community-associated methicillin-resistant *S. aureus* (CA-MRSA) has been dramatic in many countries, with as many as 50% of community-acquired "staph infections" in some U.S. cities now caused by strains resistant to β-lactam antibiotics **(Chap. 147)**. The incursion of CA-MRSA into hospitals is well documented and has impacted surveillance and control of nosocomial MRSA infections. After an encouraging 17% annual reduction in incidence of hospital-onset MRSA bloodstream infections during 2005–2012, the decline slowed in 2013–2016. CA-MRSA declined less (~7% annually), whereas hospital-onset methicillin-sensitive *S. aureus* (MSSA) has not changed and CA-MSSA infections have increased (~4% per year) from 2012 to 2017.

Second, in the global emergence of multidrug-resistant gram-negative bacilli, problems include plasmid-mediated resistance to fluoroquinolones, metallo-β-lactamase–mediated resistance to carbapenems, CRE, and pan-resistant strains of *Acinetobacter*. Many multidrug-resistant gram-negative bacilli are susceptible only to colistin, to newer combination β-lactamase inhibitor drugs, or to no available agents. The increased use of colistin, which often has been futile, has led to recognition of plasmid-mediated colistin resistance in *E. coli*—first in swine-associated strains from China and now in strains from many countries, including the United States.

Transmission of CRE has been traced in a number of outbreaks to exposure to duodenoscopes used for endoscopic retrograde cholangiopancreatography. The duodenoscope is more intricate than other endoscopes and has an "elevator mechanism" that can be difficult to clean and disinfect; this problem has led to development of disposable portions of these devices.

A number of "water bug" (e.g., *Pseudomonas* spp.) outbreaks have been traced to environmental sources, such as sinks, sink drains, and bedpan hoppers. These outbreaks have called attention to the sources and reservoirs of waterborne and often antibiotic-resistant bacteria and the need for environmental interventions to control these organisms. This is reminiscent of infection control experiences in the 1970s, when waterborne bacteria were blamed for ICU respiratory infection outbreaks.

Third, there has been renewed recognition of the role of nursing homes, and now LTACHs, in the spread of resistant gram-negative bacilli such as CRE. In some LTACHs, as many as 30–50% of patients may be colonized with CREs. The frequent transfer of patients who are colonized or infected with antibiotic-resistant bacteria between long-term and acute-care facilities (Fig. 142-1) has led to studies of the regional spread of antibiotic resistance and the push to develop regional infection-control interventions (see *https://www.cdc.gov/vitalsigns/stop-spread/index.html*) aimed at the highest-risk facilities, which often drive regional resistance rates.

Fourth, there has been increasing community-based spread of *E. coli* strains harboring an enzyme, CTX-M, that renders them broadly resistant to β-lactam antibiotics. Understanding the epidemiology of these strains will be essential for development of control measures. In the meantime, community-based antibiotic stewardship has been associated in at least one trial with reduction in resistance rates.

Fifth, as a consequence of going abroad, international travelers, especially to Latin America, Asia, and Africa, may become gastrointestinal carriers of multidrug-resistant Enterobacteriaceae that express extended-spectrum β-lactamases (ESBLs). As many as 30–40% of returning travelers can have newly acquired resistant strains that can persist for as long as 6–12 months. The frequency of clinical consequences—e.g., antibiotic-resistant UTIs or familial or local spread of resistant strains—is not yet known.

Controversial control issues include the need for continuing use of contact isolation for patients colonized with more common, often community-acquired strains, such as ESBL *E. coli*, MRSA, or VRE, and duration of contact precautions. The role of single-patient rooms for contact isolation has been questioned but seems a clear choice for anyone who ever has been hospitalized. Manipulation of patients' intestinal microbiomes has been considered as a control strategy for individual patients or for outbreaks of multidrug-resistant pathogens that have a gastrointestinal reservoir, but a report of drug-resistant *E. coli* bacteremia transmitted by fecal microbiota transplant has highlighted the need for carefully controlled trials of this approach.

In several cluster-randomized controlled trials over the past ~15 years, source control—i.e., removal of patients' fecal patinas—by daily bathing with chlorhexidine has reduced the risk of bacteremia in ICU patients. "Search-and-destroy" methods—i.e., active surveillance cultures to detect and isolate the "resistance iceberg" of patients colonized with MRSA—are credited with elimination of nosocomial MRSA in the Netherlands and Denmark. In a multicenter trial in the United States, universal source control with chlorhexidine and nasal mupirocin was significantly more effective in controlling MRSA than was a search-and-destroy approach and led to control of other pathogens as well, providing a broad (horizontal) rather than a narrower (vertical) intervention (see *https://www.ahrq.gov/hai/universal-icu-decolonization/index.html*). For some pathogens, such as VRE and *C. difficile*, enforcement of environmental cleaning can markedly reduce cross-transmission risk. Newer environmental disinfection modalities, such as ultraviolet (UV) light and hydrogen peroxide mists, are appealing but sometimes limited in application by practicality and inconsistent results.

Because the excessive use of broad-spectrum antibiotics underlies many resistance problems and adverse patient events, antibiotic stewardship programs are mandatory in acute care hospitals (see *https://www.cdc.gov/getsmart/healthcare/implementation/core-elements.html*) and are being promulgated actively for long-term care and outpatient facilities (see *https://www.cdc.gov/longtermcare/prevention/antibiotic-stewardship.html* and *https://www.cdc.gov/mmwr/volumes/65/rr/rr6506a1.htm*), where implementing such programs is challenging but of great importance. In some studies, 30–50% of antibiotic courses are inappropriate—a large target for improvement efforts. The main interventions that will save the "antimicrobial commons," limit selective pressures on nosocomial flora, and protect patients are restricting use of particular agents to narrowly defined indications; treating with the shortest efficacious courses; deescalating from empiric broad-spectrum treatment as soon as possible on the basis of the results of culture and susceptibility tests; and consulting infectious disease experts for treatment of *S. aureus* bacteremia and candidemia. Reductions in total and high-risk antibiotic use have been associated with decreased risk of nosocomial *C. difficile* infections and lowered rates of antibiotic resistance in hospitals and communities.

New stewardship teams must ensure that they have a visible and effective program champion; start with interventions that are based on well-controlled trials; focus on high impact areas, such as emergency departments where therapy often is initiated; promote guidelines that are amenable to surveillance, enforcement, and sustainability; and tailor stewardship activities to comport with the motivations and identities of physicians in different specialties, recognizing that at times internists can be from Venus and surgeons from Mars.

From a One Health perspective, antimicrobial use in animal husbandry and agriculture can be an important driver of genetic resistance elements in bacteria and fungi, which then spread predominantly among humans. This concern has led to recommendations for eliminating the use of antibiotics for growth promotion and as prophylaxis for

feed animals. The United States lags behind some European countries in control of veterinary and agricultural use of antimicrobial drugs.

Key to an understanding of the success of antibiotic stewardship initiatives is better surveillance of antibiotic use among humans and animals at regional and national levels.

BIOTERRORISM AND OTHER SURGE-EVENT PREPAREDNESS

The horrific attack on the World Trade Center in New York City on September 11, 2001; subsequent mailings of anthrax spores in the United States; the Boston Marathon bombing in 2013; and ongoing terrorist activities globally have made bioterrorism a prominent source of concern to hospital infection-control programs **(Chap. S3)**. The essentials for hospital preparedness entail education, internal and external communication, and situational awareness (see *https://emergency.cdc.gov/bioterrorism/*).

EMPLOYEE HEALTH SERVICE ISSUES

An institution's employee health service is critical for infection control. New employees should be processed through the service, where a contagious disease history can be taken; evidence of immunity to a variety of diseases, such as hepatitis B, chickenpox, measles, mumps, and rubella, can be sought; immunizations for hepatitis B, measles, mumps, rubella, varicella, and pertussis can be given as needed (an especially important step with the resurgence in the United States of vaccine-preventable diseases such as pertussis, mumps, and measles); baseline testing for latent tuberculosis can be performed; and education about personal responsibility for infection control can be initiated.

The employee health service must have protocols for dealing with workers exposed to contagious diseases (e.g., influenza) and those percutaneously or mucosally exposed to the blood of patients infected with HIV or hepatitis B or C virus. Protocols are also needed for dealing with caregivers who have common contagious diseases (e.g., chickenpox, group A streptococcal infection, influenza or another respiratory infection, or infectious diarrhea) and for those who have less common but high-visibility public health problems (e.g., chronic hepatitis B or C or HIV infection) for which exposure-control guidelines have been published by the CDC and by the Society for Healthcare Epidemiology of America.

143 Infections in Transplant Recipients

Robert W. Finberg*

The evaluation of infections in transplant recipients involves consideration of both the donor and the recipient of the transplanted cells or organ. Two central issues are of paramount importance: (1) infectious agents (particularly viruses, but also bacteria, fungi, and parasites) can be introduced into the recipient by the donor; and (2) treatment of the recipient with medicine to prevent rejection can suppress normal immune responses, greatly increasing susceptibility to infection. Thus, what might have been a latent or asymptomatic infection in an immunocompetent donor or in the recipient prior to therapy can become a life-threatening problem when the recipient becomes immunosuppressed. The pretransplantation evaluation of each patient should be guided by an analysis of both (1) what infections the recipient is currently harboring, since organisms that exist in a state of latency or dormancy before the procedure may cause fatal disease when the patient receives immunosuppressive treatment; and (2) what organisms are likely to be transmitted by the donor, particularly those to which the recipient may be naïve.

PRETRANSPLANTATION EVALUATION

THE DONOR

A variety of organisms have been transmitted by organ transplantation. Transmission of infections that may have been latent or not clinically apparent in the donor has resulted in the development of specific donor-screening protocols. Results from routine blood-bank studies, including those for antibodies to *Treponema pallidum* (syphilis), *Trypanosoma cruzi*, hepatitis B and C viruses, HIV-1 and -2, and human T-lymphotropic virus types 1 and 2 (HTLV-1 and -2), should be documented. Serologic studies should be ordered to identify latent infection with viruses, such as herpes simplex virus types 1 and 2 (HSV-1, HSV-2), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and Kaposi's sarcoma–associated herpesvirus (KSHV; also known as human herpesvirus type 8); acute infection with hepatitis A virus; and infection with the common parasite *Toxoplasma gondii*. Donors should be screened for parasites, such as *Strongyloides stercoralis, T. cruzi*, and *Schistosoma* species, if they have lived in endemic areas. Clinicians caring for prospective organ donors should examine chest radiographs for evidence of granulomatous disease (e.g., caused by mycobacteria or fungi) and should perform skin testing or obtain blood for immune cell-based assays that detect active or latent *Mycobacterium tuberculosis* infection. An investigation of the donor's dietary habits (e.g., consumption of raw meat or fish or of unpasteurized dairy products), occupations or avocations (e.g., gardening or spelunking), and travel history (e.g., travel to areas with endemic fungi causing infections such as blastomycosis, coccidioidomycosis, and histoplasmosis) also is indicated and may mandate additional testing. A number of unusual parasites (including *Balamuthia mandrillaris*) have been identified in transplanted kidneys. Uncommonly diagnosed viruses, including lymphocytic choriomeningitis virus (LCMV), West Nile virus, Zika virus, dengue virus, and rabies virus, can be transplanted in organs and are likely to be difficult to diagnose in recipients. If an unusual parasite or uncommon virus is identified in a transplant recipient, the organ-donor organization and caregivers for recipients of other organs isolated from the same donor should be notified immediately.

Creutzfeldt-Jakob disease has been transmitted through corneal transplants; however, to what degree it can be transmitted by transfused blood is unknown. Variant Creutzfeldt-Jakob disease can be transmitted with transfused non-leukodepleted blood, posing a theoretical risk to transplant recipients.

*Deceased.

THE RECIPIENT

It is expected that the recipient will have been even more comprehensively assessed than the donor. Additional studies recommended for the recipient include evaluation for acute respiratory viruses and gastrointestinal pathogens in the immediate pretransplantation period. An important caveat is that, because of immune dysfunction resulting from chemotherapy or underlying chronic disease, serologic testing of the recipient may prove less reliable than usual.

THE DONOR CELLS/ORGAN

Careful attention to the sterility of the medium used to process the donor organ, combined with meticulous microbiologic evaluation, reduces rates of transmission of bacteria (or, rarely, yeasts) that may be present or grow in the organ culture medium. From 2 to >20% of donor kidneys are estimated to be contaminated with bacteria—in most cases, with the organisms that colonize the skin or grow in the tissue culture medium used to bathe the donor organ while it awaits implantation. The reported rate of bacterial contamination of transplanted stem cells (bone marrow, peripheral blood, cord blood) is as high as 17% but most commonly is ~1%. The use of enrichment columns and monoclonal antibody depletion procedures results in a higher incidence of contamination. In some cases, because of the clinical situation, contaminated cells have been infused, usually with concomitant administration of antimicrobial agents. In one series of patients receiving contaminated stem cells, 14% had fever or bacteremia, but none died. Results of cultures performed at the time of cryopreservation and at the time of thawing were helpful in guiding therapy for the recipient.

INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Transplantation of hematopoietic stem cells (HSCs) from bone marrow or from peripheral or cord blood for cancer, immunodeficiency, or autoimmune disease is marked by a transient state of complete immunologic incompetence. Immediately after myeloablative chemotherapy and transplantation, both innate immune cells (phagocytes, dendritic cells, natural killer cells) and adaptive immune cells (T and B cells) are absent, and the host is extremely susceptible to infection. The reconstitution that follows transplantation has been likened to maturation of the immune system in neonates. The analogy does not entirely predict infections seen in HSC transplant recipients, however, because the stem cells mature in an old host who has several latent infections already. The choice among the current variety of methods for obtaining stem cells is determined by availability and by the need to optimize the chances of a cure for an individual recipient. One strategy is autologous HSC transplantation, in which the recipient's own stem cells are used. After chemotherapy, stem cells are collected and are purged (ex vivo) of residual neoplastic populations. Allogeneic HSC transplantation has the advantage of providing a graft-versus-tumor effect. In this case, the recipient is matched to varying degrees for human leukocyte antigens (HLAs) with a donor who may be related or unrelated. In some individuals, nonmyeloablative therapy (mini-allotransplantation) is used and permits recipient cells to persist for some time after transplantation while preserving the graft-versus-tumor effect and sparing the recipient intense myeloablative therapy. Cord-blood transplantation is increasingly used in adults; two independent cord-blood units are typically required for suitable neutrophil engraftment early after transplantation, even though only one of the units is likely to provide long-term engraftment. In each circumstance, a different balance is struck among the toxicity of conditioning therapy, the need for a maximal graft-versus-target effect, short-term and long-term infectious complications, and the risk of graft-versus-host disease (GVHD; acute versus chronic). The various approaches differ in terms of reconstitution speed, cell lineages introduced, and likelihood of GVHD—all factors that can produce distinct effects on the risk of infection after transplantation **(Table 143-1)**. Despite these caveats, most infections occur in a predictable time frame after transplantation **(Table 143-2)**.

BACTERIAL INFECTIONS

In the first month after HSC transplantation, infectious complications are similar to those in granulocytopenic patients receiving chemotherapy for acute leukemia **(Chap. 74)**. Because of the anticipated 1- to 4-week duration of neutropenia and the high rate of bacterial infection in this population, many centers give prophylactic antibiotics to patients upon initiation of myeloablative therapy. Quinolones decrease the incidence of gram-negative bacteremia among these patients. Bacterial infections are common in the first few days after HSC transplantation. The organisms involved are predominantly those found on skin, mucosa, or IV catheters (*Staphylococcus aureus*, coagulase-negative staphylococci, streptococci) or aerobic bacteria that colonize the bowel (*Escherichia coli*, *Klebsiella*, *Pseudomonas*). *Bacillus cereus*, although rare, has emerged as a pathogen early after transplantation and can cause meningitis, which is unusual in these patients.

TABLE 143-1 Risk of Infection, by Type of Hematopoietic Stem Cell Transplant

TYPE OF HEMATOPOIETIC STEM CELL TRANSPLANT	SOURCE OF STEM CELLS	RISK OF EARLY INFECTION: NEUTROPHIL DEPLETION	RISK OF LATE INFECTION: IMPAIRED T- AND B-CELL FUNCTION	RISK OF ONGOING INFECTION: GVHD AND IATROGENIC IMMUNOSUPPRESSION	GRAFT-VS-TUMOR EFFECT
Autologous	Recipient (self)	High risk; neutrophil recovery sometimes prolonged	~1 year	Minimal to no risk of GVHD and late-onset severe infection	None (–)
Syngeneic (genetic twin)	Identical twin	Low risk; 1–2 weeks for neutrophil recovery	~1 year	Minimal risk of GVHD and late-onset severe infection	+/–
Allogeneic related	Sibling	Low risk; 1–2 weeks for neutrophil recovery	~1 year	Minimal to moderate risk of GVHD and late-onset severe infection	++
Allogeneic related	Child/parent (haploidentical)	Intermediate risk; 2–3 weeks for neutrophil recovery	1–2 years	Moderate risk of GVHD and late-onset severe infection	++++
Allogeneic unrelated adult	Unrelated donor	Intermediate risk; 2–3 weeks for neutrophil recovery	1–2 years	High risk of GVHD and late-onset severe infection	++++
Allogeneic unrelated cord blood	Unrelated cord-blood units (×2)	Intermediate to high risk; neutrophil recovery sometimes prolonged	Prolonged	Minimal to moderate risk of GVHD and late-onset severe infection	++++
Allogeneic mini (nonmyeloablative)	Donor (transiently coexisting with recipient cells)	Low risk; neutrophil counts close to normal	1–2+ years	Variable risk of GVHD and late-onset severe infection[a]	++++ (but develops slowly)

[a]Depending on the disparity of the match (major and minor histocompatibility antigens), GVHD may be severe or mild, the requirement for immunosuppression intense or minimal, and the risk of severe late infections coordinate with the degree of immunosuppression.

Abbreviation: GVHD, graft-versus-host disease.

TABLE 143-2 Common Sources of Infection after Hematopoietic Stem Cell Transplantation

INFECTION SITE	PERIOD AFTER TRANSPLANTATION		
	EARLY (<1 MONTH)	MIDDLE (1–4 MONTHS)	LATE (>6 MONTHS)
Disseminated	Aerobic bacteria (gram-negative, gram-positive)	*Candida, Aspergillus,* EBV	Encapsulated bacteria (*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis*)
Skin and mucous membranes	HSV	HHV-6	VZV, HPV (warts)
Lungs	Aerobic bacteria (gram-negative, gram-positive), *Candida, Aspergillus,* other molds, HSV	CMV, seasonal respiratory viruses, *Pneumocystis, Toxoplasma*	*Pneumocystis, Nocardia, S. pneumoniae*
Gastrointestinal tract	*Clostridioides difficile*	CMV, adenovirus	EBV, CMV
Kidney		BK virus, adenovirus	
Brain		HHV-6, *Toxoplasma*	*Toxoplasma,* JC virus (rare)
Bone marrow		CMV, HHV-6	CMV, HHV-6

Abbreviations: CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV-6, human herpesvirus type 6; HPV, human papillomavirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

Chemotherapy, use of broad-spectrum antibiotics, and delayed reconstitution of humoral immunity place HSC transplant patients at risk for diarrhea and colitis caused by *Clostridioides difficile* overgrowth and toxin production. Reconstitution of the bowel with microbial flora from donors ("fecal transplantation") has been successful in drug-resistant cases **(Chap. 134)**.

Beyond the first few days of neutropenia, infections with nosocomial pathogens (e.g., vancomycin-resistant enterococci, *Stenotrophomonas maltophilia*, *Acinetobacter* species, and extended-spectrum β-lactamase-producing gram-negative bacteria) as well as with filamentous bacteria (e.g., *Nocardia* species) become more common. Vigilance is indicated, particularly for patients with a history of active or known latent tuberculosis, even when they have been appropriately pretreated. Episodes of bacteremia due to encapsulated organisms mark the late posttransplantation period (>6 months after HSC reconstitution); patients who have undergone splenectomy and those with persistent hypogammaglobulinemia are at particular risk.

FUNGAL INFECTIONS

Beyond the first week after HSC transplantation, fungal infections become increasingly common, particularly among patients who have received broad-spectrum antibiotics. As in most granulocytopenic patients, *Candida* infections are most commonly seen in this setting. However, with increased use of prophylactic fluconazole, infections with *Candida albicans* resistant to fluconazole and naturally fluconazole-resistant fungi—in particular, *Aspergillus* and other non-*Aspergillus* molds (*Rhizopus*, *Fusarium*, *Scedosporium*, *Penicillium*)—have become more common, prompting some centers to replace fluconazole with agents such as micafungin, voriconazole, isavuconazole, or posaconazole. Identification of *Candida auris* as a pathogen has made prophylaxis and treatment of fungal infections more difficult as these organisms are often resistant to most antifungal agents. Echinocandins are recommended for initial therapy of patients with serious *Candida* infections. Treatment should be adjusted based on sensitivities. The role of antifungal prophylaxis with these different agents, in contrast to empirical treatment for suspected infection that is based on a positive β-D-glucan assay or galactomannan antigen test, remains controversial **(Chap. 74)**. Documented infection should be aggressively treated, ideally with agents of proven activity. In patients with GVHD who require prolonged or indefinite courses of glucocorticoids and other immunosuppressive agents (e.g., cyclosporine, tacrolimus [FK506, Prograf], mycophenolate mofetil [CellCept], rapamycin [sirolimus, Rapamune], antithymocyte globulin, or anti-CD52 antibody [alemtuzumab, Campath—an antilymphocyte and antimonocyte monoclonal antibody]), there is a high risk of fungal infection (usually with *Candida* or *Aspergillus*) even after engraftment and resolution of neutropenia. These patients are also at high risk for reactivation of latent fungal infection (histoplasmosis, coccidioidomycosis, or blastomycosis) in areas where endemic fungi reside and after involvement in activities such as gardening or caving. Prolonged use of central venous catheters for parenteral nutrition (lipids) increases the risk of fungemia with *Malassezia*. Some centers administer prophylactic antifungal agents to these patients. Because of the high and prolonged risk of *Pneumocystis jirovecii* pneumonia (especially among patients being treated for hematologic malignancies), most patients receive maintenance prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) starting after engraftment and continuing for at least 1 year.

PARASITIC INFECTIONS

The regimen described above for the fungal pathogen *Pneumocystis* may also protect patients seropositive for the parasite *T. gondii*, which can cause pneumonia, visceral disease (occasionally), and central nervous system (CNS) lesions (more commonly). The advantages of maintaining HSC transplant recipients on daily TMP-SMX for 1 year after transplantation include some protection against *Listeria monocytogenes* and nocardiosis as well as late infections with *Streptococcus pneumoniae* and *Haemophilus influenzae* that stem from the inability of the immature immune system to respond to polysaccharide antigens.

With increasing international travel, parasitic diseases typically restricted to particular environmental niches may pose a risk of reactivation in certain patients after HSC transplantation. Thus, in recipients with an appropriate history who were not screened and/or treated before transplantation or in patients with recent exposures, evaluation for infection with *Strongyloides, Leishmania*, schistosomes, trypanosomes, or various parasitic causes of diarrheal illness (*Giardia, Entamoeba, Cryptosporidium*, microsporidia) may be warranted.

VIRAL INFECTIONS

HSC transplant recipients are susceptible to infection with a variety of viruses, including primary and reactivation syndromes caused by most human herpesviruses **(Table 143-3)** and acute infections caused by viruses that circulate in the community.

Herpes Simplex Virus Within the first 2 weeks after transplantation, most patients who are seropositive for HSV-1 excrete the virus from the oropharynx. The ability to isolate HSV declines with time. Administration of prophylactic acyclovir (or valacyclovir) to seropositive HSC transplant recipients has been shown to reduce mucositis and prevent HSV pneumonia (a rare condition reported almost exclusively in allogeneic HSC transplant recipients). Both esophagitis (usually due to HSV-1) and anogenital disease (commonly caused by HSV-2) may be prevented with acyclovir prophylaxis. **For further discussion, see Chap. 192.**

Varicella-Zoster Virus Reactivation of VZV manifests as herpes zoster and may occur within the first month but more commonly occurs several months after transplantation. Reactivation rates are ~40% for allogeneic HSC transplant recipients and 25% for autologous recipients. Localized zoster can spread rapidly in an immunosuppressed patient. Fortunately, disseminated disease can usually be controlled with high doses of acyclovir. Because of frequent VZV

TABLE 143-3 Herpesvirus Syndromes in Transplant Recipients

VIRUS	REACTIVATION DISEASE
Herpes simplex virus type 1	Oral lesions Esophageal lesions Pneumonia (primarily HSC transplant recipients) Hepatitis (rare)
Herpes simplex virus type 2	Anogenital lesions Hepatitis (rare)
Varicella-zoster virus	Zoster (can disseminate)
Cytomegalovirus	Associated with graft rejection Fever and malaise Bone marrow failure Pneumonitis Gastrointestinal disease
Epstein-Barr virus	B-cell lymphoproliferative disease/lymphoma Oral hairy leukoplakia (rare)
Human herpesvirus type 6	Fever Delayed monocyte/platelet engraftment Encephalitis (rare)
Human herpesvirus type 7	Undefined
Kaposi's sarcoma–associated virus (human herpesvirus type 8)	Kaposi's sarcoma Primary effusion lymphoma (rare) Multicentric Castleman's disease (rare) Marrow aplasia (rare)

Abbreviation: HSC, hematopoietic stem cell.

dissemination among patients with skin lesions, acyclovir is given prophylactically in many centers to prevent severe disease. Low doses of acyclovir appear to be effective in preventing reactivation of VZV. While the live-attenuated zoster vaccine is contraindicated in this patient population, the recombinant subunit vaccine may be given before or after transplantation. **For further discussion, see Chap. 193.**

Cytomegalovirus The onset of CMV disease (interstitial pneumonia, bone marrow suppression, graft failure, hepatitis/colitis) usually begins 30–90 days after HSC transplantation, when the granulocyte count is adequate but immunologic reconstitution has not occurred. CMV disease rarely develops earlier than 14 days after transplantation and may become evident as late as 4 months or more after the procedure. It is of greatest concern in the second month after transplantation, particularly in allogeneic HSC transplant recipients. In cases in which the donor marrow is depleted of T cells (to prevent GVHD or eliminate a T-cell tumor) and in cord-blood recipients, the disease may manifest earlier. The use of alemtuzumab to prevent GVHD in nonmyeloablative transplantation has been associated with an increase in CMV disease. Patients who receive ganciclovir for prophylaxis, preemptive treatment, or treatment (see below) may develop recurrent CMV infection even later than 4 months after transplantation, as treatment appears to delay the development of an effective immune response to CMV infection. Although CMV disease may present as isolated fever, granulocytopenia, thrombocytopenia, or gastrointestinal disease, the foremost cause of death from CMV infection in the setting of HSC transplantation is pneumonia.

With the standard use of CMV-negative or filtered blood products, CMV infection should be a major risk in allogeneic transplantation only when the recipient is CMV seropositive and the donor is CMV seronegative. This situation is the reverse of that in solid organ transplant recipients. CMV reactivates from latent reservoirs present in the recipient at a time when donor T cells (especially cord-blood T cells) are too immature to control CMV replication. If the T cells from the donor have never encountered CMV and the recipient carries the virus, the patient is at maximal risk of severe disease. Reactivation disease or superinfection with another strain from the donor also can occur in CMV-positive recipients, but clinical manifestations are typically less severe, presumably because of CMV-specific memory in transplanted donor T cells. Most patients infected with CMV who undergo HSC transplantation excrete virus, with or without clinical findings. Serious CMV disease is much more common among allogeneic than autologous recipients and is often associated with GVHD. In addition to pneumonia and marrow suppression (and, less often, graft failure), manifestations of CMV disease in HSC transplant recipients include fever with or without arthralgias, myalgias, hepatitis, and esophagitis. CMV ulcerations occur in both the lower and the upper gastrointestinal tract, and it may be difficult to distinguish diarrhea due to GVHD from that due to CMV infection. The finding of CMV in the liver of a patient with GVHD does not necessarily mean that CMV is responsible for hepatic enzyme abnormalities. It is interesting that ocular and neurologic manifestations of CMV infections are common in patients with AIDS but uncommon in patients who develop CMV disease after transplantation.

Management of CMV disease in HSC transplant recipients includes strategies directed at prophylaxis, preemptive therapy (suppression of silent replication), and treatment of disease. Prophylaxis results in a lower incidence of disease at the cost of treating many patients who otherwise would not require therapy. Because of the high fatality rate associated with CMV pneumonia in these patients and the difficulty of early diagnosis of CMV infection, prophylactic IV ganciclovir or oral valganciclovir has been used in some centers and has been shown to prevent CMV disease during the period of maximal vulnerability (from engraftment to day 120 after transplantation). Ganciclovir also prevents HSV reactivation and reduces the risk of VZV reactivation; thus, acyclovir prophylaxis should be discontinued when ganciclovir is administered. The foremost problem with the administration of ganciclovir relates to adverse effects, which include dose-related bone marrow suppression (thrombocytopenia, leukopenia, anemia, and pancytopenia). Because the frequency of CMV pneumonia is lower among autologous HSC transplant recipients (2–7%) than among allogeneic HSC transplant recipients (10–40%), prophylaxis in the former group is not routine. Letermovir, an oral agent that does not commonly cause bone marrow suppression, is effective in suppressing CMV reactivation in allogeneic HSC transplant recipients.

Preemptive treatment of CMV—that is, initiation of therapy with drugs only after CMV is detected in blood by a nucleic acid amplification test (NAAT)—is used at most centers. To limit variability between tests, the World Health Organization (WHO) has developed an international reference standard for measurement of CMV load by NAAT-based assays. A positive test (or increasing viral load) prompts the initiation of preemptive therapy with ganciclovir. Preemptive approaches that target patients who have quantitative NAAT evidence of CMV infection can still lead to unnecessary treatment of many individuals with drugs that have adverse effects on the basis of a laboratory test that is not highly predictive of disease; however, invasive disease, particularly in the form of pulmonary infection, is difficult to treat and is associated with high mortality rates. When prophylaxis or preemptive therapy is stopped, late manifestations of CMV replication may occur, although by then the HSC transplant patient is often equipped with improved graft function and is better able to combat disease. Cord-blood transplant recipients are especially vulnerable to disease caused by members of the human herpesvirus family, including CMV. Implementation of the WHO standard for CMV load measurement will facilitate large-scale comparative studies and thus the establishment of optimal guidelines for distinct patient subsets.

CMV pneumonia in HSC transplant recipients (unlike that in other clinical settings) is often treated with both IV immunoglobulin (IVIg) and ganciclovir. In patients who cannot tolerate ganciclovir, foscarnet is a useful alternative, although it may produce nephrotoxicity and electrolyte imbalance. When neither ganciclovir nor foscarnet is clinically tolerated, cidofovir can be used; however, its efficacy is less well established, and its side effects include nephrotoxicity. A lipid-conjugate form of cidofovir, brincidofovir, appears to have more activity and less toxicity than cidofovir and is in clinical trials. Transfusion of CMV-specific T cells from the donor has decreased viral load in a small series of patients; this result suggests that immunotherapy (e.g., banked T cells) may play a role in the management of this disease in the future. **For further discussion, see Chap. 195.**

Human Herpesviruses 6 and 7 Human herpesvirus type 6 (HHV-6), the cause of roseola in children, is a ubiquitous herpesvirus that is reactivated (as determined by quantitative plasma polymerase chain reaction [PCR]) in ~50% of HSC transplant recipients 2–4 weeks after transplantation. Reactivation is more common among patients requiring glucocorticoids for GVHD and among those receiving second transplants. Reactivation of HHV-6, primarily type B, may be associated with delayed monocyte and platelet engraftment. Limbic encephalitis developing after transplantation has been associated with HHV-6 in cerebrospinal fluid (CSF). The causality of the association is not well defined; in several cases, plasma viremia was detected long before the onset of encephalitis. Nevertheless, most patients with encephalitis had very high viral loads in plasma at the time of CNS illness, and viral antigen has been detected in hippocampal astrocytes. HHV-6 DNA is sometimes found in lung samples after transplantation. However, its role in pneumonitis is unclear, as co-pathogens are frequently present. While HHV-6 is susceptible to foscarnet or cidofovir (and possibly to ganciclovir) in vitro, the efficacy of antiviral treatment has not been well studied. Although treatment of HHV-6 encephalitis is recommended, there are no randomized, controlled trials demonstrating efficacy of any antiviral agent, and treatment of DNAemia (the detection of DNA in samples of plasma, whole blood, and isolated peripheral-blood leukocytes) is not recommended. Little is known about the related herpesvirus HHV-7 or its role in posttransplantation infection. **For further discussion, see Chap. 195.**

Epstein-Barr Virus Primary EBV infection can be fatal to HSC transplant recipients; EBV reactivation can cause EBV B-cell lymphoproliferative disease (EBV-LPD), which may also be fatal to patients taking immunosuppressive drugs. Latent EBV infection of B cells leads to several interesting phenomena in HSC transplant recipients. The marrow ablation that occurs as part of the HSC transplantation procedure may sometimes eliminate latent EBV from the host. Infection can then be reacquired immediately after transplantation by transfer of infected donor B cells. Rarely, transplantation from a seronegative donor may result in a cure. The recipient is then at risk for a second primary infection.

EBV-LPD can develop in the recipient's B cells (if any survive marrow ablation) but is more likely to be a consequence of outgrowth of infected donor cells. Both lytic replication and latent replication of EBV are more likely during immunosuppression (e.g., they are associated with GVHD and the use of antibodies to T cells). Although less likely in autologous transplantation, reactivation can occur in T cell–depleted autologous recipients (e.g., patients being given antibodies to T cells for the treatment of T-cell lymphoma with marrow depletion). EBV-LPD, which can become apparent as early as 1–3 months after engraftment, can cause high fevers and cervical adenopathy resembling the symptoms of infectious mononucleosis but more commonly presents as an extranodal mass. The incidence of EBV-LPD among allogeneic HSC transplant recipients is 0.6–1%, which contrasts with figures of ~5% for renal transplant recipients and up to 20% for cardiac transplant patients. In all cases, EBV-LPD is more likely to occur with high-dose, prolonged immunosuppression, especially that caused by the use of antibodies to T cells, glucocorticoids, and calcineurin inhibitors (e.g., cyclosporine, tacrolimus). Cord-blood recipients constitute another high-risk group because of delayed T-cell function. Ganciclovir, administered to preempt CMV disease, may reduce EBV lytic replication and thereby diminish the pool of B cells that can become newly infected and give rise to LPD. Increasing evidence indicates that replacement of calcineurin inhibitors with mTOR inhibitors (e.g., rapamycin) exerts an antiproliferative effect on EBV-infected B cells that decreases the likelihood of development of LPD or unrelated proliferative disorders associated with transplant-related immunosuppression.

PCR can be used to monitor EBV production after HSC transplantation. High or increasing viral loads predict an enhanced likelihood of EBV-LPD development and should prompt rapid reduction of immunosuppression and a search for nodal or extranodal disease. If reduction of immunosuppression does not have the desired effect, administration of a monoclonal antibody to CD20 (e.g., rituximab) for the treatment of B-cell lymphomas that express this surface protein has elicited dramatic responses and currently constitutes first-line therapy for CD20-positive EBV-LPD. However, long-term suppression of new antibody responses accompanies therapy, and recurrences are common. Additional B cell–directed antibodies, including anti-CD22, are under study. The role of antiviral drugs is uncertain because no available agents have been documented to have activity against the different forms of latent EBV infection. Diminishing lytic replication and virion production in these patients would theoretically produce a statistical decrease in the frequency of latent disease by decreasing the number of virions available to cause additional infection. In case reports and animal studies, ganciclovir and/or high-dose zidovudine, together with other agents, have been used to eradicate EBV-LPD and CNS lymphomas, another EBV-associated complication of transplantation. Both interferon and retinoic acid have been employed in the treatment of EBV-LPD, as has IVIg, but no large-scale prospective studies have assessed the efficacy of any of these agents. Several additional drugs are undergoing preclinical evaluation. Standard chemotherapeutic regimens are used if the disease persists after reduction of immunosuppressive agents and administration of antibodies. EBV-specific T cells generated from the donor have been used experimentally to prevent and treat EBV-LPD in allogeneic recipients, and efforts are underway to increase the activity and specificity of ex vivo–generated T cells. **For further discussion, see Chap. 194.**

Human Herpesvirus 8 (KSHV) The gammaherpesvirus KSHV, which is causally associated with Kaposi's sarcoma, primary effusion lymphoma, and multicentric Castleman's disease, has rarely resulted in disease in HSC transplant recipients, although some cases of virus-associated marrow aplasia have been reported in the peritransplantation period. The relatively low seroprevalence of KSHV in the population and the limited duration of profound T-cell suppression after HSC transplantation provide a plausible explanation for the currently low incidence of KSHV disease compared with that in recipients of solid organ transplants and patients with HIV infection. **For further discussion, see Chap. 195.**

Other (Non-Herpes) Viruses and Pneumonia The diagnosis of pneumonia in HSC transplant recipients poses special problems. Because patients have undergone treatment with multiple chemotherapeutic agents and sometimes irradiation, their differential diagnosis should include—in addition to bacterial and fungal pneumonia—CMV pneumonitis, pneumonia of other viral etiologies, parasitic pneumonia, diffuse alveolar hemorrhage, and chemical- or radiation-associated pneumonitis. Since fungi and viruses (e.g., influenza A and B viruses, respiratory syncytial virus [RSV], parainfluenza virus types 1–4, adenovirus, enterovirus, bocavirus, human metapneumovirus, coronavirus, and rhinovirus [increasingly detected by multiplex PCR]) also can cause pneumonia in this setting, it is important to obtain a specific diagnosis. Diagnostic modalities include Gram's stain, microbiologic culture, antigen testing, and—increasingly—multipathogen PCR and mass spectrometry assays. HSC transplant recipients are likely to have difficulty responding to SARS-CoV-2 infections and may have long courses of disease and/or secondary infections.

GLOBAL CONSIDERATIONS

M. tuberculosis has been an uncommon cause of pneumonia among HSC transplant recipients in Western countries (accounting for <0.1–0.2% of cases) but is common in Hong Kong (5.5%) and in countries where the prevalence of tuberculosis is high. The recipient's exposure history is clearly critical in an assessment of posttransplantation infections.

Both RSV and parainfluenza viruses, particularly type 3, can cause severe or even fatal pneumonia in HSC transplant recipients. Infections with both of these agents sometimes occur as disastrous nosocomial epidemics. Therapy with palivizumab or ribavirin for RSV infection remains controversial. New agents, some host-directed, are under study. Influenza also occurs in HSC transplant recipients and generally mirrors the presence of infection in the community. Progression to pneumonia is more common when infection occurs early after transplantation

and when the recipient is lymphopenic. The neuraminidase inhibitors oseltamivir (oral) and zanamivir (aerosolized) are active against both influenza A virus and influenza B virus and are a reasonable treatment option. Parenteral forms of neuraminidase inhibitors, such as peramivir (intravenous), are available in some countries, and several new oral agents are still being assessed in trials. Baloxavir, a single-dose oral agent, has excellent activity, but resistance may occur. An important preventive measure is immunization of household members, hospital staff members, and other frequent contacts. Adenoviruses can be isolated from HSC transplant recipients at rates varying from 5 to ≥18%. Like CMV infection, adenovirus infection usually occurs in the first to third month after transplantation and is often asymptomatic, although pneumonia, hemorrhagic cystitis/nephritis, severe gastroenteritis with hemorrhage, and fatal disseminated infection have been reported and may be strain-specific. Banked virus-specific T-cell therapy is under study for adenovirus infection (as well as for CMV and EBV infections).

Although diverse respiratory viruses can sometimes cause severe pneumonia and respiratory failure in HSC transplant recipients, mild or even asymptomatic infection may be more common. For example, rhinoviruses and coronaviruses are frequent co-pathogens in HSC transplant recipients; however, whether they independently contribute to significant pulmonary infection is unknown. At present, the overall contribution of these viral respiratory pathogens to the burden of lower respiratory tract disease in HSC transplant recipients requires further study. Infections with parvovirus B19 (presenting as anemia or occasionally as pancytopenia) and disseminated enteroviruses (sometimes fatal) can occur. Parvovirus B19 infection can be treated with IVIg **(Chap. 197)**.

Rotaviruses, a cause of gastroenteritis in HSC transplant recipients, cause disease more frequently in children. Norovirus is a common cause of vomiting and diarrhea, and symptoms can be prolonged in HSC recipients. The BK virus (a polyomavirus) is found at high titers in the urine of patients who are profoundly immunosuppressed. BK viruria may be associated with hemorrhagic cystitis in these patients. In contrast to its incidence among patients with impaired T-cell function due to AIDS (4–5%), progressive multifocal leukoencephalopathy caused by the related JC virus is relatively rare among HSC transplant recipients **(Chap. 138)**. When transmitted by mosquitoes or by blood transfusion, West Nile virus (WNV) can cause encephalitis and death after HSC transplantation.

INFECTIONS IN SOLID ORGAN TRANSPLANT RECIPIENTS

Rates of morbidity and mortality among recipients of solid organ transplants (SOTs) are reduced by the use of effective antibiotics. The organisms that cause acute infections in recipients of SOTs are different from those that infect HSC transplant recipients because SOT recipients do not go through a period of neutropenia. As the transplantation procedure involves major surgery, however, SOT recipients are subject to infections at anastomotic sites and to wound infections. Compared with HSC transplant recipients, SOT patients are immunosuppressed for longer periods (often permanently). Thus, they are susceptible to many of the same organisms as patients with chronically impaired T-cell immunity (**Chap. 74**, especially **Table 74-1**). Moreover, the persistent HLA mismatch between recipient immune cells (e.g., effector T cells) and the donor organ (allograft) places the organ at permanently increased risk of infection.

During the early period (<1 month after transplantation; **Table 143-4**), infections are most commonly caused by extracellular bacteria (staphylococci, streptococci, enterococci, and *E. coli* and other gram-negative organisms, including nosocomial organisms with broad antibiotic resistance), which often originate in surgical-wound or anastomotic sites. The type of transplant largely determines the spectrum of infection. The incidence and type of surgical site infection vary dramatically with the organ transplanted, with renal transplants having the lowest incidence and intestinal and multivisceral transplants having the highest incidence and the most varied types of organisms. *S. aureus* and coagulase-negative *Staphylococcus* are among the most common causes of infection following renal transplantation, while lung transplant recipients, in addition to being infected with *Staphylococcus*, are subject to infections with *Burkholderia*, *Pseudomonas*, and *Stenotrophomonas* as well. In subsequent weeks, the consequences of the administration of agents that suppress cell-mediated immunity become apparent, and acquisition—or, more commonly, reactivation—of viruses, mycobacteria, endemic fungi, and parasites (from the recipient or from the transplanted organ) can occur. CMV infection is often a problem, particularly in the first 6 months after transplantation, and may present as severe systemic disease or as infection of the transplanted organ. HHV-6 reactivation (assessed by plasma PCR) occurs within the first 2–4 weeks after transplantation and may be associated with fever, leukopenia, and very rare cases of encephalitis. Data suggest that replication of HHV-6 and HHV-7 may exacerbate CMV-induced

TABLE 143-4 Common Infections after Solid Organ Transplantation, by Site of Infection

	PERIOD AFTER TRANSPLANTATION		
INFECTED SITE	EARLY (<1 MONTH)	MIDDLE (1–4 MONTHS)	LATE (>6 MONTHS)
Donor organ	Bacterial and fungal infections of the graft, anastomotic site, and surgical wound	CMV infection	EBV infection (may present in allograft organ)
Systemic	Bacteremia and candidemia (often resulting from central venous catheter colonization)	CMV infection (fever, bone marrow suppression)	CMV infection, especially in patients given early posttransplantation prophylaxis; EBV proliferative syndromes (may occur in donor organs)
Lung	Bacterial aspiration pneumonia with prevalent nosocomial organisms associated with intubation and sedation	*Pneumocystis* infection; CMV pneumonia; *Aspergillus* infection	*Pneumocystis* infection; granulomatous lung diseases (nocardial and reactivated fungal and mycobacterial diseases)
Kidney	Bacterial and fungal (*Candida*) infections (cystitis, pyelonephritis) associated with urinary tract catheters (highest risk in kidney transplantation)	BK virus infection (associated with nephropathy); JC virus infection	Bacterial infections (late urinary tract infections, usually not associated with bacteremia); BK virus infection (nephropathy, graft failure, generalized vasculopathy)
Liver and biliary tract	Cholangitis	CMV hepatitis	CMV hepatitis
Heart		*Toxoplasma gondii* infection (highest risk in heart transplantation); endocarditis (*Aspergillus* and gram-negative organisms more common than in the general population)	*T. gondii* (highest risk in heart transplantation)
Gastrointestinal tract	Peritonitis, especially after liver transplantation	Colitis secondary to *Clostridioides difficile* infection (risk can persist)	Colitis secondary to *C. difficile* infection (risk can persist)
Central nervous system		*Listeria* infection (meningitis); *T. gondii* infection; CMV infection	Listerial meningitis; cryptococcal meningitis; nocardial abscess; JC virus-associated PML

Abbreviations: CMV, cytomegalovirus; EBV, Epstein-Barr virus; PML, progressive multifocal leukoencephalopathy.

disease. CMV is associated not only with generalized immunosuppression but also with organ-specific, rejection-related syndromes: glomerulopathy in kidney transplant recipients, bronchiolitis obliterans in lung transplant recipients, vasculopathy in heart transplant recipients, and the vanishing bile duct syndrome in liver transplant recipients. A complex interplay between increased CMV replication and enhanced graft rejection is well established: elevated immunosuppression leads to increased CMV replication, which is associated with graft rejection. For this reason, considerable attention has been focused on the diagnosis, prophylaxis, and treatment of CMV infection in SOT recipients. Early transmission of WNV to transplant recipients from a donated organ or transfused blood has been reported; however, the risk of WNV acquisition has been reduced by implementation of screening procedures. In rare instances, rabies virus and lymphocytic choriomeningitis virus also have been acutely transmitted in this setting; although accompanied by distinct clinical syndromes, both viral infections have resulted in fatal encephalitis. As screening for unusual viruses is not routine, only vigilant assessment of the prospective donor is likely to prevent the use of an infected organ.

Beyond 6 months after transplantation, infections characteristic of patients with defects in cell-mediated immunity—e.g., infections with *Listeria, Nocardia, Rhodococcus*, mycobacteria, various fungi, and other intracellular pathogens—may be a problem. International patients and global travelers may experience reactivation of dormant infections with trypanosomes, *Leishmania*, *Plasmodium*, *Strongyloides*, and other parasites. Reactivation of latent *M. tuberculosis* infection, while rare in Western nations, is far more common among persons from developing countries. The recipient is typically the source, although reactivation and spread from the donor organ can occur. While pulmonary disease remains most common, atypical sites can be involved and mortality rates can be high (up to 30%). Vigilance, prophylaxis/preemptive therapy (when indicated), and rapid diagnosis and treatment of infections can be lifesaving in SOT recipients, who, unlike most HSC transplant recipients, continue to be immunosuppressed.

SOT recipients are susceptible to EBV-LPD from as early as 2 months to many years after transplantation. The prevalence of this complication is increased by potent and prolonged use of T cell–suppressive drugs. Decreasing the degree of immunosuppression may in some cases reverse the condition. Among SOT patients, those with heart and lung transplants—who receive the most intensive immunosuppressive regimens—are most likely to develop EBV-LPD, particularly in the lungs. Although the disease usually originates in recipient B cells, several cases of donor origin, particularly in the transplanted organ, have been noted. High organ-specific content of B lymphoid tissues (e.g., bronchus-associated lymphoid tissue in the lung), anatomic factors (e.g., lack of access of host T cells to the transplanted organ because of disturbed lymphatics), and differences in major histocompatibility loci between the host T cells and the organ (e.g., lack of cell migration or lack of effective T-cell/macrophage/dendritic cell cooperation) may result in defective elimination of EBV-infected B cells. SOT recipients are also highly susceptible to developing Kaposi's sarcoma and, less frequently, to the B cell–proliferative disorders associated with KSHV, such as primary effusion lymphoma and multicentric Castleman's disease. Kaposi's sarcoma is 550–1000 times more common among SOT recipients than in the general population; it can develop very rapidly after transplantation and can also occur in the allograft. However, because the seroprevalence of KSHV is very low in Western countries, Kaposi's sarcoma is not common. Recipients (or donors) from Iceland, the Middle East, Mediterranean countries, and Africa are at highest risk of disease. Data suggest that a switch of immunosuppressive agents—from calcineurin inhibitors (cyclosporine, tacrolimus) to mTOR pathway–active agents (sirolimus, everolimus)—after adequate wound healing may significantly reduce the likelihood of developing Kaposi's sarcoma and perhaps of EBV-LPD and certain other posttransplantation malignancies.

KIDNEY TRANSPLANTATION

See Table 143-4.

Early Infections Bacteria often cause infections that develop in the period immediately after kidney transplantation. There is a role for perioperative antibiotic prophylaxis, and each center should consider local resistance patterns. Administration within 60–120 minutes of the surgical incision is recommended. Dosing should be adjusted for weight and duration of surgery. Urinary tract infections developing soon after transplantation are usually related to anatomic alterations resulting from surgery. Such early infections may require prolonged treatment (e.g., 6 weeks of antibiotic administration for pyelonephritis). Urinary tract infections that occur >6 months after transplantation may be treated for shorter periods because they do not seem to be associated with the high rate of pyelonephritis or relapse seen with infections that occur during the first 3 months.

Prophylaxis with TMP-SMX for the first 4–6 months after transplantation decreases the incidence of early and middle-period infections (see below, Table 143-4, and **Table 143-5**).

Middle-Period Infections Because of continuing immuno-suppression, kidney transplant recipients are predisposed to lung infections characteristic of those in patients with T-cell deficiency (i.e., infections with intracellular bacteria, mycobacteria, nocardiae, fungi, viruses, and parasites). A high mortality rate associated with *Legionella pneumophila* infection **(Chap. 159)** led to the closing of renal transplant units in hospitals with endemic legionellosis.

About 50% of all renal transplant recipients presenting with fever 1–4 months after transplantation have evidence of CMV disease; CMV itself accounts for the fever in more than two-thirds of cases and thus is the predominant pathogen during this period. CMV infection **(Chap. 195)** may also present as arthralgias, myalgias, or organ-specific symptoms. During this period, this infection may represent primary disease (in the case of a seronegative recipient of a kidney from a seropositive donor) or may represent reactivation disease or superinfection.

TABLE 143-5 Prophylactic Regimens Commonly Used to Decrease Risk of Infection in Transplant Recipients[a]

RISK FACTOR	ORGANISM	PROPHYLACTIC DRUG	EXAMINATION(S)[b]
Travel to or residence in an area with known risk of endemic fungal infection	*Histoplasma*, *Blastomyces*, *Coccidioides*	Triazoles considered in context of clinical and laboratory assessment	Chest radiography, antigen testing, serology
Latent herpesviruses	HSV, VZV, CMV, EBV	Acyclovir after HSC transplantation to prevent HSV and VZV infection or reactivation; letermovir or ganciclovir to prevent CMV infection, with possible effect on EBV/KSHV (HHV-8)/HHV-6 infections in some settings	Serologic tests for HSV, VZV, CMV, HHV-6, EBV, KSHV (HHV-8); PCR
Latent fungi and parasites	*Pneumocystis jirovecii*, *Toxoplasma gondii*	Trimethoprim-sulfamethoxazole (or alternatives)	Serologic test for *Toxoplasma*
History of exposure to active or latent tuberculosis	*Mycobacterium tuberculosis*	Isoniazid or rifampin in patients with recent seroconversion or positive chest imaging and/or no previous treatment	Chest imaging; TST and/or cell-based assay

[a]For information on latent infection with hepatitis B or C virus, see **Chap. 341**. [b]Serologic examination, tuberculin skin test, and interferon assays may be less reliable after transplantation.

Abbreviations: CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSC, hematopoietic stem cell; HSV, herpes simplex virus; KSHV, Kaposi's sarcoma–associated herpesvirus; PCR, polymerase chain reaction; TST, tuberculin skin test; VZV, varicella-zoster virus.

Patients may have atypical lymphocytosis. Unlike immunocompetent patients, however, they rarely have lymphadenopathy or splenomegaly. Therefore, clinical suspicion and laboratory confirmation are necessary for diagnosis. The clinical syndrome may be accompanied by bone marrow suppression (particularly leukopenia). CMV also causes glomerulopathy and is associated with an increased incidence of other opportunistic infections. Because of the frequency and severity of disease, a considerable effort has been made to prevent and treat CMV infection in renal transplant recipients. Ganciclovir (or valganciclovir) is beneficial for prophylaxis (when indicated) and for the treatment of serious CMV disease. The availability of valganciclovir has allowed most centers to move to oral prophylaxis for transplant recipients. Infection with the other herpesviruses may become evident within 6 months after transplantation or later. Early after transplantation, HSV may cause either oral or anogenital lesions that are usually responsive to acyclovir. Large ulcerating lesions in the anogenital area may lead to bladder and rectal dysfunction and may predispose the patient to bacterial infection. VZV may cause fatal disseminated infection in nonimmune kidney transplant recipients, but in immune patients, reactivation zoster usually does not disseminate outside the dermatome; thus, disseminated VZV infection is a less fearsome complication in kidney transplantation than in HSC transplantation. HHV-6 reactivation may occur and (although usually asymptomatic) may be associated with fever, rash, marrow suppression, or rare instances of renal impairment, hepatitis, colitis, or encephalitis.

EBV disease is more serious; it may present as an extranodal proliferation of B cells that invade the CNS, nasopharynx, liver, small bowel, heart, and other organs, including the transplanted kidney. The disease is diagnosed by identifying a mass of proliferating EBV-positive B cells. The incidence of EBV-LPD is elevated among patients who acquire EBV infection from the donor and among patients given high doses of cyclosporine, tacrolimus, glucocorticoids, and anti–T-cell antibodies. Disease may regress once immunocompetence is restored. KSHV infection can be transmitted with the donor kidney and result in the development of Kaposi's sarcoma, although it more often represents reactivation of latent infection in the recipient. Kaposi's sarcoma often appears within 1 year after transplantation, although the time of onset ranges widely (1 month to ~20 years). Avoidance of immunosuppressive agents that inhibit calcineurin has been associated with less Kaposi's sarcoma, less EBV disease, and even less CMV replication. The use of rapamycin (sirolimus) has independently led to regression of Kaposi's sarcoma.

The polyomaviruses BK virus and JC virus (polyomavirus hominis types 1 and 2) have been cultured from the urine of kidney transplant recipients (as they have from that of HSC transplant recipients) in the setting of profound immunosuppression. High levels of BK virus replication detected by PCR in urine and blood are predictive of pathology, especially in the setting of renal transplantation. JC virus may rarely cause similar disease in kidney transplantation. Urinary excretion of BK virus and BK viremia are associated with the development of ureteral strictures, polyomavirus-associated nephropathy (1–10% of renal transplant recipients), and (less commonly) generalized vasculopathy. Timely detection and early reduction of immunosuppression are critical and can reduce rates of graft loss related to polyomavirus-associated nephropathy from 90 to 10–30%. Therapeutic responses to IVIg, quinolones, leflunomide, and cidofovir have been reported, but the efficacy of these agents has not been substantiated through adequate clinical study. Most centers approach the problem by reducing immunosuppression in an effort to enhance host immunity and decrease viral titers. JC virus is associated with rare cases of progressive multifocal leukoencephalopathy. Adenoviruses may persist and cause hemorrhagic nephritis/cystitis with continued immunosuppression in these patients, but disseminated disease, like that seen in HSC transplant recipients, is much less common.

Kidney transplant recipients are also subject to infections with other intracellular organisms. These patients may develop pulmonary infections with *Mycobacterium, Aspergillus*, and *Mucor* species as well as infections with other pathogens in which the T-cell/macrophage axis plays an important role. *L. monocytogenes* is a common cause of bacteremia ≥1 month after renal transplantation and should be seriously considered in renal transplant recipients presenting with fever and headache. Kidney transplant recipients may develop *Salmonella* bacteremia, which can lead to endovascular infections and require prolonged therapy. Pulmonary infections with *Pneumocystis* are common unless the patient is maintained on TMP-SMX prophylaxis. Acute interstitial nephritis caused by TMP-SMX is rare. However, because transient increases in creatinine (artifactual) and hyperkalemia (manageable) can occur, early discontinuation of prophylaxis, especially after kidney transplantation, is recommended by some groups. Although additional monitoring is indicated, the benefits of TMP-SMX in kidney transplant recipients may outweigh the risks; otherwise, second-line prophylactic agents should be used. *Nocardia* infection **(Chap. 174)** may present in the skin, bones, and lungs or in the CNS, where it usually takes the form of single or multiple brain abscesses. Nocardiosis generally occurs ≥1 month after transplantation and may follow immunosuppressive treatment for an episode of rejection. Pulmonary manifestations most commonly consist of localized disease with or without cavities, but the disease may be disseminated. The diagnosis is made by culture of the organism from sputum or from the involved nodule. As it is for *P. jirovecii* infection, prophylaxis with TMP-SMX is often efficacious in the prevention of nocardiosis.

Toxoplasmosis can occur in seropositive patients but is less common than in other transplantation settings, usually developing in the first few months after kidney transplantation. Again, TMP-SMX is helpful in prevention. In endemic areas, histoplasmosis, coccidioidomycosis, and blastomycosis may cause pulmonary infiltrates or disseminated disease.

Late Infections Late infections (>6 months after kidney transplantation) may involve the CNS and include CMV retinitis as well as other CNS manifestations of CMV disease. Patients (particularly those whose immunosuppression has been increased) are at risk for subacute meningitis due to *Cryptococcus neoformans*. Cryptococcal disease may present in an insidious manner (sometimes as a skin infection before the development of clear CNS findings). *Listeria* meningitis may have an acute presentation and requires prompt therapy to avoid a fatal outcome. TMP-SMX prophylaxis may reduce the frequency of *Listeria* infections.

Patients who continue to take glucocorticoids are predisposed to ongoing infection. "Transplant elbow," a recurrent bacterial infection in and around the elbow that is thought to result from a combination of poor tensile strength of the skin of steroid-treated patients and steroid-induced proximal myopathy, requires patients to push themselves up with their elbows to get out of chairs. Bouts of cellulitis (usually caused by *S. aureus*) recur until patients are provided with elbow protection.

Kidney transplant recipients are susceptible to invasive fungal infections, including those due to *Aspergillus* and *Rhizopus*, which may present as superficial lesions before dissemination. Mycobacterial infection (particularly that with *Mycobacterium marinum*) can be diagnosed by skin examination. Infection with *Prototheca wickerhamii* (an achlorophyllic alga) has been diagnosed by skin biopsy. Warts caused by human papillomaviruses (HPVs) are a late consequence of persistent immunosuppression; imiquimod or other forms of local therapy are usually satisfactory. Merkel cell carcinoma, a rare and aggressive neuroendocrine skin tumor whose frequency is increased five-fold in elderly SOT (especially kidney) recipients, is causally linked to a novel polyomavirus, Merkel cell polyomavirus.

Notably, although BK virus replication and virus-associated disease can be detected far earlier, polyomavirus-associated nephropathy is clinically diagnosed at a median of ~300 days and thus qualifies as a late-onset disease. With the establishment of better screening procedures (e.g., urine cytology, urine nucleic acid load, plasma PCR), disease onset is being detected earlier (see "Middle-Period Infections," above), and preemptive strategies (decrease or modification of immunosuppression) are being instituted more promptly, as the efficacy of antiviral therapy is not well established.

HEART TRANSPLANTATION

Early Infections Sternal wound infection and mediastinitis are early complications of heart transplantation. An indolent course is common, with fever or a mildly elevated white blood cell count preceding the development of site tenderness or drainage. Clinical suspicion

based on evidence of sternal instability and failure to heal may lead to the diagnosis. Common microbial residents of the skin (e.g., *S. aureus*, including methicillin-resistant strains, and *Staphylococcus epidermidis*) as well as gram-negative organisms (e.g., *Pseudomonas aeruginosa*) and fungi (e.g., *Candida*) are often involved. In rare cases, mediastinitis in heart transplant recipients can also be due to *Mycoplasma hominis* (Chap. 188); since this organism requires an anaerobic environment for growth and may be difficult to see on conventional medium, the laboratory should be alerted that its involvement is suspected. *M. hominis* mediastinitis has been cured with a combination of surgical debridement (sometimes requiring muscle-flap placement) and the administration of clindamycin and tetracycline. Organisms associated with mediastinitis may sometimes be cultured from pericardial fluid.

Middle-Period Infections *T. gondii* (Chap. 228) residing in the heart of a seropositive donor may be transmitted to a seronegative recipient. Thus, serologic screening for *T. gondii* infection is important before and in the months after cardiac transplantation. Rarely, active disease can be introduced at the time of transplantation. The overall incidence of toxoplasmosis is so high in the setting of heart transplantation that some prophylaxis is always warranted. Although alternatives are available, the most frequently used agent is TMP-SMX, which prevents infection with *Pneumocystis* as well as with *Nocardia* and several other bacterial pathogens. CMV also has been transmitted by heart transplantation. *Toxoplasma*, *Nocardia*, and *Aspergillus* can cause CNS infections. *L. monocytogenes* meningitis should be considered in heart transplant recipients with fever and headache.

CMV infection is associated with poor outcomes after heart transplantation. The virus is usually detected 1–2 months after transplantation, causes early signs and laboratory abnormalities (usually fever and atypical lymphocytosis or leukopenia and thrombocytopenia) at 2–3 months, and can produce severe disease (e.g., pneumonia) at 3–4 months. An interesting observation is that seropositive recipients usually develop viremia faster than patients whose primary CMV infection is a consequence of transplantation. Between 40 and 70% of patients develop symptomatic CMV disease in the form of (1) CMV pneumonia, the form most likely to be fatal; (2) CMV esophagitis and gastritis, sometimes accompanied by abdominal pain with or without ulcerations and bleeding; and (3) CMV syndrome, consisting of CMV in the bloodstream along with fever, leukopenia, thrombocytopenia, and hepatic enzyme abnormalities. Ganciclovir is efficacious in the treatment of CMV infection; prophylaxis with ganciclovir or possibly with other antiviral agents may reduce the overall incidence of CMV-related disease.

Late Infections EBV infection usually presents as a lymphoma-like proliferation of B cells late after heart transplantation, particularly in patients maintained on intense immunosuppressive therapy. A subset of heart and heart–lung transplant recipients may develop early fulminant EBV-LPD (within 2 months). Treatment includes the reduction of immunosuppression (if possible), the use of glucocorticoid and calcineurin inhibitor–sparing regimens, and the consideration of therapy with anti–B-cell antibodies (rituximab and possibly others). Immunomodulatory and antiviral agents continue to be studied. Ganciclovir prophylaxis for CMV disease may indirectly reduce the risk of EBV-LPD through reduced spread of replicating EBV to naïve B cells. Aggressive chemotherapy is a last resort, as discussed earlier for HSC transplant recipients. KSHV-associated disease, including Kaposi's sarcoma and primary effusion lymphoma, has been reported in heart transplant recipients. GVHD prophylaxis with sirolimus may decrease the risk of both rejection and outgrowth of KSHV-infected cells. Antitumor therapy is discussed in Chap. 73. Prophylaxis for *Pneumocystis* infection is required for these patients (see "Lung Transplantation, Late Infections," below).

Left Ventricular Assist Devices Increasingly, left ventricular assist devices (LVADs) have been used as a "bridge to transplant." These devices are implantable pumps that assist failing left ventricles. The internal pump is connected to an external power source through a subcutaneously tunneled cable termed a *driveline*, and they can be used for long periods (>80% lasting at least a year). However, infections are common, largely in the driveline, and affect 12–35% of patients. *S. aureus* and coagulase-negative staphylococci are the most common causes of infection, followed by enterococci, *Corynebacterium*, *P. aeruginosa*, *Klebsiella* species, and *E. coli*. A variety of prophylactic antibiotic regimens have been used by various centers. The most common cause of infection following surgery is thought to relate to trauma to the driveline, and local care of the entry site is important.

LUNG TRANSPLANTATION

Early Infections It is not surprising that lung transplant recipients are predisposed to the development of pneumonia. The combination of ischemia and the resulting mucosal damage, together with accompanying denervation and lack of lymphatic drainage, probably contributes to the high rate of pneumonia (66% in one series). The prophylactic use of high doses of broad-spectrum antibiotics for the first 3–4 days after surgery may decrease the incidence of pneumonia. Gram-negative pathogens (Enterobacteriaceae and *Pseudomonas* species) are troublesome in the first 2 weeks after surgery (the period of maximal vulnerability). Pneumonia can also be caused by *Candida* (including drug-resistant strains of *C. auris*), possibly as a result of colonization of the donor lung, and by *Aspergillus* and *Cryptococcus*. Many centers use antifungal prophylaxis (typically fluconazole or liposomal amphotericin B) for the first 1–2 weeks.

Mediastinitis may occur at an even higher rate among lung transplant recipients than among heart transplant recipients and most commonly develops within 2 weeks of surgery. In the absence of prophylaxis, pneumonitis due to CMV (which may be transmitted as a consequence of transplantation) usually presents between 2 weeks and 3 months after surgery, with primary disease occurring later than reactivation disease.

Middle-Period Infections The incidence of CMV infection, either reactivated or primary, is 75–100% if either the donor or the recipient is seropositive for CMV. CMV-induced disease after SOT appears to be most severe in recipients of lung and heart–lung transplants. Whether this severity relates to the mismatch in lung antigen presentation and host immune cells or is attributable to nonimmunologic factors is unknown. More than half of lung transplant recipients with symptomatic CMV disease have pneumonia. Difficulty in distinguishing the radiographic picture of CMV infection from that of other infections or from organ rejection further complicates therapy. CMV can also cause bronchiolitis obliterans in lung transplants. The development of pneumonitis related to HSV has led to the prophylactic use of acyclovir. Such prophylaxis may also decrease rates of CMV disease, but ganciclovir is more active against CMV and is also active against HSV. The prophylaxis of CMV infection with IV ganciclovir—or increasingly with valganciclovir, the oral alternative—is recommended for lung transplant recipients. Antiviral alternatives are discussed in the earlier section on HSC transplantation. Although the overall incidence of serious disease is decreased during prophylaxis, late disease may occur when prophylaxis is stopped—a pattern observed increasingly in recent years. With recovery from peritransplantation complications and, in many cases, a decrease in immunosuppression, the recipient is often better equipped to combat late infection.

Late Infections The incidence of *Pneumocystis* infection (which may present with a paucity of findings) is high among lung and heart–lung transplant recipients. Some form of prophylaxis for *Pneumocystis* pneumonia are indicated in all organ transplant situations (Table 143-5). Prophylaxis with TMP-SMX for 12 months after transplantation may be sufficient to prevent *Pneumocystis* disease in patients whose immunosuppression is not increased.

As in other transplant recipients, EBV infection in lung and heart–lung recipients may cause either a mononucleosis-like syndrome or EBV-LPD. The tendency of the B-cell blasts to present in the lung appears to be greater after lung transplantation than after the transplantation of other organs, possibly because of a rich source of B cells in bronchus-associated lymphoid tissue. Reduction of immunosuppression and switching of regimens, as discussed in earlier sections, cause remission in some cases, but mTOR inhibitors such as rapamycin may contribute to lung toxicity. Airway compression can be fatal, and rapid intervention may, therefore, become necessary. The approach to EBV-LPD is similar to that described in other sections.

LIVER TRANSPLANTATION

Early Infections As in other transplantation settings, early bacterial infections are a major problem after liver transplantation. Many centers administer systemic broad-spectrum antibiotics for the first 24 h or sometimes longer after surgery, even in the absence of documented infection. However, despite prophylaxis, infectious complications are common and correlate with the duration of the surgical procedure and the type of biliary drainage. An operation lasting >12 h is associated with an increased likelihood of infection. Patients who have a choledochojejunostomy with drainage of the biliary duct to a Roux-en-Y jejunal bowel loop have more fungal infections than those whose bile is drained via anastomosis of the donor common bile duct to the recipient common bile duct. Overall, liver transplant patients have a high incidence of fungal infections, and the occurrence of fungal (often candidal) infection in the setting of choledochojejunostomy correlates with re-transplantation, elevated creatinine levels, long procedures, transfusion of >40 units of blood, reoperation, preoperative use of glucocorticoids, prolonged treatment with antibacterial agents, and fungal colonization 2 days before and 3 days after surgery. Many centers give antifungal agents prophylactically in this setting.

Peritonitis and intraabdominal abscesses are common complications of liver transplantation. Bacterial peritonitis or localized abscesses may result from biliary leaks. Early leaks are especially common with live-donor liver transplants. Peritonitis in liver transplant recipients is often polymicrobial, frequently involving enterococci, aerobic gram-negative bacteria, staphylococci, anaerobes, or *Candida* and sometimes involving other invasive fungi. Only one-third of patients with intraabdominal abscesses have bacteremia. Abscesses within the first month after surgery may occur not only in and around the liver but also in the spleen, pericolic area, and pelvis. Treatment includes antibiotic administration and drainage as necessary. Not surprisingly, *C. difficile* colitis is also a problem in this setting **(Chap. 134)**.

Middle-Period Infections The development of postsurgical biliary stricture predisposes patients to cholangitis. The incidence of strictures is increased in live-donor liver transplantation. Transplant recipients who develop cholangitis may have high spiking fevers and rigors but often lack the characteristic signs and symptoms of classic cholangitis, including abdominal pain and jaundice. Although these findings may suggest graft rejection, rejection is typically accompanied by marked elevation of liver function enzymes. In contrast, in cholangitis in transplant recipients, results of liver function tests (with the possible exception of alkaline phosphatase levels) are often within the normal range. Definitive diagnosis of cholangitis in liver transplant recipients requires demonstration of aggregated neutrophils in bile duct biopsy specimens. Unfortunately, invasive studies of the biliary tract (either T-tube cholangiography or endoscopic retrograde cholangiopancreatography) may themselves lead to cholangitis. For this reason, many clinicians recommend an empirical trial of therapy with antibiotics covering gram-negative organisms and anaerobes before these procedures are undertaken as well as antibiotic coverage if procedures are eventually performed.

Reactivation of viral hepatitis is a common complication of liver transplantation **(Chap. 339)**. Recurrent hepatitis B and C infections, for which transplantation may be performed, are problematic. To prevent hepatitis B virus reinfection, prophylaxis with an optimal antiviral agent or combination of agents (lamivudine, adefovir, entecavir) and hepatitis B immune globulin is currently recommended, although the optimal dose, route, and duration of therapy remain controversial. Success in preventing reinfection with hepatitis B virus has increased in recent years. Complications related to hepatitis C infection are the most common reason for liver transplantation in the United States. Without treatment, reinfection of the graft with hepatitis C virus occurs in all patients, with a variable time frame. Recent studies employing direct-acting antivirals have provided impressive results in both the treatment of existing infections before transplantation and the prevention of infections after transplantation in patients with hepatitis C **(Chap. 339)**.

As in other transplantation settings, reactivation disease with herpesviruses is common (Table 143-3). Herpesviruses can be transmitted in donor organs. Although CMV hepatitis occurs in ~4% of liver transplant recipients, it is usually not so severe as to require re-transplantation. Without prophylaxis, CMV disease develops in the majority of seronegative recipients of organs from CMV-positive donors, but fatality rates are lower among liver transplant recipients than among lung or heart–lung transplant recipients. Disease due to CMV has also been associated with the vanishing bile duct syndrome after liver transplantation. Liver transplant recipients with high levels of CMV respond to treatment with ganciclovir; prophylaxis with oral forms of ganciclovir or valganciclovir decreases the frequency of disease. A role for HHV-6 reactivation in early posttransplantation fever and leukopenia has been proposed, although the more severe sequelae described in HSC transplantation are unusual. HHV-6 and HHV-7 appear to exacerbate CMV disease in this setting. EBV-LPD after liver transplantation shows a propensity for involvement of the liver, and such disease may be of donor origin. See previous sections for discussion of EBV infections in SOT.

PANCREAS TRANSPLANTATION

Pancreas transplantation is most frequently performed together with or after kidney transplantation, although it may be performed alone. Transplantation of the pancreas can be complicated by early bacterial and yeast infections. Most pancreatic transplants are drained into the bowel, and the rest are drained into the bladder. A cuff of duodenum is used in the anastomosis between the pancreatic graft and either the gut or the bladder. Bowel drainage poses a risk of early intraabdominal and allograft infections with enteric bacteria and yeasts. These infections can result in loss of the graft. Bladder drainage causes a high rate of urinary tract infection and sterile cystitis; however, such infection can usually be cured with appropriate antimicrobial agents. In both procedures, prophylactic antimicrobial agents are commonly used at the time of surgery. Aggressive immunosuppression, especially when the patient receives a kidney and a pancreas from different donors, is associated with late-onset systemic fungal and viral infections; thus, many centers administer an antifungal drug and an antiviral agent (ganciclovir or a congener) for extended prophylaxis.

Issues related to the development of CMV infection, EBV-LPD, and infections with opportunistic pathogens in patients receiving a pancreatic transplant are similar to those in other SOT recipients.

COMPOSITE-TISSUE TRANSPLANTATION

Composite-tissue allotransplantation (CTA) is a new field in which, rather than a single organ, multiple tissue types composing a major body part are transplanted. The sites involved have included hands, feet, arms, legs, face, trachea, and abdominal wall. The numbers of recipients are limited. The different procedures and the associated infectious complications vary. Nevertheless, some early trends related to infectious complications have become apparent, as very intense and prolonged immunosuppression is typically required to prevent rejection. For example, in the early postoperative period, bacterial infections are especially frequent in facial transplant recipients. Perioperative prophylaxis is tailored to the organisms likely to complicate the different procedures. As in SOT recipients, complicated CMV infections have been observed in several CTA settings, particularly when the recipient is seronegative and the donor is seropositive. In some patients, anti-CMV immune globulin in addition to ganciclovir (as used in HSC transplant recipients with CMV pneumonia) was needed to control disease, and ganciclovir resistance requiring alternative therapies developed in several patients. Infectious complications from reactivation of other members of the human herpesvirus family and other latent viruses also caused significant morbidity, as discussed for SOT recipients. Prophylaxis for CMV infection, *P. jirovecii* infection, toxoplasmosis, and fungal infection is administered for several months on the basis of the limited studies available.

MISCELLANEOUS INFECTIONS IN SOLID ORGAN TRANSPLANTATION

Indwelling IV Catheter Infections The prolonged use of indwelling IV catheters for administration of medications, blood products, and nutrition is common in diverse transplantation settings and

poses a risk of local and bloodstream infections. Exit-site infection is most commonly caused by staphylococcal species. Bloodstream infection most frequently develops within 1 week of catheter placement or in patients who become neutropenic. Coagulase-negative staphylococci are the most common isolates from blood. Although infective endocarditis in HSC transplant recipients is uncommon, the incidence of endocarditis among SOT recipients has been estimated to be as high as 1%, and this infection is associated with excessive high mortality in this population. Although staphylococci predominate, the involvement of fungal and gram-negative organisms may be more common than in the general population. **For further discussion of differential diagnosis and therapeutic options, see Chap. 74.**

Tuberculosis The incidence of tuberculosis within the first 12 months after SOT is greater than that observed after HSC transplantation (0.23–0.79%) and ranges broadly worldwide (1.2–15%), reflecting the prevalence of tuberculosis in local populations. Lesions suggesting prior tuberculosis on chest radiography, older age, diabetes, chronic liver disease, GVHD, and intense immunosuppression are predictive of tuberculosis reactivation and development of disseminated disease in a host with latent disease. Tuberculosis has rarely been transmitted from the donor organ. In contrast to the low mortality rate among HSC transplant recipients, mortality rates among SOT recipients are reported to be as high as 30%. Vigilance is indicated, as the presentation of disease is often extrapulmonary (gastrointestinal, genitourinary, central nervous, endocrine, musculoskeletal, laryngeal) and atypical; tuberculosis in this setting sometimes manifests as fever of unknown origin. Careful elicitation of a history and direct evaluation of both the recipient and the donor prior to transplantation are optimal. Skin testing of the recipient with purified protein derivative may be unreliable because of chronic disease and/or immunosuppression. Cell-based assays that measure interferon-γ and/or cytokine production may prove more sensitive in the future. Isoniazid toxicity has not been a significant problem except in the setting of liver transplantation. Therefore, appropriate prophylaxis should be used (see recommendations from the Centers for Disease Control and Prevention [CDC] at *www.cdc.gov/tb/topic/treatment/ltbi.htm*). An assessment of the need to treat latent disease should include careful consideration of the possibility of a false-negative test result. Pending final confirmation of suspected tuberculosis, aggressive multidrug treatment in accordance with the guidelines of the CDC, the Infectious Diseases Society of America, and the American Thoracic Society is indicated because of the high mortality rates among these patients. Altered drug metabolism (e.g., upon coadministration of antituberculous medications and certain immunosuppressive agents) can be managed with careful monitoring of drug levels and appropriate dose adjustment. Close follow-up of hepatic enzymes is warranted. Drug-resistant tuberculosis is especially problematic in these individuals **(Chap. 178)**.

SARS-CoV-2 SARS-CoV-2 infections in SOT recipients are associated with high mortality, long courses of disease, and infections with new strains of this virus after resolution of initial infections. Unfortunately, early vaccine studies indicate that SOT recipients do not respond as well as healthy controls. Further studies are needed to define optimal approaches to treatment and prevention of disease in this group. In the meantime, as with influenza, vaccination of family members and other close contacts is recommended.

Virus-Associated Malignancies In addition to malignancy associated with gammaherpesvirus infection (EBV, KSHV) and simple warts (HPV), other tumors that are virus-associated or suspected of being virus-associated are more likely to develop in transplant recipients, particularly those who require long-term immunosuppression, than in the general population. The interval to tumor development is usually >1 year. Transplant recipients develop nonmelanoma skin or lip cancers that, in contrast to de novo skin cancers, have a high ratio of squamous cells to basal cells. HPV may play a major role in these lesions. Cervical and vulvar carcinomas, which are quite clearly associated with HPV, develop with increased frequency in female transplant recipients. The frequency of Merkel cell carcinoma associated with Merkel cell polyomavirus is also increased among transplant recipients; however, it is unclear whether recipients infected with HTLV-1 are at increased risk of leukemia. Among renal transplant recipients, rates of melanoma are modestly increased and rates of cancers of the kidney and bladder are increased. Recommendations for dealing with these problems include vaccination against HPV, a switch from calcineurin inhibitors to mTOR inhibitors (see above), and reduction of immunosuppression to the lowest level possible without graft rejection.

VACCINATION OF TRANSPLANT RECIPIENTS

(See also Chap. 123) In addition to receiving antibiotic prophylaxis, transplant recipients should be vaccinated against likely pathogens **(Table 143-6)**. In the case of HSC transplant recipients, optimal responses cannot be achieved until after immune reconstitution, despite previous immunization of both donor and recipient. Recipients of an allogeneic HSC transplant must be reimmunized if they are to be protected against pathogens. The situation is less clear-cut in the case of autologous transplantation. T and B cells in the peripheral blood may reconstitute the immune response if they are transferred in adequate numbers. However, cancer patients (particularly those with Hodgkin's disease, in whom vaccination has been extensively studied) who are undergoing chemotherapy do not respond normally to immunization, and titers of antibodies to infectious agents fall more rapidly than in healthy individuals. Therefore, even immunosuppressed patients who have not undergone HSC transplantation may need booster vaccine injections. If memory cells are specifically eliminated as part of a stem cell "cleanup" procedure, it will be necessary to reimmunize the recipient with a new primary series. Optimal times for immunizations of different transplant populations are being evaluated. Yearly immunization of household and other contacts (including health care personnel) against influenza benefits the patient by preventing local spread.

In the absence of compelling data as to optimal timing, it is reasonable to administer the pneumococcal and *H. influenzae* type b conjugate vaccines to both autologous and allogeneic HSC transplant recipients beginning 12 months after transplantation. A series that includes both the 13-valent pneumococcal conjugate vaccine (Prevnar®) and the 23-valent pneumococcal polysaccharide vaccine (Pneumovax®) is now recommended (according to CDC guidelines). The pneumococcal and *H. influenzae* type b vaccines are particularly important for patients who have undergone splenectomy. The *Neisseria meningitidis* polysaccharide conjugate vaccine (Menactra® or Menveo®) also is recommended. In addition, diphtheria, tetanus, acellular pertussis, and inactivated polio vaccines can all be given at these same intervals (12 months and, as required, 24 months after transplantation). Some authorities recommend a new primary series for tetanus/diphtheria/pertussis and inactivated poliovirus vaccines beginning 12 months after transplantation. Vaccination to prevent hepatitis B and hepatitis A (both killed vaccines) also seems advisable. HPV vaccination, which can prevent genital warts as well as specific cancers, is recommended through age 26 for healthy young adults who previously have not been vaccinated or have not received the full series. Live-virus measles/mumps/rubella (MMR) vaccine can be given to autologous HSC transplant recipients 24 months after transplantation and to most allogeneic HSC transplant recipients at 24 months if they are not receiving maintenance therapy with immunosuppressive drugs and do not have ongoing GVHD. The risk of spread from a household contact is low for MMR vaccine. In parts of the world where live poliovirus vaccine is used, patients as well as contacts should be advised to receive only the killed vaccine. In the rare setting where both donor and recipient are VZV naïve and the recipient is no longer receiving acyclovir or ganciclovir prophylaxis, the patient should be counseled to receive varicella-zoster immune globulin (VariZIG®) up to 10 days after exposure to a person with chickenpox or uncovered zoster; such patients should avoid close contact with persons recently vaccinated with Varivax®. Neither patients nor their household contacts should receive vaccinia vaccine unless they have been exposed to smallpox virus. Among patients who have active GVHD and/or are taking high maintenance doses of glucocorticoids, it may be prudent to avoid all live-virus vaccines.

TABLE 143-6 Vaccination of Hematopoietic Stem Cell Transplant (HSCT) and Solid Organ Transplant (SOT) Recipients

VACCINE	TYPE OF TRANSPLANTATION	
	HSCT	SOT[a]
Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis	Immunize after transplantation with *H. influenzae* conjugate vaccine and *N. meningitidis* conjugate vaccine. *S. pneumoniae* vaccine is given in two steps.[b]	Immunize before transplantation with *H. influenzae* conjugate and *N. meningitidis* conjugate vaccines. *S. pneumoniae* vaccine is given in two steps.[b]
Influenza	Vaccinate in the fall. Vaccinate close contacts.	Vaccinate in the fall. Vaccinate close contacts.
Polio	Administer inactivated vaccine.	Administer inactivated vaccine.
Measles/mumps/rubella	Immunize 24 months after transplantation if GVHD is absent.	Immunize before transplantation.
Diphtheria, pertussis, tetanus	Reimmunize after transplantation with primary series, DTaP. See *www.cdc.gov/vaccines/hcp/acip-recs/general-recs/immunocompetence.html.*	Immunize or boost before transplantation with Tdap; give Td boosters at 10-year intervals or as required.
Hepatitis B and A	Reimmunize after transplantation. See recommendations.	Immunize before transplantation.
Human papillomavirus	3 doses for persons 9–45 years of age[c]	3 doses for persons 9–45 years of age[c]

[a]Immunizations should be given before transplantation whenever possible. [b]Step 1: Administer one dose of the pneumococcal conjugate vaccine Prevnar® (13-valent pneumococcal vaccine, PCV13) to all transplant candidates. If a candidate has previously been vaccinated with Pneumovax® (23-valent pneumococcal vaccine, PPSV23), at least 6 months should have elapsed before Prevnar is administered. Step 2: Administer one dose of Pneumovax at least 8 weeks after vaccination with PCV13; follow with a booster dose of Pneumovax 5 years later. If the patient has previously been vaccinated with Pneumovax (i.e., before receiving Prevnar), at least 3 years should have elapsed before the second dose of Pneumovax is administered. [c]The second and third doses should follow the first dose after 1–2 months and 6 months, respectively. Centers for Disease Control and Prevention (CDC) current recommendations: *https://www.cdc.gov/vaccines/hcp/acip-recs/general-recs/immunocompetence.html.* Some authorities recommend vaccination of all transplant recipients because of the risk of new sexual contacts later in life and the potential for human papillomavirus replication in immunocompromised patients.

Note: Recommendations from the CDC should be checked regularly as they frequently change upon receipt of new clinical information and new formulations of specific vaccines. See *www.cdc.gov/vaccines/hcp/acip-recs/general-recs/immunocompetence.html.*

Abbreviations: DTaP, full-level diphtheria and tetanus toxoids and acellular pertussis, adsorbed; GVHD, graft-versus-host disease; IDSA, Infectious Diseases Society of America; Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis.

In the case of SOT recipients, administration of all the usual vaccines and of the indicated booster doses should be completed before immunosuppression, if possible, to maximize responses. If vaccinations have not been completed prior to transplantation, many centers will wait 3–6 months before vaccinating. An exception is the seasonal influenza vaccine, which can be given 1 month after transplant with good results and should be given if a delay would result in the loss of protection during the season. For patients taking immunosuppressive agents, the administration of pneumococcal vaccine should be repeated every 5 years. No data are available for the meningococcal vaccine, but it is probably reasonable to administer it along with the pneumococcal vaccine. *H. influenzae* conjugate vaccine is safe and should be efficacious in this population; therefore, its administration before transplantation is recommended. Booster doses of this vaccine are not recommended for adults. SOT recipients who continue to receive immunosuppressive drugs should not receive live-virus vaccines. A person in this group who is exposed to measles should be given measles immune globulin. Similarly, an immunocompromised patient who is seronegative for varicella and who comes into contact with a person who has chickenpox should be given varicella-zoster immune globulin as soon as possible (optimally within 96 h; up to 10 days after contact); if this is not possible, a 10- to 14-day course of acyclovir therapy should be started immediately. Upon the discontinuation of treatment, clinical disease may still occur in a small number of patients; thus, vigilance is indicated. Rapid re-treatment with acyclovir should limit the symptoms of disease. Household contacts of transplant recipients can receive live attenuated VZV vaccine, but vaccinees should avoid direct contact with the patient if a rash develops. Virus-like particle vaccines have been licensed for the prevention of infection with several HPV serotypes most commonly implicated in cervical and anal carcinomas and in anogenital and laryngeal warts. These vaccines are not live; current CDC recommendations are for three doses in immunocompromised hosts.

Immunocompromised patients who travel may benefit from some but not all vaccines **(Chaps. 123 and 124)**. In general, these patients should receive any killed or inactivated vaccine preparation appropriate to the area they are visiting; this recommendation includes the vaccines for Japanese encephalitis, hepatitis A and B, poliomyelitis, meningococcal infection, and typhoid. Live typhoid vaccines are not recommended for use in most immunocompromised patients, but an inactivated or purified polysaccharide typhoid vaccine can be used. Live yellow fever vaccine should not be administered, nor should live cholera vaccine. On the other hand, primary immunization or boosting with the purified-protein hepatitis B vaccine is indicated. Inactivated hepatitis A vaccine should also be used in the appropriate setting **(Chap. 123)**. A vaccine is now available that provides dual protection against hepatitis A and hepatitis B. If hepatitis A vaccine is not administered, travelers should consider receiving passive protection with immune globulin (the dose depending on the duration of travel in the high-risk area).

IN MEMORIAM

Dr. Robert W. Finberg, Richard M. Haidack Distinguished Professor and Chair of Medicine, University of Massachusetts Chan Medical School (2000-2020), Professor of Medicine and Chair of Infectious Diseases, Dana Farber Cancer Institute (1996-1999), passed away on August 30, 2021. In addition to this chapter, he authored Chapter 74, "Infections in Patients with Cancer." Dr. Finberg was an internationally renowned physician-scientist and an academic leader whose career spanned four decades. A brilliant talented researcher focused on viral pathogenesis he was also a consummate clinician who attended at the bedside throughout his career. Dr. Finberg played an important role in the COVID-19 pandemic by leading clinical trials for SARS-CoV-2 vaccines and therapeutics. Warm and generous with a keen wit, he was a beloved family man, colleague and friend. As an educator and mentor he truly cared about training the next generation, as evidenced by the legacy of a very large number of trainees he leaves behind. We are indebted to Dr. Finberg for his outstanding contributions to nine editions of Harrison's Principles of Internal Medicine and to his considerable and significant contributions to the field of human health.

144 Treatment and Prophylaxis of Bacterial Infections

David C. Hooper, Erica S. Shenoy, Ramy H. Elshaboury

Antimicrobial agents have had a major impact on human health. Together with vaccines, they have contributed to reduced mortality, extended lifespan, and enhanced quality of life. Among drugs used in human medicine, however, they are distinctive in that their use promotes the occurrence of drug resistance in the pathogens they are designed to treat as well as in other "bystander" organisms. Indeed, the history of antimicrobial development has been driven in large part by the medical need engendered by the emergence of resistance to each generation of agents. Thus, the careful and appropriate use of antimicrobial drugs is particularly important not only for optimizing efficacy and minimizing adverse effects but also for minimizing the risk of resistance and preserving the value of existing agents. Although this chapter focuses on antibacterial agents, the optimal use of all antimicrobials depends on an understanding of each drug's mechanism of action, spectrum of activity, mechanisms of resistance, pharmacology, and adverse effect profile. This information is applied in the context of the patient's clinical presentation, underlying conditions, and epidemiology to define the site and likely nature of the infection or other condition and thus to choose the best therapy. Gathering of microbiologic information is especially important for refining therapeutic choices on the basis of documented pathogen and susceptibility data whenever possible; this information also makes it possible to choose more targeted therapy, thereby reducing the risk of selection of resistant bacteria. Durations of therapy are chosen according to the nature of the infection and the patient's response to treatment and are informed by clinical studies when they are available, with the understanding that shorter courses are less likely than longer courses to promote the emergence of resistance. This chapter and the one that follows provide specific information that is necessary for making informed choices among antibacterial agents. The mechanisms of action of antibacterial agents are discussed in detail in the text of this chapter, and mechanisms of resistance are discussed in detail in Chap. 145. Both types of mechanisms, which are related to each other, are summarized for the most commonly used groups of agents in Table 145-1. A schematic of antibacterial targets is provided in Fig. 145-1.

MECHANISMS OF ACTION (SEE TABLE 145-1)

Multiple essential components of bacterial cell structures and metabolism have been the targets of antibacterial agents used in clinical medicine, and the interaction of an agent with its target results in either inhibition of bacterial growth and replication (*bacteriostatic effect*) or bacterial killing (*bactericidal effect*). In general, targets have been chosen because they either do not exist in mammalian cells and physiology or are sufficiently different from their bacterial counterparts to allow selective bacterial targeting. Treatment with bacteriostatic agents is effective when the patient's host defenses are sufficient to contribute to eradication of the infecting pathogen. In patients with impaired host defenses (e.g., neutropenia) or infections at body sites with impaired or limited host defenses (e.g., meningitis and endocarditis), bactericidal agents are generally preferred.

INHIBITION OF CELL WALL SYNTHESIS

The bacterial cell wall, which is external to the cytoplasmic membrane and has no counterpart in mammalian cells, protects bacterial cells from lysis under low osmotic conditions. The cell wall is a cross-linked peptidoglycan composed of a polymer of alternating units of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM), four-amino-acid stem peptides linked to each NAM, and a peptide cross-bridge that links adjacent stem peptides to form a netlike structure. Several steps in peptidoglycan synthesis are targets of antibacterial agents. Inhibition of cell wall synthesis generally results in a bactericidal effect that is linked to cell lysis. This effect results not only from the blocking of new cell-wall formation but from the uninhibited action of cell wall–remodeling enzymes called *autolysins*, which cleave peptidoglycan as part of normal cell-wall growth.

In gram-positive bacteria the peptidoglycan is the most external cell structure, but in gram-negative bacteria, an asymmetric lipid outer membrane is external to the peptidoglycan and contains diffusion channels called *porins*. The space between the outer membrane and the peptidoglycan and cytoplasmic membrane is referred to as the *periplasmic space*. Most antibacterial drugs enter the gram-negative bacterial cell through a porin channel, since the outer membrane is a major diffusion barrier. Although the peptidoglycan layer is thicker in gram-positive (20–80 nm) than in gram-negative (1 nm) bacteria, peptidoglycan itself constitutes only a limited diffusion barrier for antibacterial agents.

β-Lactams The β-lactam drugs, including penicillins, cephalosporins, monobactams, and carbapenems, target transpeptidase enzymes (also called *penicillin-binding proteins* or PBPs) involved in the stem-peptide cross-linking step. Inhibitors of β-lactamases—bacterial enzymes that can degrade β-lactams—are used in combination with some β-lactams to expand their spectrum of activity.

Glycopeptides and Lipoglycopeptides The glycopeptides, including vancomycin and teicoplanin, and the lipoglycopeptides, including telavancin, dalbavancin, and oritavancin, bind the two terminal D-alanine residues of the stem peptide, hindering the glycosyltransferase involved in polymerizing NAG–NAM units as well as transpeptidases. Vancomycin also binds to the lipid II intermediate that delivers cell wall precursor subunits. The additional binding of teicoplanin, telavancin, dalbavancin, and oritavancin to the bacterial cytoplasmic membrane contributes to their increased potency. Both β-lactams and glycopeptides interact with their targets external to the cytoplasmic membrane.

Bacitracin (Topical) and Fosfomycin These agents interrupt enzymatic steps in the production of peptidoglycan precursors in the cytoplasm.

INHIBITION OF PROTEIN SYNTHESIS

Most inhibitors of bacterial protein synthesis target bacterial ribosomes, whose difference from eukaryotic ribosomes allows selective antibacterial action. Some inhibitors bind to the 30S ribosomal subunit and others to the 50S subunit. Most protein synthesis–inhibiting agents are bacteriostatic; aminoglycosides are an exception and are bactericidal.

Aminoglycosides Aminoglycosides (amikacin, gentamicin, kanamycin, netilmicin, streptomycin, tobramycin, and plazomicin) bind irreversibly to 16S ribosomal RNA (rRNA) of the 30S ribosomal subunit, blocking the translocation of peptidyl transfer RNA (tRNA) from the A (aminoacyl) to the P (peptidyl) site and, at low concentrations, causing misreading of messenger RNA (mRNA) codons and thus causing the introduction of incorrect amino acids into the peptide chain; at higher concentrations, translocation of the peptide chain is blocked. Cellular uptake of aminoglycosides is dependent on the electrochemical gradient across the bacterial membrane. Under anaerobic conditions, this gradient is reduced, with a consequent reduction in the uptake and activity of the aminoglycosides. Spectinomycin is a related aminocyclitol antibiotic that also binds to 16S rRNA of the 30S ribosomal subunit but at a different site. This drug inhibits translocation of the growing peptide chain but does not trigger codon misreading and produces only a bacteriostatic effect.

Tetracyclines Tetracyclines (doxycycline, minocycline, tetracycline) bind reversibly to the 16S rRNA of the 30S ribosomal subunit and block the binding of aminoacyl tRNA to the ribosomal A site, thereby inhibiting peptide elongation. Active transport of tetracyclines into bacterial but not mammalian cells contributes to the selectivity of these agents. Tigecycline, a derivative of minocycline and the only available glycylcycline, acts similarly to the tetracyclines but is distinctive for its ability to circumvent the most common mechanisms of resistance to the tetracyclines. Other new tetracycline derivatives—eravacycline, a fluorocycline, and omadacycline, an aminomethylcycline—like tigecycline are notable for being little affected by prior common tetracycline resistance mechanisms.

Macrolides and Ketolides In contrast to the aminoglycosides and tetracyclines, the macrolides (azithromycin, clarithromycin, and erythromycin) and ketolides (telithromycin) bind to the 23S rRNA of the 50S ribosomal subunit. These agents block translocation of the growing peptide chain by binding to the tunnel from which the chain exits the ribosome.

Lincosamides Clindamycin is the only lincosamide in clinical use. It binds to the 23S rRNA of the 50S ribosomal subunit, interacting with both the ribosomal A and P sites and blocking peptide bond formation.

Streptogramins The only streptogramin in clinical use is a combination of quinupristin, a group B streptogramin, and dalfopristin, a group A streptogramin. Both components bind to 23S rRNA of the 50S ribosome: dalfopristin binds to both the A and P sites of the peptidyl transferase center, and quinupristin binds to a site that overlaps the macrolide-binding site, blocking the emergence of nascent peptide from the ribosome. The combination is bactericidal, but macrolide-resistant bacteria exhibit cross-resistance to quinupristin, and the remaining activity of dalfopristin alone is only bacteriostatic.

Chloramphenicol Chloramphenicol binds reversibly to the 23S rRNA of the 50S subunit in a manner that interferes with the proper positioning of the aminoacyl component of tRNA in the A site. This site of binding is near those of the macrolides and lincosamides.

Oxazolidinones Linezolid and tedizolid are the only oxazolidinones in clinical use. They bind directly to the A site in the 23S rRNA of the 50S ribosomal subunit and block binding of aminoacyl tRNA, inhibiting the initiation of protein synthesis.

Pleuromutilins Lefamulin is the only systemic pleuromutilin in clinical use. It binds to the peptidyl transferase center of the 50S ribosomal subunit and prevents the correct positioning of tRNAs, thereby inhibiting peptide bond formation and protein synthesis.

Mupirocin Mupirocin (pseudomonic acid) is used topically. It competes with isoleucine for binding to isoleucyl tRNA synthetase, depleting stores of isoleucyl tRNA and thereby inhibiting protein synthesis.

INHIBITION OF BACTERIAL METABOLISM

Available inhibitors (antimetabolites) target the pathway for synthesis of folate, which is a cofactor in a number of one-carbon transfer reactions involved in the synthesis of some nucleic acids, including the pyrimidine thymidine and all purines (adenine and guanine), as well as some amino acids (methionine and serine) and acetyl coenzyme A. Two sequential steps in folate synthesis are targeted. The selective antibacterial effect stems from the inability of mammalian cells to synthesize folate; they depend instead on exogenous sources. Antibacterial activity, however, may be reduced in the presence of high exogenous concentrations of the end products of the folate pathway (e.g., thymidine and purines) that may occur in some infections, resulting from local breakdown of leukocytes and host tissues.

Sulfonamides Sulfonamides, including sulfadiazine, sulfisoxazole, and sulfamethoxazole, inhibit dihydropteroate synthetase (DHPS), which adds *p*-aminobenzoic acid (PABA) to pteridine, producing dihydropteroate. Sulfonamides are structural analogues of PABA and act as competing enzyme substrates.

Trimethoprim Subsequent steps in folate synthesis are catalyzed by dihydrofolate synthase, which adds glutamate to dihydropteroate, and dihydrofolate reductase (DHFR), which then generates the final product, tetrahydrofolate. Trimethoprim is a structural analogue of pteridine and inhibits DHFR. Trimethoprim is available alone but is most often used in combination products that also contain sulfamethoxazole and thus block two sequential steps in folate synthesis.

INHIBITION OF DNA AND RNA SYNTHESIS OR ACTIVITY

A variety of antibacterial agents act on these processes.

Quinolones The quinolones include nalidixic acid, the first agent in the class, and newer, more widely used fluorinated derivatives (fluoroquinolones), including norfloxacin, ciprofloxacin, levofloxacin, moxifloxacin, gemifloxacin, and delafloxacin. The quinolones are synthetic compounds that inhibit bacterial DNA synthesis by interacting with the DNA complexes of two essential enzymes, DNA gyrase and DNA topoisomerase IV, which alter DNA topology. Quinolones trap enzyme–DNA complexes in such a way that they block movement of the DNA replication apparatus and can generate lethal double-strand breaks in DNA, resulting in bactericidal activity. Although mammalian cells also have type II DNA topoisomerases related to gyrase and topoisomerase IV, the structures of the mammalian enzymes are sufficiently different from those of the bacterial enzymes that quinolones have substantially selective antibacterial activity.

Rifamycins Rifampin, rifabutin, and rifapentine are semisynthetic derivatives of rifamycin B and bind the β subunit of bacterial RNA polymerase, thereby blocking elongation of mRNA. Their action is highly selective for the bacterial enzyme over mammalian RNA polymerases.

Nitrofurantoin The reduction of nitrofurantoin, a nitrofuran compound, by bacterial enzymes produces highly reactive derivatives that are thought to cause DNA strand breakage. Nitrofurantoin is used only for the treatment of lower urinary tract infections.

Metronidazole Metronidazole is a synthetic nitroimidazole with activity limited to anaerobic bacteria and certain anaerobic protozoa. Reduction of its nitro group by the electron-transport system in anaerobic bacteria produces reactive intermediates that damage DNA and result in bactericidal activity. Both nitrofurantoin and metronidazole have selective antibacterial activity because the reducing activity needed to produce active derivatives is generated only by bacterial and not mammalian enzymes.

DISRUPTION OF MEMBRANE INTEGRITY

The integrity of the bacterial cytoplasmic membrane—and, in gram-negative bacteria, the outer membrane—is important for bacterial viability. Two bactericidal drugs have membrane targets.

Polymyxins The polymyxins, including polymyxin B and polymyxin E (colistin), are cationic cyclic polypeptides that disrupt the cytoplasmic membrane and the outer membrane (the latter by binding lipopolysaccharide, which is negatively charged).

Daptomycin Daptomycin is a lipopeptide that binds the cytoplasmic membrane of gram-positive bacteria in the presence of calcium, generating a channel that leads to leakage of cytoplasmic potassium ions and membrane depolarization.

PHARMACOKINETICS AND PHARMACODYNAMICS

The term *pharmacokinetics* describes the disposition of a drug in the body, whereas *pharmacodynamics* describes the drug action on the pathogen in relation to pharmacokinetic factors. An understanding of the principles governing these two areas is required for effective drug selection, dosing, and prevention of toxicities.

PHARMACOKINETICS

The process of drug disposition consists of four principal phases: absorption, distribution, metabolism, and excretion. These phases determine the time course of drug concentrations in serum and other tissues and body fluids.

Absorption When a drug is administered, *absorption* is defined as the percentage of the dose that reaches the vasculature. The fraction of a drug, however, that reaches the systemic circulation or the pharmacologic site of action is termed *bioavailability*. The bioavailability is more relevant when non-IV routes are used—e.g., the oral, IM, SC, and topical routes. For example, since IV administration provides direct access to the systemic circulation, the bioavailability is 100%. IV and oral dosing for highly bioavailable agents result in equivalent systemic concentrations; examples of such agents include metronidazole, fluoroquinolones, tetracyclines, and linezolid. Additionally, many factors can influence a drug's oral bioavailability, including the timing of food consumption relative to drug administration, drug-metabolizing enzymes, efflux transporters, concentration-dependent solubility, and acid degradation. Underlying conditions such as diarrhea or ileus can also affect the site of drug absorption and thereby alter its bioavailability. Certain orally administered drugs may have lower bioavailability because of the *first-pass effect*—the process by which drugs are absorbed in the small intestine through the portal circulation and directly transported to the liver for metabolism before reaching their intended site of action.

Distribution *Distribution* describes the process of drug transfer reversibly between the general circulation and body tissues. After absorption into the general circulation and the central compartment (the extensively perfused organs), the drug also distributes into the peripheral compartment (less well-perfused tissues). The volume of distribution (Vd) is a pharmacokinetic parameter that describes the amount of drug in the body at a given time relative to the measured serum concentration. Properties such as the drug's lipophilicity, partition coefficient within different body tissues, protein binding, blood flow, penetration of the blood-brain barrier, and pH can affect the Vd and subsequently the concentration in various tissues. Drugs with a small Vd are limited to certain areas within the body (typically extracellular fluid), whereas those with a higher Vd penetrate extensively into tissues. Some antibacterial drugs can bind to serum proteins, resulting in typically lower Vd as only the unbound (free) fraction of the drug distributes into body tissues and fluids. Furthermore, only the unbound fraction of the drug is considered therapeutically active and available to exert antibacterial effects.

Metabolism *Metabolism* is the chemical transformation of a drug by the body. This modification can occur within several areas; the liver is the organ most commonly involved. Drugs are metabolized by enzymes, but enzyme systems have a finite capacity to metabolize a substrate. If a drug is given in a dose at which the concentration does not exceed the rate of metabolism, the metabolic process is generally linear. If the dose exceeds the amount that can be metabolized, drug accumulation and potential toxicity may occur. Drugs are metabolized through phase I or phase II reactions. In phase I reactions, the drug is made more polar through dealkylation, hydroxylation, oxidation, and deamination. Polarity increases water solubility and facilitates removal from the body (e.g., renal elimination). Phase II reactions, which include glucuronidation, sulfation, and acetylation, result in compounds larger and more polar than the parent drug. Both phases usually inactivate the parent drug, although some drugs are rendered more active. The hepatic cytochrome P450 (CYP) enzyme system is mostly responsible for phase I reactions. CYP3A4 is a common subfamily within this system that is responsible for the majority of phase I metabolism. Antibacterial drugs can be substrates, inhibitors, or inducers of a particular CYP enzyme. Inducers, e.g., rifampin, can increase the production of CYP enzymes and consequently increase the metabolism of other drugs. Inhibitors, such as macrolides, cause a decrease in enzyme activity and therefore an increase in the concentration of the interacting drug by decreasing the rate of its metabolism.

Excretion *Excretion* describes the body's mechanisms of drug elimination. Drugs can be eliminated through more than one mechanism. Renal clearance is the most common route and includes elimination through glomerular filtration, tubular secretion, and/or passive diffusion. Some agents undergo nonrenal clearance and rely on the biliary tract or the intestine for excretion. Rate of excretion affects the half-life of a drug—i.e., defined as the time it takes for the blood concentration of a drug to decrease by one-half. This value can range from minutes to days. Half-life and overall drug clearance can be extended if the organ responsible for clearance is impaired. For example, patients with renal or hepatic impairment may require dose adjustments that take delayed clearance into account and prevent drug accumulation and toxicity. For example, the majority of beta-lactam agents are cleared predominantly through glomerular filtration, and in the presence of renal impairment, the dosing interval is typically increased to account for the increased half-life.

PHARMACODYNAMICS

The term *pharmacodynamics* describes the relationship between the serum concentrations that determine the efficacy of the drug and those that may produce toxic effects. For an antibacterial agent, the pharmacodynamic focus is the type of drug exposure needed for optimal antibacterial effect in relation to the minimal inhibitory concentration (MIC)—the lowest drug concentration that inhibits the growth of a microorganism under standardized laboratory conditions. Antibacterial effect usually correlates with one or more of the following parameters: (1) concentration-dependent killing (defined as the ratio of peak serum concentration to the MIC), (2) time-dependent killing (defined as duration of drug concentrations above the MIC), or (3) the area under the concentration–time curve to the MIC (AUC/MIC) **(Fig. 144-1)**.

For *concentration-dependent* killing agents, as the designation implies, the higher the drug peak concentration (C_{max}), the higher the rate and extent of bacterial killing. Aminoglycosides fit into the C_{max}/MIC model of pharmacodynamics activity, and a particular peak serum concentration is often targeted to achieve optimal killing. In contrast, *time-dependent* killing agents reach a ceiling at which higher concentrations do not result in increased effect. Rather, these agents are active against bacteria only when the drug concentration exceeds the MIC. The T > MIC predicts clinical efficacy for all β-lactams. The longer the concentration of the β-lactam remains above the MIC for an infecting pathogen during the dosing interval, the greater is the killing effect. Fluoroquinolones and vancomycin exemplify agents for which the AUC/MIC is a predictor of efficacy. For example, studies have found that an AUC/MIC ratio of >30 will maximize killing of *S. pneumoniae* by fluoroquinolones, while AUC/MIC ratios >125 are required to exert their effects against gram-negative pathogens. Finally, for some antibacterial drugs such as aminoglycosides, a *postantibiotic*

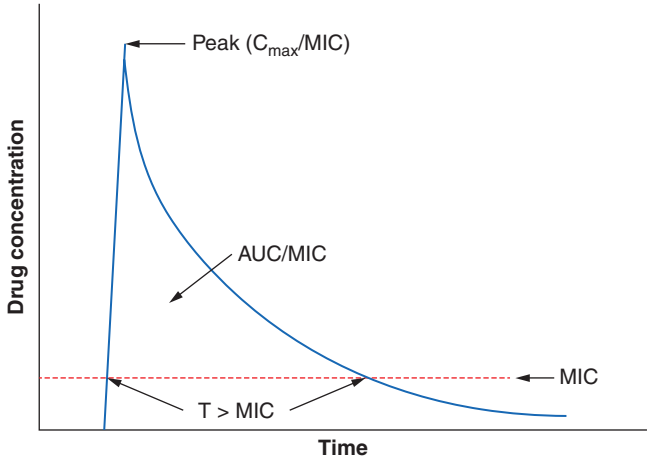

FIGURE 144-1 Pharmacokinetic and pharmacodynamic model predicting efficacy of antibacterial drugs. AUC, area under the time–concentration curve; C_{max}, peak serum concentration of drug; MIC, minimal inhibitory concentration; T > MIC, duration of drug concentrations above the MIC.

effect—the delayed regrowth of surviving bacteria after exposure to an antibiotic—supports less frequent dosing.

APPROACH TO THERAPY

The approach to antibiotic therapy is driven by host factors, site of infection, and local resistance profiles of suspected or known pathogens. Further, national and local drug shortages and formulary restrictions can affect available therapies. Regular monitoring of the patient and collection of laboratory data should be undertaken to streamline antibacterial therapy as appropriate and to investigate the possibility of treatment failure if the patient fails to respond appropriately.

EMPIRICAL AND DIRECTED THERAPY

Therapy is considered *empirical* when the causative agent has yet to be determined and therapeutic decisions are based on the severity of illness, the clinician's assessment of likely pathogens in light of the clinical syndrome, the patient's medical conditions and prior therapy, and relevant epidemiologic factors. For patients with severe illness, empirical therapy often takes the form of an antibacterial combination that provides broad coverage of diverse agents and thus ensures adequate treatment of possible pathogens while additional data are being collected. *Directed* therapy is predicated on identification of the pathogen, determination of its susceptibility profile, and establishment of the extent of the infection. Directed therapy generally allows the use of more targeted and narrower-spectrum antibacterial agents than does empirical therapy.

Information on epidemiology, exposures, and local antibacterial susceptibility patterns can help guide empirical therapy. When empirical treatment is clinically appropriate, care should be taken to obtain clinical specimens for microbiologic analysis before the initiation of therapy and to adjust therapy as new information is obtained about the patient's clinical condition and the causal pathogens. Change to directed therapy can limit unnecessary risks of drug side effects as well as selection for antibacterial resistance.

SITE OF INFECTION

The site of infection is a consideration in antibacterial therapy, largely because of the differing abilities of drugs to penetrate and achieve adequate concentrations at particular body sites. For example, to be effective in the treatment of meningitis, an agent must (1) be able to cross the blood-brain barrier and reach adequate concentrations in the cerebrospinal fluid (CSF) and (2) be active against the relevant pathogen(s). Dexamethasone, administered with or 15–20 min before the first dose of an antibacterial drug, has been shown to improve outcomes in patients with some types of acute bacterial meningitis, but its use may reduce penetration of some antibacterial agents, such as vancomycin, into the CSF. In this case, rifampin is added because its penetration is not reduced by dexamethasone. Infections at sites where pathogens are protected from normal host defenses, penetration of an antibacterial drug is limited, or local conditions (e.g., low pH) limit activity of some agents include, in addition to meningitis, osteomyelitis, prostatitis, intraocular infections, and abscesses. In such cases, consideration must be given to the route of drug delivery (e.g., intravitreal injections) as well as to interventions to drain, debride, or otherwise reduce bacterial load and necrotic material that can reduce antibacterial activity.

HOST FACTORS

Host factors, including immune function, pregnancy, allergies, age, renal and hepatic function, drug–drug interactions, comorbid conditions, and occupational or social exposures, should be considered.

Immune Dysfunction Patients with deficits in immune function that blunt the response to bacterial infection, including neutropenia, deficient humoral immunity, and asplenia (either surgical or functional), are all at increased risk of severe bacterial infection. Such patients should be treated aggressively and often broadly in the early stages of suspected infection pending results of microbiologic tests. For asplenic patients, treatment should include coverage of encapsulated organisms, particularly *Streptococcus pneumoniae*, that may cause rapidly life-threatening infection. For neutropenic patients, initial treatment typically includes antibacterial agents with broad activity against gram-negative bacteria.

Pregnancy Pregnancy affects decisions regarding antibacterial therapy in two respects. First, pregnancy is associated with an increased risk of particular infections (e.g., those caused by *Listeria*). Second, the potential risks to the fetus that are posed by specific drugs must be considered. As for other drugs, the safety of the vast majority of antibacterial agents in pregnancy has not been established, and such agents are grouped in categories B and C by the U.S. Food and Drug Administration (FDA). Drugs in categories D and X are contraindicated in pregnancy or lactation due to established risks. Note that in accordance with the Pregnancy and Lactation Labeling Final Rule (PLLR), drugs submitted to the FDA for approval after 2015 do not use the pregnancy risk categories. The risks associated with antibacterial use in pregnancy and during lactation are summarized in **Table 144-1**.

Allergies Allergies to antibiotics are among the most common allergies reported, and an allergy history should be obtained whenever possible before therapy is chosen. A detailed allergy history can shed light on the type of reaction experienced previously and on whether rechallenge with the same or a related medication is advisable (and, if so, under what circumstances). Allergies to the penicillins are most common. Although as many as 10% of patients may report an allergy to penicillin, studies suggest that more than 90% of these patients could tolerate a penicillin or cephalosporin. Adverse effects **(Table 144-2)** should be distinguished from true allergies to ensure appropriate selection of antibacterial therapy.

Drug–Drug Interactions Patients commonly receive other drugs that may interact with antibacterial agents. A summary of the most common drug–drug interactions, by antibacterial class, is provided in **Table 144-3**.

Exposures Exposures, both occupational and social, may provide clues to likely pathogens. When relevant, inquiries about exposure to ill contacts, animals, insects, and water should be included in the history, along with sites of residence and travel.

Other Host Factors Age, renal and hepatic function, and comorbid conditions are all considerations in the choice of and schedule for therapy. Dose adjustments should be made accordingly. In patients with decreased or unreliable oral absorption, IV therapy may be preferred to ensure adequate blood levels of drug and delivery of the antibacterial agent to the site of infection. In general, initial treatment for severe and life-threatening infections is given by intravenous injection to assure prompt and adequate drug delivery.

DURATION OF THERAPY

Whether empirical or directed, the duration of therapy should be determined in most clinical situations. Guidelines that synthesize available literature and expert opinion provide recommendations on therapy duration that are based on infecting organism, organ system, and patient factors. For example, the American Heart Association has published guidelines endorsed by the Infectious Diseases Society of America (IDSA) on diagnosis, antibacterial therapy, and management of complications of infective endocarditis. Similar guidelines from the IDSA exist for bacterial meningitis, urinary tract infections (including those that are catheter-associated), intraabdominal infections, community- and hospital-acquired pneumonia, skin and soft tissue infections, and other infections. In general, where data on adequate durations of therapy exist, shorter courses are preferred to reduce the likelihood of drug adverse effects and selection of resistant bacteria.

FAILURE OF THERAPY

If a patient does not respond to therapy, investigations often should include imaging and the collection of additional specimens for microbiologic testing as indicated. Failure to respond can be the result of an antibacterial regimen that does not address the underlying causative organism, the development of resistance during therapy, or the existence of a focus of infection at a site poorly penetrated by systemic

TABLE 144-1 Risks Associated with Use of Antibacterial Drugs in Pregnancy and Lactation

PREGNANCY CATEGORY[a]	ANTIBACTERIAL DRUG	FETAL RISK RECOMMENDATION[b]	BREAST-FEEDING RISK RECOMMENDATION[b]
B	Azithromycin	Limited human data. Animal data suggest low risk.	Limited human data; probably compatible
	Cephalosporins (including cephalexin, cefuroxime, cefixime, cefpodoxime, cefotaxime, ceftriaxone)	Compatible	Compatible
	Ceftazidime-avibactam	No human data; no fetal harm in animal studies	Ceftazidime is excreted into human milk in low concentrations. Avibactam is excreted into the milk of lactating rats; no human studies have been conducted.
	Ceftolozane-tazobactam	Compatible	Unknown
	Clindamycin	Compatible	Compatible
	Ertapenem	No human data; probably compatible	Limited human data; probably compatible
	Erythromycin	Compatible (except for estolate salt)	Compatible
	Meropenem and meropenem-vaborbactam	No human data. Animal data suggest low risk.	No human data; probably compatible
	Metronidazole	Human data suggest low risk.	Interrupt breast-feeding for 12–24 h after single 2-g dose. Limited human data; potential toxicity in divided doses
	Nitrofurantoin	Human data suggest risk in third trimester.	Limited human data; probably compatible. Higher risk associated with younger infants and those with G6PD deficiency
	Penicillins (including amoxicillin, ampicillin, cloxacillin)	Compatible	Compatible
	Quinupristin-dalfopristin	Compatible. Maternal benefit must far outweigh risk to embryo/fetus.	No human data; potential toxicity
	Vancomycin	Compatible	Limited human data; probably compatible
C	Chloramphenicol	Compatible	Limited human data; potential toxicity
	Fluoroquinolones	Human data suggest low risk.	Limited human data; probably compatible
	Clarithromycin	Limited human data. Animal data suggest high risk.	No human data; probably compatible
	Imipenem-cilastatin	Limited human data. Animal data suggest low risk.	Limited human data; probably compatible
	Linezolid	Compatible. Maternal benefit must far outweigh risk to embryo/fetus.	No human data; potential toxicity
	Telavancin	No human data. Animal studies have revealed evidence of teratogenicity.[c]	No human data. Animal studies have revealed evidence of teratogenicity.[c]
	Tedizolid	Limited data. Embryofetal studies in mice, rats, and rabbits have demonstrated fetal developmental toxicities. Use only if benefit outweighs risk.	Excreted in the breast milk of rats; unknown in humans; caution use
	Dalbavancin	Limited human data. At high doses in animal studies, delayed fetal maturation, increased embryo and offspring death. Use only if benefit outweighs risk.	Excreted in the breast milk of animals; unknown in humans; caution use
	Oritavancin	Limited human data. Studies in rats and rabbits demonstrated no harm at 25% of recommended human dose. Use only if benefit outweighs risk.	Excreted in the breast milk of rats; unknown in humans; caution use
C/D	Amikacin	Human data suggest low risk.	Compatible
	Gentamicin	Human data suggest low risk.	Compatible
D	Kanamycin	Human data suggest risk.	Limited human data; probably compatible
	Streptomycin	Human data suggest risk.	Compatible
	Sulfonamides	Human data suggest risk in third trimester.	Limited human data; potential toxicity. Avoid in ill, stressed, premature infants and in infants with hyperbilirubinemia or G6PD deficiency.
	Tetracyclines	Contraindicated in second and third trimesters.	Compatible
	Tigecycline	Human data suggest risk in second and third trimesters.	No human data; potential toxicity
Not assigned[d]	Cefiderocol	No controlled data in human pregnancy; animal studies have not provided evidence of fetal harm.	Unknown if excreted in human milk; excreted in animal milk.
	Eravacycline	No controlled data in human pregnancy; animal data indicate drug crosses placenta and is associated with risk at higher doses,	Unknown if excreted in human milk; excreted in animal milk. Not recommended during and for a period after treatment.
	Imipenem-cilastatin-relebactam	No controlled data in human pregnancy; animal studies have not revealed teratogenicity but have shown evidence of increased fetal loss.	Imipenem and cilastatin are excreted into human milk; no data on relebactam in human milk. Relebactam is excreted in animal milk. No human data regarding potential effect on infant.
	Lefamulin[e]	No controlled data in human pregnancy; animal studies have revealed evidence of fetal harm.	Unknown if excreted in human milk; excreted in animal milk. Breastfeeding is not recommended during use and for 2 days afterward.

(*Continued*)

TABLE 144-1 Risks Associated with Use of Antibacterial Drugs in Pregnancy and Lactation (Continued)

PREGNANCY CATEGORY[a]	ANTIBACTERIAL DRUG	FETAL RISK RECOMMENDATION[b]	BREAST-FEEDING RISK RECOMMENDATION[b]
	Meropenem-vaborbactam	No controlled data in human pregnancy; animal studies have revealed evidence of fetal harm (related to vaborbactam component).	Meropenem is excreted in human milk; it is unknown if vaborbactam is excreted in human milk. Data on excretion of vaborbactam in animal milk is unknown.
	Omadacycline	No controlled data in human pregnancy; however, as this is a tetracycline class antibiotic, may cause deciduous tooth discoloration and bone growth inhibition in second and third trimesters of pregnancy; animal data have demonstrated embryofetal lethality, teratogenicity, and embryofetal toxicity.	Unknown if excreted in human milk; data not available regarding excretion in animal milk. Not recommended during and for a period after treatment.
	Plazomicin	No controlled data in human pregnancy; however, aminoglycoside antibiotics are known to cause fetal harm in pregnancy.	Unknown if excreted in human milk; excreted in animal milk.

[a] *Category B: Either* animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women; *or* animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester. *Category C:* Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. *Category D:* There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. [b] Fetal risk recommendation and breast-feeding risk recommendation adapted from GG Briggs et al (eds): *Drugs in Pregnancy and Lactation,* 9th ed. Philadelphia, Lippincott Williams and Wilkins, 2011; and the U.S. Food and Drug Administration (Drugs@FDA). [c] A registry has been established to monitor pregnancy outcomes of pregnant women exposed to telavancin. Physicians are encouraged to register pregnant patients or pregnant women may enroll themselves by calling 1-855-633-8479. [d] The U.S. Food and Drug Administration is phasing out use of pregnancy categories A, B, C, D, and X. [e] A pregnancy pharmacovigilance program is available: If this drug is inadvertently administered during pregnancy or if a patient becomes pregnant while receiving this drug, healthcare providers or patients should report drug exposure by calling 1-855-5NABRIVA (1-855-56227482) to enroll.

Abbreviation: G6PD, glucose-6-phosphate dehydrogenase.

therapy. Some infections may also require surgical interventions (e.g., large abscesses, myonecrosis). Fever due to allergic drug reactions can sometimes complicate assessment of the patient's response to antibacterial treatment.

EXPERT GUIDANCE

Selected websites with the most up-to-date information and guidance for the clinician include the following:

- Johns Hopkins ABX Guide (*www.hopkins-abxguide.org*)
- IDSA Practice Guidelines (*https://www.idsociety.org/practice-guideline/practice-guidelines/#/date_na_dt/DESC/0/+/*)
- Center for Disease Dynamics, Economics and Policy Antibiotic Resistance Map (*https://resistancemap.cddep.org/AntibioticResistance.php*)
- Centers for Disease Control and Prevention Antibiotic/Antimicrobial Resistance (*www.cdc.gov/drugresistance/*)

CLINICAL USE OF ANTIBACTERIAL AGENTS

The clinical application of antibacterial therapy is guided by the spectrum of the agent and the suspected or known target pathogen. Infections for which specific antibacterial agents are among the drugs of choice are listed, along with associated pathogens and susceptibility data, in **Table 144-4**. Resistance rates of specific organisms are dynamic and should be taken into account in the approach to antibacterial therapy. While national resistance rates can serve as a reference, the most useful reference for the clinician is the most recent local laboratory antibiogram, which provides details on local resistance patterns, often on an annual or semiannual basis.

β-LACTAMS

The β-lactam class of antibiotics consists of penicillins, cephalosporins, carbapenems, and monobactams. The term *β-lactam* reflects the drugs' four-membered lactam ring, which is their core structure. The differing side chains among the agents of this family determine the spectrum of activity. All β-lactams exert a bactericidal effect by inhibiting bacterial cell-wall synthesis. The β-lactams are classified as time-dependent killing agents; therefore, their clinical efficacy is best correlated with the proportion of the dosing interval during which drug levels remain above the MIC for the targeted pathogen.

Penicillins and β-Lactamase Inhibitors Penicillin, the first β-lactam, was discovered in 1928 by Alexander Fleming. Natural penicillins, such as penicillin G, are active against non-β-lactamase-producing gram-positive and gram-negative bacteria, anaerobes, and some gram-negative cocci. Penicillin G is used for penicillin-susceptible streptococcal infections, pneumococcal and meningococcal meningitis, enterococcal endocarditis, and syphilis. The antistaphylococcal penicillins, which have potent activity against methicillin-susceptible *Staphylococcus aureus* (MSSA), include nafcillin, oxacillin, dicloxacillin, and flucloxacillin. Aminopenicillins, such as ampicillin and amoxicillin, provide added coverage beyond penicillin against gram-negative cocci, such as *Haemophilus influenzae*, and some Enterobacterales, including *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, and *Shigella*. The aminopenicillins are hydrolyzed by many common β-lactamases. These drugs are commonly used for infections caused by susceptible enterococcal and streptococcal species. IV ampicillin is commonly used in meningitis and endocarditis. Oral amoxicillin may be an option for otitis media, respiratory tract infections, and urinary tract infections. The antipseudomonal penicillins include ticarcillin and piperacillin. These penicillin groups generally offer adequate anaerobic coverage; the exceptions are *Bacteroides* species (such as *Bacteroides fragilis*), which produce β-lactamases and are generally resistant. The rising prevalence of β-lactamase-producing bacteria has led to the increased use of β-lactam–β-lactamase inhibitor combinations, such as ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, ceftolozane-tazobactam, ceftazidime-avibactam, meropenem-vaborbactam, and imipenem-relebactam. The β-lactamase inhibitors themselves do not have antibacterial activity (with the exception of sulbactam, which has activity against *Acinetobacter baumannii*) but typically inhibit the *S. aureus* class A β-lactamase, β-lactamases of *H. influenzae* and *Bacteroides* species, and a number of plasmid-encoded β-lactamases. These combination agents are typically used when broader-spectrum coverage is needed—e.g., in pneumonia and intraabdominal infections. Piperacillin-tazobactam is a useful agent for broad coverage in febrile neutropenic patients. Avibactam, vaborbactam, and relebactam inhibit a broader spectrum of β-lactamases than the other inhibitors, including extended-spectrum β-lactamases (ESBLs), AmpC β-lactamases, and some carbapenemases **(see Chap. 145)**.

Cephalosporins The cephalosporin drug class encompasses several generations distinguished by a spectrum of antibacterial activity. The first generation (cefazolin, cefadroxil, and cephalexin) largely has activity against gram-positive bacteria, with some additional activity against *E. coli*, *P. mirabilis*, and *Klebsiella pneumoniae*. First-generation cephalosporins are commonly used for infections caused by MSSA and

TABLE 144-2 Common Adverse Reactions to Antibacterial Agents

ANTIBACTERIAL(S)	POTENTIAL ADVERSE EFFECTS	COMMENTS
β-Lactams	Hypersensitivity reactions	Range from rash to anaphylaxis. Cross-reactivity among β-lactams is related to chemical structure and side chain similarity.
	Neurotoxicity	More commonly described with cefepime and imipenem, but likely a class effect. Risk is increased in patients with history of seizures, renal impairment, and advanced age.
	Neutropenia/hematologic reactions	May be related to high doses and prolonged duration.
Vancomycin	Nephrotoxicity	Risk increases with vancomycin trough levels >20 μg/mL or concomitant administration with other potentially nephrotoxic agents. The effect is usually reversible.
	Infusion reaction formerly known as "red man syndrome"	Can be managed with a slower vancomycin infusion and pretreatment with antihistamine.
Telavancin	QT prolongation	
	Interference with coagulation tests	May falsely affect INR, PT, aPTT. Perform these tests before the next dose of telavancin (when serum drug levels are at their nadir).
	Taste disturbances	
	Nephrotoxicity	
Oritavancin	Interference with coagulation tests	May falsely affect INR, PT, aPTT. Perform these tests at least 24 h after the dose is administered.
	Gastrointestinal distress	
Dalbavancin	Gastrointestinal distress	
Daptomycin	Myopathy	Monitor CPK levels during therapy. Rhabdomyolysis has been reported but appears to be rare.
	Eosinophilic pneumonia	
Aminoglycosides	Nephrotoxicity	Associated with prolonged use; usually reversible
	Ototoxicity	Can cause both vestibular and cochlear toxicity. Ototoxicity may be irreversible.
Fluoroquinolones	QT_c prolongation	Moxifloxacin appears more likely than other quinolones to exert this effect. Risk of arrhythmia increases when these drugs are given concomitantly with other QT_c-prolonging agents.
	Tendinitis	Risk is greater among the elderly and patients receiving steroids.
	Dysglycemia	
	Exacerbation of myasthenia gravis	
Rifampin	Hepatotoxicity	Risk is greater when drug is given with other antituberculosis agents. When rifampin is given alone, LFT values may be transiently elevated without symptoms.
	Orange discoloration of body fluids	
Tetracyclines, including tigecycline, eravacycline, and omadacycline	Photosensitivity	
	Gastrointestinal distress	High incidence of diarrhea, nausea, vomiting
Macrolides	Gastrointestinal distress	Erythromycin is occasionally used as a therapeutic agent for some gastric motility disorders.
	QT_c prolongation	Azithromycin use is associated with an increased risk of death from cardiovascular causes among patients at high baseline risk.
Metronidazole	Peripheral neuropathy	Associated with prolonged use
Clindamycin	Diarrhea and pseudomembranous colitis	
Linezolid, tedizolid	Myelosuppression	Associated with prolonged use
	Optic and peripheral neuropathy	Associated with prolonged use
	Lactic acidosis	
TMP-SMX	Hypersensitivity reactions	Allergy usually associated with sulfonamide moiety
	Nephrotoxicity	Associated with high doses
	Hematologic effects	Associated with prolonged use
Nitrofurantoin	Pneumonitis and other pulmonary reactions	Associated with prolonged use
	Peripheral neuropathy	Associated with accumulation of nitrofurantoin in renal failure. Avoid use in renal impairment.
Fosfomycin	Gastrointestinal effects	
Polymyxins	Nephrotoxicity	Associated with high dose
	Neurotoxicity	Neuromuscular blockade and muscle weakness are well described and usually reversible.
Quinupristin-dalfopristin	Arthralgias and myalgias	
Chloramphenicol	Bone marrow suppression	Aplastic anemia or hematopoietic toxicity
Pleuromutilin	Gastrointestinal	Diarrhea
	QT_c prolongation	When used in conjunction with CYP3A4 substrates

Note: All systemic antibiotics have the potential to alter abdominal flora and induce *Clostridioides difficile* infection.

Abbreviations: aPTT, activated partial thromboplastin time; CPK, creatine phosphokinase; INR, international normalized ratio; LFT, liver function test; PT, prothrombin time; TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 144-3 Important Antibacterial Drug Interactions

ANTIBACTERIAL(S)	INTERACTING AGENT(S)	POTENTIAL EFFECT AND MANAGEMENT
Nafcillin	Warfarin, cyclosporine, tacrolimus	Decreased effects of interacting drug via CYP3A4 induction. Monitor levels of affected drug closely if drugs are given concomitantly.
Ceftriaxone	Calcium-containing IV solutions	Concomitant use is contraindicated in neonates (<28 days); the combination can lead to precipitation of ceftriaxone-calcium particulate. Ceftriaxone and calcium-containing solutions can be given to infants >28 days of age provided they are given sequentially and the lines are thoroughly flushed between infusions, or infused via separate lines.
Carbapenems	Valproic acid	Diminished levels of valproic acid. Monitor valproic acid levels closely if drugs are given concomitantly and consider alternative therapies.
Linezolid, tedizolid	Serotonergic and adrenergic agents (e.g., SSRIs, vasopressors)	Increased levels of serotonergic and adrenergic agents. Monitor for serotonin syndrome. Tedizolid may have less potential than linezolid to cause this drug interaction.
Quinupristin-dalfopristin	Substrates of CYP3A4 (e.g., warfarin, ritonavir, cyclosporine, diazepam, verapamil)	Can result in increased levels of interacting drug
Fluoroquinolones	Theophylline[a]	Can result in theophylline toxicity
	Sucralfate; antacids containing aluminum, calcium, or magnesium; ferrous sulfate– and zinc-containing multivitamins	Can result in decreased oral absorption of fluoroquinolones. Administer fluoroquinolone 2 h before or 6 h after interacting drug.
	Tizanidine[a]	Can result in increased levels of tizanidine and hypotensive, sedative effects. Monitor for side effects if drugs are given concomitantly.
	QT_c-prolonging drugs (e.g., azoles, sotalol, amiodarone, dofetilide, fluoxetine)	Increased risk of cardiotoxicity and arrhythmias. Monitor QT_c.
Rifampin	Substrates of CYP3A4 (e.g., warfarin, ritonavir, cyclosporine, diazepam, verapamil, protease inhibitors, voriconazole)	Can result in decreased levels of interacting drug. Avoid concomitant use if possible. If giving drugs concomitantly, monitor drug levels if possible.
	Substrates of CYP2C19 (e.g., omeprazole, lansoprazole)	
	Substrates of CYP2C9 (e.g., warfarin, tolbutamide)	
	Substrates of CYP2C8 (e.g., repaglinide, rosiglitazone)	
	Substrates of CYP2B6 (e.g., efavirenz)	
	Hormone therapy (e.g., norethindrone)	Can result in decreased levels of hormone. If oral contraceptive and rifampin are given concomitantly, use alternative or additional forms of birth control.
Tetracyclines	Antacids or drugs containing calcium, magnesium, iron, or aluminum	Can result in decreased oral absorption of tetracyclines. Administer tetracycline 2 h before or 6 h after interacting drug.
	Warfarin	Increased effect of warfarin. Monitor levels closely if drugs are given concomitantly.
	Eravacycline: Strong CYP3A4 inducers (e.g., rifampin)	Reduced eravacycline efficacy
Macrolides[b]	Substrates of CYP3A4 (e.g., warfarin, ritonavir, cyclosporine, diazepam, verapamil, amiodarone)	Avoid concomitant administration if possible.
	QT_c-prolonging agents (e.g., fluoroquinolones, sotalol)	Increased risk of cardiotoxicity and arrhythmias. Monitor QT_c.
	Protease inhibitors (e.g., ritonavir)	Can result in increased levels of both macrolides and protease inhibitors. Avoid concomitant use if possible.
	Cimetidine	Cimetidine can increase levels of macrolides.
Metronidazole	Ethanol	Can result in disulfiram-like reaction. Ethanol may be present in some formulations of oral drug suspensions (e.g., ritonavir).
	Warfarin	Can increase warfarin effects. Monitor INR closely if drugs are given concomitantly.
TMP-SMX	Warfarin	Increased effect of warfarin. Monitor levels closely if drugs are given concomitantly.
	Phenytoin	Increased levels of phenytoin. Monitor levels closely if drugs are given concomitantly.
	Methotrexate	Increased levels of methotrexate and prolonged exposure. Monitor levels closely if drugs are given concomitantly.
Oritavancin	Substrates of CYP3A4 (e.g., cyclosporine, warfarin) and CYP2D6 (e.g., aripiprazole) Substrates of CYP2C19 (e.g., omeprazole) and CYP2C9 (e.g., warfarin)	Can result in decreased levels of interacting drug. Avoid concomitant use if possible. If giving drugs concomitantly, monitor drug levels if possible.
Lefamulin	QT_c-prolonging drugs (e.g., azoles, sotalol, amiodarone, dofetilide, fluoxetine)	Increased risk of cardiotoxicity and arrhythmias. Monitor QT_c.
	Strong CYP3A4 inducers (e.g., rifampin)	Reduced lefamulin efficacy
	Strong CYP3A4 strong inhibitors (e.g., ritonavir)	Increased lefamulin exposure

[a]Drug reaction described with ciprofloxacin only. [b]Clarithromycin and erythromycin are potent CYP3A4 inhibitors; the probability of a drug interaction with azithromycin is lower.

Abbreviations: INR, international normalized ratio; SSRI, selective serotonin-reuptake inhibitor; TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 144-4 Drug Indications for Specific Infections, Associated Pathogens, and Sample Susceptibility Rates

ANTIMICROBIAL(S)	INFECTIONS	COMMON PATHOGENS (% SUSCEPTIBLE); RESISTANCE AS NOTED[a]
Penicillin G	Syphilis; yaws; leptospirosis; streptococcal infections; pneumococcal infections; actinomycosis; oral and periodontal infections; meningococcal meningitis and meningococcemia; viridans streptococcal endocarditis; clostridial myonecrosis; tetanus; rat-bite fever; *Pasteurella multocida* infections; erysipeloid (*Erysipelothrix rhusiopathiae*)	*Neisseria meningitidis*; viridans streptococci (69%); *Streptococcus pneumoniae* (97% nonmeningitis; 75% meningitis)
Ampicillin, amoxicillin	Salmonellosis; acute otitis media; *Haemophilus influenzae* meningitis and epiglottitis; *Listeria monocytogenes* meningitis; *Enterococcus faecalis* UTI	*Escherichia coli* (51%); *H. influenzae* (70%); *Salmonella* spp. (85%)
Nafcillin, oxacillin	MSSA bacteremia and endocarditis	*Staphylococcus aureus* (70%); coagulase-negative staphylococci (50%)
Piperacillin-tazobactam	Intraabdominal infections (facultative enteric gram-negative bacilli and obligate anaerobes); infections caused by mixed flora (aspiration pneumonia, diabetic foot ulcers); infections caused by *Pseudomonas aeruginosa*	*P. aeruginosa* (82%)
Cefazolin	*E. coli* UTI; surgical prophylaxis; MSSA bacteremia and endocarditis	*E. coli* (82%)
Cefoxitin, cefotetan	Intraabdominal infections and pelvic inflammatory disease	*Bacteroides fragilis* (60%)[b]
Ceftriaxone	Gonococcal infections; pneumococcal meningitis; viridans streptococcal endocarditis; salmonellosis and typhoid fever; hospital-acquired infections caused by nonpseudomonal facultative gram-negative enteric bacilli	*S. pneumoniae* (91% meningitis; 99% nonmeningitis); *E. coli* (90%); *Klebsiella pneumoniae* (88%)
Ceftazidime, cefepime	Hospital-acquired infections caused by facultative gram-negative bacilli and *Pseudomonas* spp.	*P. aeruginosa* (86%)
Ceftaroline	CAP caused by *S. pneumoniae*, MSSA, *H. influenzae, K. pneumoniae, Klebsiella oxytoca*, and *E. coli*; acute bacterial skin and skin-structure infections caused by MSSA, MRSA, *Streptococcus pyogenes, Streptococcus agalactiae, E. coli, K. pneumoniae*, and *K. oxytoca*	Mostly susceptible; four strains of MRSA with ceftaroline MICs >4 μg/mL reported in isolates from a single Greek hospital[c]; additional case reports, including in patients without prior exposure to ceftaroline[d,e]
Ceftazidime-avibactam, meropenem-vaborbactam	Complicated UTIs (ceftazidime-avibactam and meropenem-vaborbactam) and complicated intraabdominal infections (ceftazidime-avibactam in combination with metronidazole) caused by resistant gram-negative organisms, including *Pseudomonas*, and some anaerobes	*P. aeruginosa* (84–97%)[f] MDR Enterobacterales, including carbapenem-resistant Enterobacterales that produce KPCs No activity against metallo-β-lactamases (e.g., NDM)
Ceftolozane-tazobactam	Complicated UTIs and complicated intraabdominal infections (in combination with metronidazole) caused by resistant gram-negative organisms, including *Pseudomonas*, and some anaerobes	*P. aeruginosa* (>86% overall; 60–80% of ceftazidime- and meropenem-resistant strains)[f] MDR Enterobacterales No activity against KPC-producing organisms
Imipenem, meropenem	Intraabdominal infections, infections caused by *Enterobacter* spp. and ESBL-producing gram-negative bacilli	*P. aeruginosa* (84%); *Acinetobacter calcoaceticus-baumannii* complex (85%) (meropenem susceptibilities reported)
Ertapenem	CAP; complicated UTIs, including pyelonephritis; acute pelvic infections; complicated intraabdominal infections; complicated skin and skin-structure infections, excluding diabetic foot infections accompanied by osteomyelitis or caused by *P. aeruginosa*	*Enterobacter cloacae* (90%); *K. pneumoniae* (98%)
Aztreonam	Infections caused by facultative gram-negative bacilli and *Pseudomonas* in penicillin-allergic patients	*P. aeruginosa* (69%)
Vancomycin	Bacteremia, endocarditis, and other invasive disease caused by MRSA; pneumococcal meningitis; oral formulation for CDAD	*S. aureus* (100%); *E. faecalis* (96%); *E. faecium* (34%)
Telavancin	Hospital- and ventilator-associated pneumonia or skin and soft tissue infections caused by MRSA	*S. aureus*: none reported
Dalbavancin, oritavancin	Complicated skin and soft tissue infections	*S. aureus*: rarely reported for dalbavancin,[g] rarely reported for oritavancin[h]
Daptomycin	VRE infections; MRSA bacteremia	*E. faecalis* (99.9%)[i]; *E. faecium* (99.7%)[i]; *S. aureus* (99.9%)[g]
Gentamicin, tobramycin, amikacin	Combined with penicillin for staphylococcal, enterococcal, or streptococcal endocarditis; combined with β-lactam for gram-negative bacteremia; pyelonephritis	*E. coli* (gentamicin, 91%); *P. aeruginosa* (amikacin, 82%; gentamicin, 84%); *A. calcoaceticus-baumannii* complex (gentamicin, 89%)
Azithromycin, clarithromycin, erythromycin	*Legionella, Campylobacter*, and *Mycoplasma* infections; CAP; GAS pharyngitis in penicillin-allergic patients; bacillary angiomatosis; gastric infections due to *Helicobacter pylori*; MAC infections	*S. pneumoniae* (60%); group A streptococci (82%); *H. pylori* (75%)[j]
Clindamycin	Severe, invasive GAS infections (with a β-lactam); infections caused by obligate anaerobes; infections caused by susceptible staphylococci	*S. aureus* (70%)
Doxycycline, minocycline	Acute bacterial exacerbations of chronic bronchitis; granuloma inguinale; brucellosis (with streptomycin); tularemia; glanders; melioidosis; spirochetal infections caused by *Borrelia* (Lyme disease and relapsing fever; doxycycline); infections caused by *Vibrio vulnificus*; some *Aeromonas* infections; infections due to *Stenotrophomonas* (minocycline); plague; ehrlichiosis; chlamydial infections (doxycycline); granulomatous infections due to *Mycobacterium marinum* (minocycline); rickettsial infections; mild CAP; skin and soft tissue infections caused by gram-positive cocci (e.g., CA-MRSA infections); leptospirosis; syphilis; and actinomycosis in the penicillin-allergic patient	*S. pneumoniae* (63%); *S. aureus* (97%)

(*Continued*)

TABLE 144-4 Drug Indications for Specific Infections, Associated Pathogens, and Sample Susceptibility Rates (Continued)

ANTIMICROBIAL(S)	INFECTIONS	COMMON PATHOGENS (% SUSCEPTIBLE); RESISTANCE AS NOTED[a]
Tigecycline	CAP caused by *S. pneumoniae, H. influenzae*, or *Legionella pneumophila*; complicated skin infections caused by *E. coli*, MRSA, MSSA, *S. pyogenes, Streptococcus anginosus, S. agalactiae, B. fragilis*; complicated intraabdominal infections caused by *E. coli*, vancomycin-susceptible *E. faecalis, Citrobacter freundii, E. cloacae, K. pneumoniae, K. oxytoca, Bacteroides* spp., *Clostridium perfringens*, and *Peptostreptococcus* spp.	Mostly susceptible, although case reports of resistance in *A. baumannii* and *K. pneumoniae*
TMP-SMX	Community-acquired UTI; CA-MRSA skin and soft tissue infections	*E. coli* (73%); *S. aureus* (95%)
Sulfonamides	Nocardial infections; leprosy (dapsone); toxoplasmosis (sulfadiazine)	Unknown
Ciprofloxacin, levofloxacin, moxifloxacin, delafloxacin	CAP (levofloxacin and moxifloxacin); UTI; bacterial gastroenteritis; hospital-acquired gram-negative enteric infections; *Pseudomonas* infections (ciprofloxacin and levofloxacin); skin and skin-structure infections (delafloxacin)	*S. pneumoniae* (99% levofloxacin); *E. coli* (79% for ciprofloxacin and levofloxacin); *P. aeruginosa* (ciprofloxacin, 76%; levofloxacin, 70%); *Salmonella* spp. (72% for ciprofloxacin and levofloxacin)
Rifampin	Staphylococcal foreign body infections (in combination with other antistaphylococcal agents); *Legionella* pneumonia; *Mycobacterium tuberculosis*; atypical nontuberculous mycobacterial infection; pneumococcal meningitis when organisms are susceptible or response is delayed	*S. aureus* (99%), although staphylococci rapidly develop resistance with monotherapy
Metronidazole	Obligate anaerobic gram-negative bacteria (e.g., *Bacteroides* spp.); abscess in lung, brain, or abdomen; bacterial vaginosis; CDAD	Mostly susceptible; resistance very rare
Linezolid, tedizolid	VRE; uncomplicated and complicated skin and soft tissue infections caused by MSSA and MRSA; CAP with concurrent bacteremia; hospital-acquired pneumonia	Mostly susceptible; resistance occasionally seen in VRE
Chloramphenicol	Infections due to gram-positive and gram-negative organisms resistant to standard alternatives (e.g., *Burkholderia*)	Unknown
Colistin	Infections due to gram-negative bacilli resistant to all other chemotherapy (e.g., *P. aeruginosa, Acinetobacter* spp., and *Stenotrophomonas maltophilia*)	*P. aeruginosa* (case reports, outbreaks)
Quinupristin-dalfopristin	VRE; complicated skin and skin-structure infections due to MSSA and *S. pyogenes*	*E. faecalis* (<20%)[k]; *E. faecium* (>90%)[k]
Mupirocin	Topical application to nares for *S. aureus* decolonization	*S. aureus* (74–100%)[l]
Nitrofurantoin	UTI caused by most gram-negative bacilli and some gram-positive organisms; prophylaxis in recurrent cystitis	*E. coli* (95%); *E. faecalis* (99%)
Fosfomycin	UTI caused by most gram-negative bacilli and some gram-positive organisms; prophylaxis in recurrent cystitis	Considered low prevalence[l]
Cefiderocol	Complicated UTIs and/or pyelonephritis caused by multidrug-resistant gram-negative bacteria, including extended-spectrum beta-lactamase- or carbapenemase-producing organisms and multidrug-resistant *P. aeruginosa*, *A. baumannii*, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia* complex	Very low resistance rates in initial studies
Eravacycline	Complicated intra-abdominal infections caused by *E. coli, K. pneumoniae, C. freundii, E. cloacae, K. oxytoca, E. faecalis, E. faecium, S. aureus, S. anginosus* group, *C. perfringens, Bacteroides* spp., and *Parabacteroides distasonis*	Resistance noted in both gram-negative and gram-positive bacteria[m]
Imipenem-cilastatin-relebactam	Complicated intraabdominal infections, pneumonia, and complicated UTI including pyelonephritis caused by multidrug-resistant organisms including Enterobacterales and against some imipenem-nonsusceptible *P. aeruginosa*	Low resistance rates in initial studies
Lefamulin[e]	CAP caused by MRSA, *S. pneumoniae*, and atypical CAP pathogens	Low resistance rates in target pathogens in initial studies
Meropenem-vaborbactam	Complicated UTI caused by KPC-producing Enterobacteriaceae	Identified in KPC-producing strains of *K. pneumoniae*[n]
Omadacycline	Community-acquired bacterial pneumonia caused by *S. pneumoniae, S. aureus* (methicillin-susceptible isolates), *H. influenzae, Haemophilus parainfluenzae, K. pneumoniae, L. pneumophila, Mycoplasma pneumoniae*, and *Chlamydophila pneumoniae*	Broad spectrum overall, but resistance can occur in gram-negative isolates; not active against *Pseudomonas*
Plazomicin	Complicated UTIs caused by carbapenemase-producing Enterobacteriaceae	Resistance uncommon except in infrequent isolates with plasmid-encoded ribosome-modifying methylases

[a]Unless otherwise noted, susceptibility rates are based on isolates from the Massachusetts General Hospital Clinical Microbiology Laboratory collected between January and December 2012. Local rates will vary. [b]JA Karlowsky et al: Antimicrob Agents Chemother 56:1247, 2012. [c]RE Mendes et al: J Antimicrob Chemother 67:1321, 2012. Abbreviations: CA-MRSA, community-acquired MRSA; CAP, community-acquired pneumonia; CA-UTI, community-acquired UTI; CDAD, *Clostridioides difficile*–associated diarrhea; ESBL, extended-spectrum β-lactamase; GAS, group A streptococcal; KPCs, *Klebsiella pneumoniae* carbapenemases; MAC, *M. avium* complex; MDR, multidrug-resistant; MIC, minimal inhibitory concentration; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus*; NDM, New Delhi metallo-β-lactamase; TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection; VRE, vancomycin-resistant *Enterococcus*.

streptococci (e.g., skin and soft tissue infections). Cefazolin is a popular choice for surgical prophylaxis against skin organisms. The second generation (cefamandole, cefuroxime, cefaclor, cefprozil, cefuroxime axetil, cefoxitin, and cefotetan) has additional activity against *H. influenzae* and *Moraxella catarrhalis*. Cefoxitin and cefotetan have potent activity against anaerobes as well. Second-generation cephalosporins have been used to treat community-acquired pneumonia because of their activity against *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. They are also used for other mild or moderate infections, such as acute otitis media and sinusitis. The third-generation cephalosporins

are characterized by greater potency against gram-negative bacilli and reduced potency against gram-positive cocci. These cephalosporins, which include cefoperazone, cefotaxime, ceftazidime, ceftriaxone, cefdinir, cefixime, and cefpodoxime, are used for infections caused by Enterobacterales, although resistance is an increasing concern. Ceftriaxone penetrates the CSF and can be used to treat meningitis caused by *H. influenzae*, *N. meningitidis*, and susceptible strains of *S. pneumoniae*. It is also used for the treatment of later-stage Lyme disease, gonococcal infections, and streptococcal endocarditis. It is noteworthy that ceftazidime is the only third-generation cephalosporin with activity against *Pseudomonas aeruginosa*, but it lacks activity against gram-positive bacteria. This drug is frequently used for pulmonary infections in cystic fibrosis, postneurosurgical meningitis, and febrile neutropenia. The fourth generation of cephalosporins includes cefepime and cefpirome, broad-coverage agents with potent activity against both gram-negative bacilli, including *P. aeruginosa*, and gram-positive cocci. The fourth generation has clinical applications similar to those of the third generation and may offer additional activity over the first, second, and third generations in the presence of certain β-lactamases. These agents can be used in bacteremia, febrile neutropenia, and intraabdominal and urinary tract infections. Ceftaroline, a fifth-generation cephalosporin, differs from the other cephalosporins in its added activity against MRSA, which is resistant to all other β-lactams. Ceftaroline's gram-negative activity is similar to that of the third-generation cephalosporins but does not include *P. aeruginosa*. Ceftaroline may be used in community-acquired pneumonia and skin infections, and emerging data support its use in more severe infections such as bacteremia. Adverse reactions to ceftaroline have included hypersensitivity reactions and neutropenia. Ceftolozane-tazobactam and ceftazidime-avibactam are novel cephalosporin–β-lactamase inhibitor combinations with activity against gram-negative bacteria, including *Pseudomonas*, and some anaerobes. Both agents have been studied in complicated intraabdominal infections and complicated urinary tract infections. Ceftolozane-tazobactam is thought to be stable against many ESBL-producing organisms because of the tazobactam component. The addition of avibactam to ceftazidime yields a combination agent with activity against AmpC-, ESBL-, and *K. pneumoniae* carbapenemase (KPC)–producing organisms. These cephalosporin–β-lactamase inhibitor combinations may be of clinical benefit in multidrug-resistant gram-negative infections.

Carbapenems Carbapenems, including doripenem, imipenem, meropenem, and ertapenem, offer the most reliable coverage for strains containing ESBLs. All carbapenems have broad activity against gram-positive cocci, gram-negative bacilli, and anaerobes. None is active against methicillin-resistant *S. aureus* (MRSA), but all are active against MSSA, *Streptococcus* species, and Enterobacterales. Ertapenem is the only carbapenem that has poor activity against *P. aeruginosa* and *Acinetobacter*. Imipenem is active against penicillin-susceptible *Enterococcus faecalis* but not *Enterococcus faecium*. Carbapenems are not active against Enterobacterales containing carbapenemases. *Stenotrophomonas maltophilia* and some *Bacillus* species are intrinsically resistant to carbapenems because of a zinc-dependent carbapenemase. Addition of vaborbactam to meropenem and relebactam to imipenem results in inhibition of AmpC β-lactamases, ESBLs, and KPCs but not metallo-carbapenemases, such as NDM (New Delhi metallo-β-lactamases).

Monobactams Aztreonam is the sole monobactam in clinical use. Its activity is limited to gram-negative bacteria and includes *P. aeruginosa* and most other Enterobacterales. This drug is inactivated by ESBLs and carbapenemases. The principal use for aztreonam is as an alternative to penicillins, cephalosporins, or carbapenems in patients with a serious β-lactam allergy. Aztreonam is structurally related to ceftazidime and should be used cautiously in individuals with a serious ceftazidime allergy. It is used in febrile neutropenia and intraabdominal infections when other β-lactams cannot be used.

Adverse Reactions to β-Lactam Drugs Agents within the β-lactam class are known for several adverse effects. Gastrointestinal side effects, mainly diarrhea, are common, but hypersensitivity reactions constitute the most common adverse effect of β-lactams. The reactions' severity can range from rash to anaphylaxis, but the rate of true anaphylactic reactions is only 0.05%. An individual with an accelerated IgE-mediated reaction to one β-lactam agent may still receive another agent within the class, but caution should be used and a β-lactam that has a dissimilar side chain and a low level of cross-reactivity would be the preferred choice. For example, the second-, third-, and fourth-generation cephalosporins and the carbapenems display very low cross-reactivity in patients with penicillin allergy. Aztreonam is the only β-lactam that has no cross-reactivity with the penicillin group. In cases of severe allergy, desensitization (a graded challenge) to the indicated β-lactam, with close monitoring, may be warranted if other antibacterial options are not suitable.

β-Lactams can rarely cause serum sickness, Stevens-Johnson syndrome, nephropathy, hematologic reactions, and neurotoxicity. Neutropenia appears to be related to high doses or prolonged use. Neutropenia and interstitial nephritis caused by β-lactams generally resolve upon discontinuation of the agent. Imipenem and cefepime are associated with an increased risk of seizure, but this risk is likely a class effect and related to high doses or doses that are not adjusted in renal impairment.

GLYCOPEPTIDES AND LIPOGLYCOPEPTIDES

Vancomycin is a glycopeptide antibiotic with activity against staphylococci (including MRSA and coagulase-negative staphylococci), streptococci (including *S. pneumoniae*), and enterococci. It is not active against gram-negative organisms. Vancomycin also displays activity against *Bacillus* species, *Corynebacterium jeikeium*, and gram-positive anaerobes such as *Peptostreptococcus*, *Actinomyces*, *Clostridium*, and *Propionibacterium* species. Vancomycin has several important clinical uses. It is used for serious infections caused by MRSA, including health care–associated pneumonia, bacteremia, osteomyelitis, and endocarditis. It is also commonly used for skin and soft tissue infections. Oral vancomycin is not absorbed systemically and is reserved for the treatment of *Clostridioides difficile* infection. Vancomycin is also an alternative for the treatment of infections caused by MSSA in patients who cannot tolerate β-lactams. Resistance to vancomycin is a rising concern. Strains of vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant enterococci (VRE) are not uncommon. Vancomycin appears to be a concentration-dependent killer, with the AUC/MIC ratio being the best predictor of efficacy (Fig. 144-1). Guidelines recommend targeting a vancomycin trough level of 15–20 μg/mL in MRSA infections in order to maintain an AUC/MIC ratio >400. When using vancomycin, clinicians should monitor for nephrotoxicity. The risk of nephrotoxicity increases when trough levels are >20 μg/mL. Concomitant therapy with other nephrotoxic agents, such as aminoglycosides, also increases the risk. Ototoxicity was reported with early formulations of vancomycin but is currently uncommon because purer formulations are available. Both of these adverse effects are reversible upon discontinuation of vancomycin. Clinicians should be aware of the infusion reaction formerly known as "red man syndrome," a common reaction that presents as a rapid onset of erythematous rash or pruritus on the head, face, neck, and upper trunk. This reaction is caused by histamine release from basophils and mast cells and can be treated with diphenhydramine and slowing of the vancomycin infusion.

Telavancin, dalbavancin, and oritavancin are structurally similar to vancomycin and are referred to as *lipoglycopeptides*. They have antibacterial activity against *S. aureus* (including MRSA and some strains of VISA and vancomycin-resistant *S. aureus* [VRSA]), streptococci, and enterococci. Oritavancin may have activity against some strains of VRE. These lipoglycopeptide agents also provide coverage against anaerobic gram-positive organisms except for *Lactobacillus* and some *Clostridium* species. The clinical efficacy of telavancin has been demonstrated in both skin and soft tissue infections and nosocomial pneumonia, and the efficacy of dalbavancin and oritavancin has been shown in skin and soft tissue infections. The vancomycin resistance phenotype may reduce the potency of all three lipoglycopeptides, but the rate of resistance to these drugs among *S. aureus* and enterococcal

isolates has been low. Adverse effects of telavancin include nephrotoxicity, metallic taste, and gastrointestinal side effects. Clinicians should be aware of the potential for electrocardiographic QT_c prolongation that can increase the risk of cardiac arrhythmias when telavancin is used concomitantly with other QT_c-prolonging agents. Telavancin may interfere with certain coagulation tests (e.g., causing false elevations in prothrombin time). Dalbavancin and oritavancin have safety profiles similar to that of vancomycin, with common effects reported as headache and gastrointestinal side effects. These glycolipopeptides should be used cautiously in patients with hypersensitivity reactions to vancomycin, as cross-allergy may be possible.

LIPOPEPTIDES

Daptomycin is a lipopeptide antibiotic with activity against a broad range of gram-positive organisms. This drug is active against staphylococci (including MRSA and coagulase-negative staphylococci), streptococci, and enterococci. Daptomycin remains active against enterococci that are resistant to vancomycin. In addition, it exhibits activity against *Bacillus*, *Corynebacterium*, *Peptostreptococcus*, and *Clostridium* species. Daptomycin's pharmacodynamic parameter for efficacy is concentration-dependent killing. Resistance to daptomycin is rare, but MICs may be higher for some VISA strains. Daptomycin can be used in skin and soft tissue infections, bacteremia, endocarditis, and osteomyelitis. It is an important alternative for MRSA and other gram-positive infections when bactericidal therapy is needed and vancomycin cannot be used. Daptomycin is generally well tolerated, and its main toxicity consists of elevation of creatine phosphokinase (CPK) levels and myopathy. CPK should be monitored during daptomycin treatment, and the drug should be discontinued if muscular toxicities occur. There have also been case reports of reversible eosinophilic pneumonia associated with daptomycin use.

AMINOGLYCOSIDES

The aminoglycosides are a class of antibacterial agents with concentration-dependent activity against most gram-negative organisms. The most commonly used aminoglycosides are gentamicin, tobramycin, and amikacin, although others, such as streptomycin, kanamycin, neomycin, and paromomycin, may be used in special circumstances. Plazomicin is a new aminoglycoside that is less affected by common resistance mechanisms and is approved for treatment of complicated urinary tract infections and acute pyelonephritis. Aminoglycosides have a significant dose-dependent postantibiotic effect; i.e., they have an antibacterial effect even after serum drug levels fall below inhibitory concentrations. The postantibiotic effect and concentration-dependent killing form the rationale behind extended-interval aminoglycoside dosing, in which a larger dose is given once daily rather than smaller doses multiple times daily. Aminoglycosides are active against gram-negative bacilli, such as Enterobacterales, *P. aeruginosa*, and *Acinetobacter*. They also enhance the activity of cell wall–active agents such as β-lactams or vancomycin against some gram-positive bacteria, including staphylococci and enterococci. This combination therapy is termed *synergistic* because the effect of both agents provides a killing effect greater than would be predicted from the effects of either agent alone. Amikacin and streptomycin have activity against *Mycobacterium tuberculosis*, and amikacin has activity against *M. avium* complex. The aminoglycosides do not have activity against anaerobes, *S. maltophilia*, or *Burkholderia cepacia* complex. Aminoglycosides are used in clinical practice in a variety of infections caused by gram-negative organisms, including bacteremia and urinary tract infections. They are frequently used either alone or in combination for the treatment of *P. aeruginosa* infection. When used in combination with a cell wall–active agent, gentamicin and streptomycin are also important for the treatment of gram-positive bacterial endocarditis. All aminoglycosides can cause nephrotoxicity and ototoxicity. The risk of nephrotoxicity is not well defined; however, some studies have indicated that the effect may be related to the duration of therapy as well as to the concomitant use of other nephrotoxic agents. Nephrotoxicity is usually reversible, but ototoxicity can be irreversible.

MACROLIDES AND KETOLIDES

The macrolides (azithromycin, clarithromycin, and erythromycin) and ketolides (telithromycin) are classes of antibiotics that inhibit protein synthesis. Compared with erythromycin (the older antibiotic), azithromycin and clarithromycin have better oral absorption and tolerability. Azithromycin, clarithromycin, and telithromycin all have broader spectra of activity than erythromycin, which is less frequently used. These agents are commonly used in the treatment of upper and lower respiratory tract infections caused by *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and atypical organisms (e.g., *Chlamydophila pneumoniae*, *Legionella pneumophila*, and *Mycoplasma pneumoniae*); group A streptococcal pharyngitis in penicillin-allergic patients; and nontuberculous mycobacterial infections (e.g., caused by *Mycobacterium marinum* and *Mycobacterium chelonae*) as well as in the prophylaxis and treatment of *M. avium* complex infection in patients with HIV/AIDS and in combination therapy for *Helicobacter pylori* infection and bartonellosis. Enterobacterales, *Pseudomonas* species, and *Acinetobacter* species are intrinsically resistant to macrolides as a result of decreased membrane permeability, although azithromycin is active against gram-negative diarrheal pathogens. The major adverse effects of this drug class include nausea, vomiting, diarrhea and abdominal pain, prolongation of QT_c interval, exacerbation of myasthenia gravis, tinnitus and reversible deafness, especially in the elderly. Azithromycin specifically has been associated with an increased risk of death, especially among patients with underlying heart disease, because of the risk of QT_c interval prolongation and torsades de pointes arrhythmia. Erythromycin, clarithromycin, and telithromycin inhibit the CYP3A4 hepatic drug-metabolizing enzyme and can result in increased levels of coadministered drugs, including benzodiazepines, statins, warfarin, cyclosporine, and tacrolimus. Azithromycin does not inhibit CYP3A4 and therefore does not interact with these drugs.

CLINDAMYCIN

Clindamycin is a lincosamide antibiotic and is bacteriostatic against some organisms and bactericidal against others. It is used most often to treat bacterial infections caused by anaerobes (e.g., *B. fragilis*, *Clostridium perfringens*, *Fusobacterium* species, *Prevotella melaninogenicus*, and *Peptostreptococcus* species) and susceptible staphylococci and streptococci. Clindamycin is used for treatment of dental infections, anaerobic lung abscess, and skin and soft tissue infections. It is used together with bactericidal agents (penicillins or vancomycin) to inhibit new toxin synthesis in the treatment of streptococcal or staphylococcal toxic shock syndrome. Other uses include treatment of infections caused by *Capnocytophaga canimorsus*, combination therapy for babesiosis and occasionally malaria, and therapy for toxoplasmosis. Clindamycin has excellent oral bioavailability. Adverse effects include nausea, vomiting, diarrhea, *C. difficile*–associated diarrhea and pseudomembranous colitis, maculopapular rash, and rarely Stevens-Johnson syndrome.

TETRACYCLINES

The older (doxycycline, minocycline, and tetracycline) and newer (tigecycline, eravacycline, and omadacycline) tetracyclines inhibit protein synthesis and are bacteriostatic. These drugs have wide clinical uses. They are used in the treatment of skin and soft tissue infections caused by gram-positive cocci (including MRSA), spirochetal infections (e.g., Lyme disease, syphilis, leptospirosis, and relapsing fever), rickettsial infections (e.g., Rocky Mountain spotted fever, scrub typhus), atypical pneumonia, sexually transmitted infections (e.g., *Chlamydia trachomatis* infection, lymphogranuloma venereum, and granuloma inguinale), infections with *Nocardia* and *Actinomyces*, brucellosis, tularemia, Whipple's disease, and malaria. Tigecycline is a glycylcycline derived from minocycline and is available only in IV formulation. It is indicated in the treatment of complicated skin and soft tissue infections, complicated intraabdominal infections, and community-acquired bacterial pneumonia in adults. Tigecycline has activity against MRSA, vancomycin-sensitive enterococci, many Enterobacterales, and *Bacteroides* species; it has no activity against *P. aeruginosa*. This drug has been used in combination with colistin for the treatment of serious infections with multidrug-resistant

gram-negative organisms. A pooled analysis of 13 clinical trials found an increased risk of death and treatment failure among patients given tigecycline alone; as a result, the FDA mandated a black box warning. Eravacycline is a fluorocycline derivative available in IV formulation with a similar spectrum but more potent than tigecycline in vitro. It has been approved for complicated intraabdominal infections. Omadacycline is an aminomethylcycline derivative available in both IV and oral formulations. It has activity similar to that of tigecycline against gram-positive pathogens but is less active against gram-negative pathogens. Omadacycline has been approved for treatment of bacterial skin and skin structure infections and community-acquired bacterial pneumonia. Tetracyclines have reduced absorption when orally coadministered with calcium- and iron-containing compounds, including milk, and doses should be spaced at least 2 h apart. The major adverse reactions to old and new tetracyclines are nausea, vomiting, diarrhea, and photosensitivity. Tetracyclines have been associated with fetal bone-growth abnormalities and should be avoided during pregnancy and in the treatment of children <8 years old.

TRIMETHOPRIM-SULFAMETHOXAZOLE

Trimethoprim-sulfamethoxazole (TMP-SMX) is an antibiotic with two components that each inhibit a separate step in folate synthesis and produce antibacterial activity. TMP-SMX is active against gram-positive bacteria such as staphylococci and streptococci; however, its use against MRSA is usually limited to community-acquired infections, and its activity against *Streptococcus pyogenes* may not be reliable. This drug is also active against many gram-negative bacteria, including *H. influenzae*, *E. coli*, *P. mirabilis*, *Neisseria gonorrhoeae*, and *S. maltophilia*. TMP-SMX is not active against anaerobes or *P. aeruginosa*. It has many uses because of its wide spectrum of activity and high oral bioavailability. Urinary tract infections, skin and soft tissue infections, and respiratory tract infections are among the common uses. Another important indication is for both prophylaxis and treatment of *Pneumocystis jirovecii* infections in immunocompromised patients. Resistance to TMP-SMX has limited its use against many Enterobacterales. Resistance rates among urinary isolates of *E. coli* are almost 25% in the United States. The most common adverse reactions associated with TMP-SMX are gastrointestinal effects such as nausea, vomiting, and diarrhea. In addition, rash is a common allergic reaction and may preclude the subsequent use of other sulfonamides. With prolonged use, leukopenia, thrombocytopenia, and granulocytopenia can develop. TMP-SMX can also cause nephrotoxicity, hyperkalemia, and hyponatremia, which are more common at high doses. TMP-SMX has several important interactions with other drugs (Table 144-3), including warfarin, phenytoin, and methotrexate.

FLUOROQUINOLONES

The fluoroquinolones include norfloxacin, ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, gemifloxacin, and delafloxacin. Ciprofloxacin and levofloxacin have the broadest spectrum of activity against gram-negative bacteria, including *P. aeruginosa* (similar to that of third-generation cephalosporins). Because of the risk of selection of resistance during fluoroquinolone treatment of serious pseudomonal infections, these agents are usually used in combination with an antipseudomonal β-lactam. Levofloxacin, moxifloxacin, gemifloxacin, and delafloxacin have additional gram-positive activity, including that against *S. pneumoniae* and some strains of MSSA, and, with the exception of delafloxacin, these agents are used for treatment of community-acquired pneumonia. Strains of MRSA are commonly resistant to all fluoroquinolones except delafloxacin. Moxifloxacin is used as one component of second-line regimens for multidrug-resistant tuberculosis. Fluoroquinolones are no longer used for treatment of gonorrhea because of common resistance in *N. gonorrhoeae*. Fluoroquinolones exhibit concentration-dependent killing, are well absorbed orally, and have elimination half-lives that usually support once- or twice-daily dosing. Oral coadministration with compounds containing high concentrations of aluminum, magnesium, or calcium can reduce fluoroquinolone absorption. The penetration of fluoroquinolones into prostate tissue supports their use for bacterial prostatitis. Fluoroquinolones are generally well tolerated but can cause central nervous system (CNS) stimulatory effects, including seizures; peripheral neuropathy; glucose dysregulation; and tendinopathy associated with Achilles tendon rupture, particularly in older patients, organ transplant recipients, and patients taking glucocorticoids. Other potential effects on connective tissues include an association with increased risk of aortic aneurysm. Worsening of myasthenia gravis also has been associated with quinolone use. Moxifloxacin causes modest prolongation of the QT_c interval and should be used with caution in patients receiving other QT_c-prolonging drugs.

RIFAMYCINS

The rifamycins include rifampin, rifabutin, and rifapentine. Rifampin is the most commonly used rifamycin. For almost all therapeutic indications, it is used in combination with other agents to reduce the likelihood of selection of high-level rifampin resistance. Rifampin is used foremost in the treatment of mycobacterial infections—specifically, as a mainstay of combination therapy for *M. tuberculosis* infection or as a single agent in the treatment of latent *M. tuberculosis* infection. In addition, it is often used in the treatment of nontuberculous mycobacterial infection. Rifampin is used in combination regimens for the treatment of staphylococcal infections, particularly prosthetic-valve endocarditis and bone infections with retained hardware. It is a component of combination therapy for brucellosis (with doxycycline) and leprosy (with dapsone for tuberculoid leprosy and with dapsone and clofazimine for lepromatous disease). Rifampin can be used alone for prophylaxis in close contacts of patients with *H. influenzae* or *N. meningitidis* meningitis. The drug has high oral bioavailability, which is further enhanced when it is taken on an empty stomach. Rifampin has several adverse effects, including elevated aminotransferase levels (14%), rash (1–5%), and gastrointestinal events such as nausea, vomiting, and diarrhea (1–2%). Its many clinically relevant interactions with other drugs (Table 144-3) mandate the clinician's careful review of the patient's medications before rifampin initiation to assess safety and the need for additional monitoring, including monitoring of drug levels.

METRONIDAZOLE

Metronidazole is used in the treatment of anaerobic bacterial infections as well as infections caused by protozoa (e.g., amebiasis, giardiasis, trichomoniasis). It is the agent of choice as a component of combination therapy for polymicrobial abscesses in the lung, brain, or abdomen, the etiology of which often includes anaerobic bacteria, and for bacterial vaginosis, pelvic inflammatory disease, and anaerobic infections, such as those due to *Bacteroides*, *Fusobacterium*, and *Prevotella* species. This drug is an alternative agent for treatment of mild to moderate *C. difficile*–associated diarrhea. Metronidazole is bactericidal against anaerobic bacteria and exhibits concentration-dependent killing. It has high oral bioavailability and tissue penetration, including penetration of the blood-brain barrier. The majority of *Actinomyces*, *Propionibacterium*, and *Lactobacillus* species are intrinsically resistant to metronidazole. The major adverse effects include nausea, diarrhea, and a metallic taste. Concomitant ingestion of alcohol may result in a disulfiram-like reaction, and patients are usually instructed to avoid alcohol during treatment. Long-term treatment carries the risk of leukopenia, neutropenia, peripheral neuropathy, and CNS toxicity manifesting as confusion, dysarthria, ataxia, nystagmus, and ophthalmoparesis. Through metronidazole's effect on the CYP2C9 drug-metabolizing enzyme, its coadministration with warfarin can result in decreased metabolism and enhanced anticoagulant effects that require close monitoring. Concomitant administration of metronidazole with lithium can result in increased serum levels of lithium and associated toxicity; coadministration with phenytoin can result in phenytoin toxicity and possibly decreased levels of metronidazole.

OXAZOLIDINONES

Linezolid is a bacteriostatic agent and is indicated for serious infections due to resistant gram-positive bacteria, such as MRSA and VRE. The intrinsic resistance of gram-negative bacteria is mediated primarily by endogenous efflux pumps. Linezolid has excellent oral bioavailability. Adverse effects include myelosuppression and ocular and peripheral

neuropathy with prolonged therapy. Peripheral neuropathy may be irreversible. Linezolid is a weak, reversible monoamine oxidase inhibitor, and coadministration with sympathomimetics and foods rich in tyramine should be avoided. Linezolid has been associated with serotonin syndrome when coadministered with selective serotonin reuptake inhibitors. Tedizolid has properties similar to those of linezolid, but with lower dosing due to greater potency, it may be less likely to cause adverse hematologic and neuropathic effects.

PLEUROMUTILINS

Lefamulin is the only member of the pleuromutilin class approved for systemic use; it is available in IV and oral formulations. Lefamulin has in vitro activity against *S. aureus* (including MRSA), *S. pneumoniae*, *H. influenzae*, and atypical respiratory pathogens, including *L. pneumophila*, *M. pneumoniae*, and *C. pneumoniae*, and has been approved for treatment of community-acquired bacterial pneumonia. Adverse effects are most commonly gastrointestinal, including diarrhea (12%), nausea (5%), and vomiting (3%). Prolongation of QT_c interval and hepatic transaminase elevations occur in some patients. There can be interactions with drugs that are either inducers or inhibitors of CYP3A4 or P-glycoprotein transporter.

NITROFURANTOIN

Nitrofurantoin's antibacterial activity results from the drug's conversion to highly reactive intermediates that can damage bacterial DNA and other macromolecules. Nitrofurantoin is bactericidal, and its action is concentration dependent. It displays activity against a range of gram-positive bacteria, including *S. aureus*, *Staphylococcus epidermidis*, *Staphylococcus saprophyticus*, *E. faecalis*, *Streptococcus agalactiae*, group D streptococci, viridans streptococci, and corynebacteria, as well as gram-negative organisms, including *E. coli, Enterobacter*, *Salmonella*, and *Shigella* species. Nitrofurantoin is used primarily in the treatment of urinary tract infections and is preferred in the treatment of such infections in pregnancy. It may be used for the prevention of recurrent cystitis. Recently, there has been interest in the use of nitrofurantoin for treatment of urinary tract infections caused by ESBL-producing Enterobacterales such as *E. coli*, although resistance has been growing in Latin America and parts of Europe. Coadministration with magnesium should be avoided because of decreased absorption, and patients should be encouraged to take the drug with food to increase its bioavailability and decrease the risk of adverse effects, which include nausea, vomiting, and diarrhea. Nitrofurantoin may also cause pulmonary fibrosis and drug-induced hepatitis. Because the risk of adverse reactions increases with age, the use of nitrofurantoin in elderly patients is not recommended. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are at elevated risk for nitrofurantoin-associated hemolytic anemia.

POLYMYXINS

Colistin and polymyxin B act by disrupting bacterial cell membrane integrity and are active against the nonenteric pathogens *P. aeruginosa* and *A. baumannii* but not against *Burkholderia*. These drugs also exhibit activity against many Enterobacterales, with the exceptions of *Proteus*, *Providencia*, and *Serratia* species. They lack activity against gram-positive bacteria. Polymyxins are bactericidal and are available in IV formulations. Colistimethate is converted to the active form (colistin) in plasma. Polymyxins are most often used for infections due to pathogens resistant to multiple other antibacterial agents, including urinary tract infections, hospital-acquired pneumonia, and bloodstream infections. Nebulized formulations have been used for adjunctive treatment of refractory ventilator-associated pneumonia. The most important adverse effect is dose-dependent reversible nephrotoxicity. Neurotoxicity, including paresthesias, muscle weakness, and confusion, is reversible and less common than nephrotoxicity.

QUINUPRISTIN-DALFOPRISTIN

Quinupristin-dalfopristin contains two members of the streptogramin class of antibiotics and kills bacteria by inhibiting protein synthesis. The antibacterial spectrum of quinupristin-dalfopristin includes staphylococci (including MRSA), streptococci, and *E. faecium* (but not *E. faecalis*). This drug combination is also active against *Corynebacterium* species and *L. monocytogenes*. Quinupristin-dalfopristin is not reliably active against gram-negative organisms. It exhibits concentration-dependent killing, with an AUC/MIC ratio predicting efficacy. The clinical use of quinupristin-dalfopristin is largely for infections due to vancomycin-resistant *E. faecium* and other gram-positive bacterial infections. The drug has demonstrated efficacy in a variety of infections, including urinary tract infections, bone and joint infections, and bacteremia. Adverse effects associated with quinupristin-dalfopristin include infusion-related reactions, arthralgias, and myalgias. The arthralgias and myalgias may be severe enough to warrant drug discontinuation. Quinupristin-dalfopristin inhibits the CYP3A4 drug-metabolizing enzyme, with consequent drug interactions (Table 144-3).

FOSFOMYCIN

Fosfomycin is a phosphonic acid antibiotic that has greater activity in acidic environments and is excreted in its active form in the urine. Thus, its use is primarily for prophylaxis and treatment of uncomplicated cystitis and should be avoided if there is concern about pyelonephritis. The drug is administered as a single 3-g dose that results in high urine concentrations for up to 48 h. Fosfomycin is active against *S. aureus*, vancomycin-susceptible enterococci and VRE, and a wide range of gram-negative organisms, including *E. coli*, *Enterobacter* species, *Serratia marcescens*, *P. aeruginosa*, and *K. pneumoniae*. Notably, the vast majority of ESBL-producing Enterobacterales are susceptible to fosfomycin. *A. baumannii* and *Burkholderia* species are resistant. The emergence of resistance to fosfomycin has not been observed during treatment of cystitis but has been documented during treatment of respiratory tract infections and osteomyelitis. The few adverse effects that have been reported include nausea and diarrhea.

CHLORAMPHENICOL

The use of chloramphenicol is limited by its potentially serious toxicities. When other agents are contraindicated or ineffective, chloramphenicol represents an alternative treatment for infections, including meningitis caused by susceptible bacteria such as *N. meningitidis*, *H. influenzae*, and *S. pneumoniae*. It has also been used for the treatment of anthrax, brucellosis, *Burkholderia* infections, chlamydial infections, clostridial infections, ehrlichiosis, rickettsial infections, and typhoid fever. Adverse reactions include aplastic anemia, myelosuppression, and gray baby syndrome. Chloramphenicol inhibits the CYP2C19 and CYP3A4 drug-metabolizing enzymes and consequently increases levels of many classes of drugs.

APPROACH TO PROPHYLAXIS OF INFECTION

Antibacterial prophylaxis is indicated only in selected circumstances **(Table 144-5)** and should be supported by well-designed studies or expert panel recommendations. In all cases, the risk or severity of the infection to be prevented should be greater than the adverse consequences of antibacterial therapy, including the potential for selection of resistance. In addition, the timing and duration of antibacterial treatment should be targeted for maximal effect and minimal required exposure. Prophylaxis of surgical infections targets bacteria that may contaminate the wound during the surgical procedure, including the skin flora of the patient or operating team and the air in the operating room. Delivery of the antibacterial drug within 1 h before the surgical incision is most effective. For prolonged procedures, redosing may be necessary to maintain effective blood and tissue levels until the wound is closed. Additional dosing is not recommended after the incision is closed. In patients with nasal carriage of *S. aureus*, preoperative decolonization with nasal mupirocin reduces the rate of *S. aureus* surgical-site infections and is generally recommended for high-risk procedures such as cardiac surgery and orthopedic implantation of prosthetic devices. For dental procedures, preprocedure antibacterial drugs are given to prevent transient bacteremia during the procedure and the seeding of certain high-risk cardiac lesions. Prophylaxis is also used in nonprocedural settings in certain patients who have recurrent infections or

TABLE 144-5 Prophylaxis of Bacterial Infections in Adults

CONDITION	ANTIBACTERIAL AGENTS[a]	TIMING OR DURATION OF PROPHYLAXIS
Surgical		
Clean (cardiac, thoracic, neurologic, orthopedic, vascular, plastic)	Cefazolin (vancomycin,[b] clindamycin)	1 h before incision; re-dose with long procedures
Clean (ophthalmic)	Topical neomycin–polymyxin B–gramicidin, topical moxifloxacin	Every 5–15 min for 5 doses immediately prior to procedure
Clean-contaminated (head and neck)	Cefazolin + metronidazole, ampicillin-sulbactam[c] (clindamycin)	1 h before incision; re-dose with long procedures
Clean-contaminated (hysterectomy, gastroduodenal, biliary, unobstructed small intestine, urologic)	Cefazolin, ampicillin-sulbactam[c] (clindamycin + aminoglycoside, aztreonam, or fluoroquinolone)	1 h before incision; re-dose with long procedures
Clean-contaminated (colorectal, appendectomy)	Cefazolin + metronidazole, ampicillin-sulbactam,[c] ertapenem (clindamycin + aminoglycoside, aztreonam, or fluoroquinolone)	1 h before incision; re-dose with long procedures
Dirty (ruptured viscus)	Therapeutic regimen directed at anaerobes and gram-negative bacteria (e.g., ceftriaxone + metronidazole)	1 h before incision; re-dose with long procedures; continue for 3–5 days after procedure
Dirty (traumatic wound)	Therapeutic regimen: cefazolin (clindamycin ± aminoglycoside, aztreonam, or fluoroquinolone)	1 h before incision; re-dose with long procedures; continue for 3–5 days after procedure
Nonsurgical		
Dental, oral, or upper respiratory procedures in patients with high-risk cardiac lesions (prosthetic valves, congenital heart defects, prior endocarditis)	Amoxicillin PO, ampicillin IM (clindamycin PO, IV)	Oral agents 1 h before procedure; injection 30 min before procedure
Recurrent *S. aureus* skin infections[d]	Mupirocin[e]	Intranasal application for 5 days
Recurrent cellulitis associated with lymphatic disruption[d]	Benzathine penicillin IM monthly, oral penicillin or erythromycin twice daily	Undefined
Recurrent cystitis in women[d]	Nitrofurantoin, TMP-SMX, fluoroquinolone	After sexual intercourse *or* 3 times weekly for up to 1 year
Bite wounds	Amoxicillin-clavulanate (doxycycline, moxifloxacin)	3–5 days
Recurrent spontaneous bacterial peritonitis in cirrhotic patients[d]	Fluoroquinolone[f]	Undefined
Recurrent pneumococcal meningitis in patient with CSF leak or humoral immune defect[d]	Penicillin	Undefined
Exposure to patient with meningococcal meningitis	Rifampin, ciprofloxacin	2 days (rifampin), single dose (ciprofloxacin)
High-risk neutropenia (ANC, ≤100/μL for >7 days)[d]	Levofloxacin or ciprofloxacin[f]	Until neutropenia resolves or fever dictates use of other antibacterials

[a]Regimens in parentheses are alternatives for patients allergic to β-lactams. [b]Vancomycin may be given together with cefazolin to patients known to be colonized with methicillin-resistant *Staphylococcus aureus*. [c]Cefoxitin or cefotetan may also be considered. [d]Not considered routine for all patients, but an acceptable consideration among alternative approaches. [e]Usually coupled with bathing with chlorhexidine-containing skin antiseptic. [f]Choice of fluoroquinolone prophylaxis must be balanced against the risk of selection of resistance.

Abbreviations: ANC, absolute neutrophil count; CSF, cerebrospinal fluid; TMP-SMX, trimethoprim-sulfamethoxazole.

who are at risk of serious infection from a specific exposure (e.g., close contact with a patient with meningococcal meningitis). Extension of prophylaxis beyond the period of infection risk (24 h in the case of surgical procedures) does not add further benefit and may increase the risk of resistance selection or *C. difficile* disease.

ANTIMICROBIAL STEWARDSHIP

In an era of increasing prevalence of multidrug-resistant bacteria and with a substantial amount of inappropriate antimicrobial use, the need for rational antimicrobial prescribing has never been greater **(Chap. 145)**. *Antimicrobial stewardship* describes the practice of promoting the selection of the appropriate drug, dosage, route, and duration of antimicrobial therapy. Antimicrobial stewardship programs implement a variety of strategies to (1) improve patient care through appropriate antimicrobial use; (2) preserve a vital health care resource by curbing the development of resistance within patient populations; (3) reduce the incidence of adverse effects; and (4) control costs. The Centers for Disease Control and Prevention (CDC) guidelines, The Joint Commission (TJC) Medication Management Standards, and the Centers for Medicare and Medicaid Services (CMS) Conditions of Participation, as well as the 2015 National Action Plan for Combating Antibiotic-Resistant Bacteria, have all supported *antimicrobial stewardship* in various health care settings. Antimicrobial stewardship programs are typically multidisciplinary and often include infectious disease physicians, clinical pharmacists (usually with special training in infectious disease), clinical microbiologists, information systems specialists, infection prevention and control practitioners, and epidemiologists. These teams employ a variety of approaches to achieve the program's goals.

Established strategies of antimicrobial stewardship programs include (1) prospective audit of antimicrobial use, with intervention and feedback; (2) formulary restriction; and (3) preauthorization. *Prospective audit and feedback* are usually undertaken by an infectious disease physician or a pharmacist. In this process, orders for broad-spectrum antimicrobials (e.g., carbapenems) or agents for which more cost-effective alternatives may exist (e.g., daptomycin, ceftazidime-avibactam) are reviewed on a regular basis for appropriateness. In circumstances when antimicrobial use can be further optimized, the stewardship program team can intervene to recommend an alternative. This process has been successful in several quasi-experimental studies, resulting in declines in use of broad-spectrum drugs and decreases in adverse events, such as *C. difficile* infection. *Formulary restriction* is the inclusion of a limited set of antimicrobial agents in a hospital formulary for the purpose of limiting indiscriminate use of antimicrobials in the absence of demonstrated benefit. Such restriction coincidentally serves to avoid unnecessary drug expenditure. *Preauthorization* is the practice of requiring clinicians to obtain approval before using selected antimicrobials. Approval may be provided electronically with sophisticated Computerized Provider Order Entry (CPOE) software, after specific criteria for use are met, or after communication with an

infectious disease specialist as designated by the stewardship program. These strategies have led to a decrease in *C. difficile* infections and to improvements in drug susceptibility patterns.

Additional strategies used in specific health care settings are guidelines and pathways, dose optimization, parenteral-to-oral conversion, antibiotic time-out, and de-escalation of therapy. Documentation of the indication for which each antimicrobial is prescribed is also encouraged. Finally, antimicrobial stewardship teams provide ongoing education of antimicrobial best practices. An evolving and an increasingly active area of clinical research to identify best practices, antimicrobial stewardship continues to grow as an essential service in various health care settings. The IDSA, in collaboration with several other professional organizations, has published guidelines for developing institutional antimicrobial stewardship programs (*www.idsociety.org/Antimicrobial_Agents/*).

145 Bacterial Resistance to Antimicrobial Agents

David C. Hooper

DEFINITION OF RESISTANCE

The action of antimicrobial agents on a range of targets within the bacterial cell can result in inhibition of bacterial growth or in killing of the bacterial cell **(Chap. 144)**. Reduction in or loss of an agent's antibacterial effect is referred to as *resistance*, and the properties of or alterations in the bacterium that result in reduced antimicrobial activity are termed *resistance mechanisms*. Bacteria can be resistant to single or multiple antimicrobials, as detailed in the sections that follow. The occurrence and magnitude of resistance are often assessed in clinical microbiology laboratories by measurement of the lowest drug concentration that inhibits growth of a bacterium (minimal inhibitory concentration, or MIC) with a standardized inoculum and growth conditions. MIC values are generally interpreted as representing bacterial susceptibility, intermediate susceptibility, or resistance; the interpretation is based on correlations of the MIC values with the pharmacokinetics and delivery of a drug to the site of infection in the body as well as with data from clinical trials. Thus, a clinical laboratory result of "susceptible" for a bacterium predicts a likely clinical response to an appropriately dosed antimicrobial drug by a patient infected with that organism, whereas a result of "resistant" predicts poor or no clinical response to that drug. Breakpoint MIC values for categorization of bacteria as susceptible, intermediate, or resistant are generally developed by regulatory and advisory groups and are often based on the distribution of MIC values from a large collection of recent clinical bacterial isolates. Research studies on the mechanisms and epidemiology of resistance may in some cases use different and less rigid definitions of resistance based on determination of a reproducible increase in an MIC value relative to a baseline reference MIC, independent of clinical breakpoints.

MECHANISMS OF RESISTANCE

Bacteria use a wide variety of mechanisms to block or circumvent the activity of antibacterial agents **(Table 145-1** and **Fig. 145-1)**. Although myriad, these mechanisms can generally be grouped into three categories: (1) alteration or bypassing of targets that exhibit reduced binding of the drug, (2) altered access of the drug to its target by reductions in uptake or increases in active efflux, and (3) a modification of the drug that reduces its activity. These mechanisms result from either mutations in bacterial chromosomal genes occurring spontaneously during bacterial DNA replication or the acquisition of new genes by DNA transfer from other bacteria or uptake of exogenous DNA. New genes are most often acquired on self-replicating plasmids or other DNA elements transferred from other bacteria. However, some bacteria, such as *Streptococcus pneumoniae* and *Neisseria gonorrhoeae*, can also take up fragments of environmental DNA from related bacterial species and recombine that DNA directly into their own chromosomes, a process called *transformation*. Not uncommonly, resistant bacteria have combinations of resistance mechanisms either within one category or among categories, and many plasmids contain more than one resistance gene. Thus, plasmid acquisition itself can in many cases confer resistance to multiple antibacterial agents. Resistance to multiple, structurally unrelated antibiotics can also occur by mutations that cause increased expression of certain bacterial efflux pumps, some of which have broad substrate profiles enabling transport of multiple antibacterial agents out of the cell.

Many antibacterial drugs are derived from natural products of environmental microbial species. Some genes encoding resistance to these drugs originate in the drug-producer organism to protect it from its product and have then been mobilized onto plasmids that spread into other organisms. Surviving nonproducer bacteria in the exposed natural environment may also have evolved resistance under selection pressure that adds to the reservoir of resistance mechanisms. Exposure to antibacterial agents either in nature or during human, animal, or other use then results in the selection of resistant strains within an otherwise susceptible bacterial population. In some cases, resistance mechanisms may confer disadvantages that render bacterial growth or survival fitness inferior to that of susceptible strains. In a number of examples, however, fitness defects are often mitigated over time by compensatory mutational mechanisms that make the bacteria both resistant and fit and thereby more likely to persist in a reservoir even in the absence of continued antimicrobial selection pressures. Discussed below are the major classes of antimicrobial agents currently in clinical use and the most important mechanisms of resistance encountered in clinical infections.

β-Lactams β-lactams, the largest class of antibiotics, inhibit bacterial cell-wall synthesis by binding to cell-wall transpeptidases, cross-linking enzymes that are also called penicillin-binding proteins (PBPs); PBPs are targets that are unique to bacteria and have no mammalian counterpart. The most common mechanism of resistance to β-lactams, particularly in gram-negative bacteria, is their degradation

TABLE 145-1 The Most Common Mechanisms of Resistance to Antibacterial Agents

ANTIBACTERIAL AGENT(S)	MAJOR TARGET	MECHANISM(S) OF ACTION	MECHANISM(S) OF RESISTANCE
β-Lactams (penicillins, cephalosporins, monobactams, carbapenems)	Cell-wall synthesis	Bind cell-wall cross-linking enzymes (PBPs, transpeptidases)	1. Drug inactivation by β-lactamases 2. Altered PBP targets 3. Reduced diffusion through porin channels 4. Altered iron uptake proteins (cefiderocol)
Glycopeptides and lipoglycopeptides (vancomycin, teicoplanin, telavancin, dalbavancin, oritavancin)	Cell-wall synthesis	Block cell wall glycosyltransferases by binding D-Ala-D-Ala stem-peptide terminus Teicoplanin, telavancin, dalbavancin, and oritavancin: affect membrane function	1. Altered D-Ala-D-Ala target (D-Ala-D-Lac) 2. Increased D-Ala-D-Ala target binding at sites distant from cell wall synthesis enzymes
Bacitracin	Cell-wall synthesis	Blocks lipid carrier of cell wall precursors	Active drug efflux
Fosfomycin	Cell-wall synthesis	Blocks linkage of stem peptide to NAG by enoyltransferase	1. Target enzyme overexpression 2. Drug-modifying enzymes
Aminoglycosides (gentamicin, tobramycin, amikacin, plazomicin)	Protein synthesis	Bind 30S ribosomal subunit Block translocation of peptide chain Cause misreading of mRNA	1. Drug-modifying enzymes 2. Methylation at ribosome binding site 3. Decreased permeation to target due to active efflux
Tetracyclines (tetracycline, doxycycline, minocycline)	Protein synthesis	Bind 30S ribosomal subunit Inhibit peptide elongation	1. Active drug efflux 2. Ribosomal protection proteins
Tigecycline, eravacyclin, omadacycline	Protein synthesis	Same as tetracyclines	Active drug efflux (pumps different from those affecting tetracyclines)
Macrolides (erythromycin, clarithromycin, azithromycin) and the ketolide telithromycin	Protein synthesis	Bind 50S ribosomal subunit Block peptide chain exit	1. Methylation at ribosome binding site 2. Active drug efflux
Lincosamides (clindamycin)	Protein synthesis	Bind 50S ribosomal subunit Block peptide bond formation	Methylation at ribosome binding site
Streptogramins (quinupristin, dalfopristin)	Protein synthesis	Same as macrolides	1. Same as macrolides 2. Drug-modifying enzymes
Chloramphenicol	Protein synthesis	Binds 50S ribosomal subunit Blocks aminoacyl tRNA positioning	Drug-modifying enzymes
Oxazolidinones (linezolid, tedizolid)	Protein synthesis	Bind 50S ribosomal subunit Inhibit initiation of peptide synthesis	1. Altered rRNA binding site 2. Methylation of ribosome binding site
Pleuromutilins (lefamulin)	Protein synthesis	Bind 50S ribosomal subunit Blocks peptidyl transferase center	1. Altered L3 and L4 protein binding site 2. Methylation of ribosome binding site
Mupirocin	Protein synthesis	Blocks isoleucyl tRNA synthetase	1. Acquired resistant tRNA synthetase (drug bypass) 2. Altered native tRNA synthetase target
Sulfonamides (sulfadiazine, sulfisoxazole, and sulfamethoxazole)	Folate synthesis	Inhibit dihydropteroate synthetase	Acquired resistant dihydropteroate synthetase (drug bypass)
Trimethoprim	Folate synthesis	Inhibits dihydrofolate reductase	Acquired resistant dihydrofolate reductase (drug bypass)
Quinolones (norfloxacin, ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, gemifloxacin, delafloxacin)	DNA synthesis	Inhibit DNA gyrase and DNA topoisomerase IV Enzyme–DNA–drug complex: blocks DNA replication apparatus	1. Altered target(s) 2. Active efflux 3. Protection of target from drug 4. Drug-modifying enzyme (ciprofloxacin)
Rifamycins (rifampin, rifabutin, rifapentine)	RNA synthesis	Inhibit RNA polymerase	Altered target
Nitrofurantoin	Nucleic acid synthesis	Reduces reactive drug derivatives that damage DNA	Altered drug-activating enzymes
Metronidazole	Nucleic acid synthesis	Reduces reactive drug derivatives that damage DNA	1. Altered drug-activating enzyme 2. Acquired detoxifying enzymes 3. Active efflux
Polymyxins (polymyxin B and polymyxin E [colistin])	Cell membrane	Bind LPS and disrupt both outer and cytoplasmic membranes	Altered cell-membrane charge with reduced drug binding
Daptomycin	Cell membrane	Produces membrane channel and membrane leakage	Altered cell-membrane charge with reduced drug binding

Abbreviations: LPS, lipopolysaccharide; NAG, *N*-acetylglucosamine; PBP, penicillin-binding protein.

by β-lactamases, enzymes that break down the core β-lactam ring and destroy drug activity. β-Lactamases differ in the spectrum of β-lactams they can degrade. Some β-lactamases are encoded on the bacterial chromosome, and their activity contributes to the intrinsic susceptibility profile of a particular species. Chromosomally encoded β-lactamases can be produced in varying amounts that affect the degree of resistance. In some cases, enzyme expression is physiologically induced by exposure to certain β-lactams; in other cases, enzyme expression can become constant or constitutive through mutations in genes that encode the regulators of expression of a β-lactamase gene.

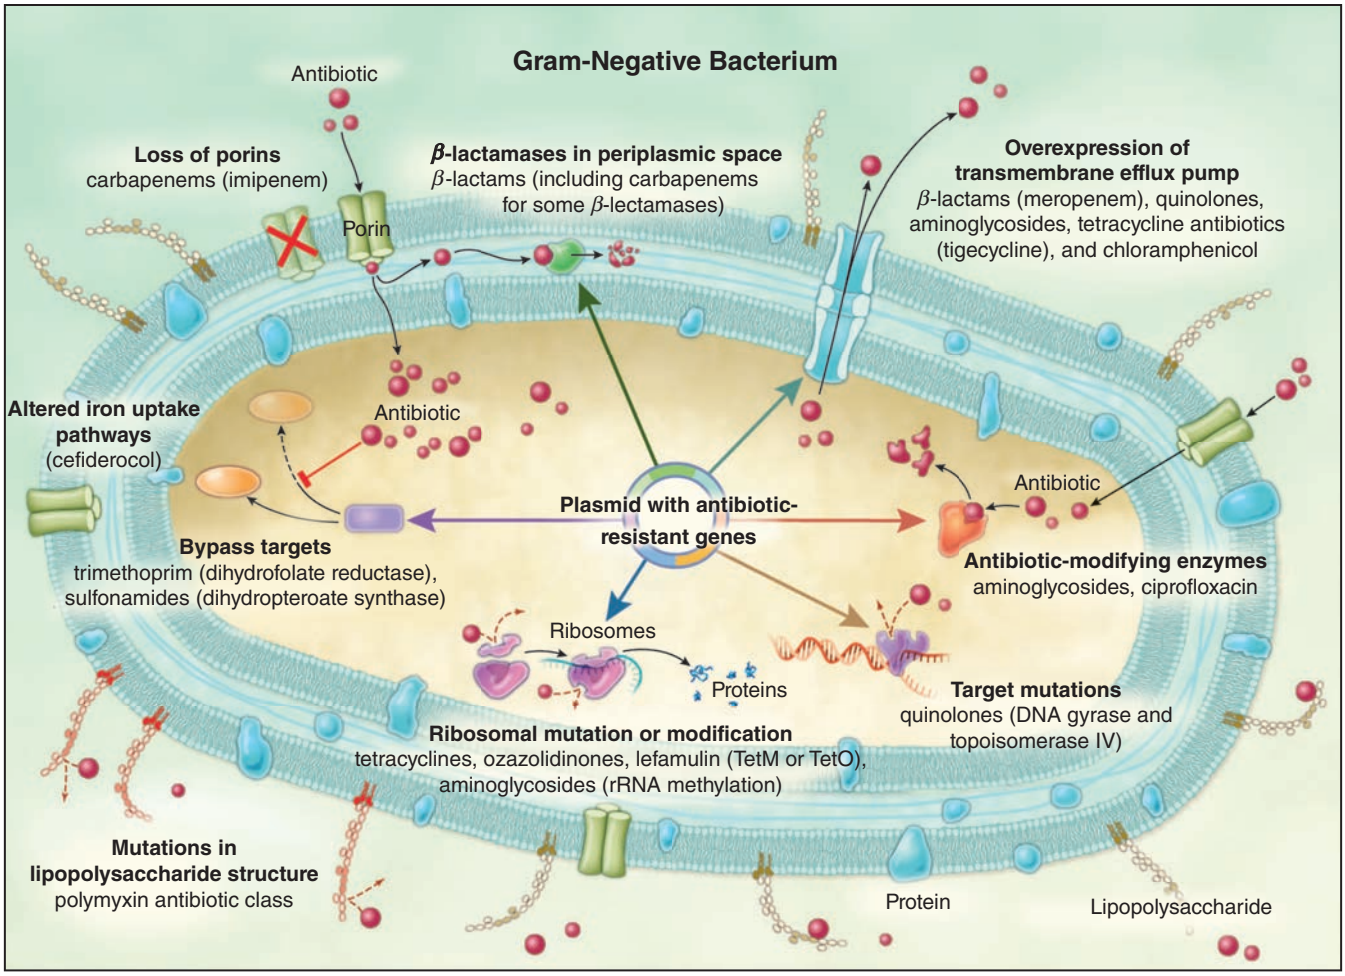

FIGURE 145-1 Antibacterial targets and mechanisms of resistance to antibacterial agents, as illustrated in a gram-negative bacterium. Similar mechanisms are found in gram-positive bacteria, but their lack of an outer membrane causes β-lactamases to be excreted outside the cell, rather than into the periplasmic space between the inner and outer membranes, and reduces the efficiency of efflux pumps because exported drugs can re-enter the cell after crossing a single membrane, rather than the two membranes in gram-negative bacteria. Red spheres indicate antibiotics. *(From AY Peleg, DC Hooper: Hospital-acquired infections due to gram-negative bacteria. N Engl J Med 362:1084, 2010. Copyright © 2010 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

Other β-lactamases are encoded by genes on acquired plasmids and are usually constitutively expressed. The resistance profiles due to plasmids may be present in some strains of a species but not others, depending on which plasmids the strain has acquired. In gram-positive bacteria β-lactamases are secreted into the extracellular environment, whereas in gram-negative bacteria these enzymes are secreted into the periplasmic space between the cytoplasmic and outer membranes—a limited space that permits the presence of high concentrations of β-lactamase. Thus, in gram-negative bacteria, access of β-lactams both to their target PBPs and to β-lactamases requires diffusion across the outer membrane, generally through the porin diffusion channels. Reductions in outer-membrane diffusion channels due to mutation can further augment the efficiency of β-lactamase degradation of β-lactams: slow diffusion acts together with the high enzyme concentrations in the periplasmic space to enhance drug degradation and resistance.

Most strains of *Staphylococcus aureus* produce a plasmid-encoded β-lactamase that degrades penicillin but not semisynthetic penicillins, such as oxacillin and nafcillin. The greatest diversity among β-lactamases, however, is found in gram-negative bacteria. The most common and earliest identified plasmid-encoded β-lactamases of gram-negative bacteria can inactivate all penicillins and most early-generation cephalosporins. Multiple extended-spectrum β-lactamase (ESBL) variants of these early enzymes have emerged and are now widely disseminated. These ESBLs can degrade later-generation cephalosporins (ceftriaxone, cefotaxime, ceftazidime) as well as the monobactam aztreonam, and some ESBLs also degrade the fourth-generation cephalosporin cefepime. Carbapenems (imipenem, meropenem, ertapenem, doripenem) generally are not degraded by ESBLs, but additional β-lactamases, called *carbapenemases*, which degrade carbapenems and most if not all other β-lactams, have emerged and are increasing in prevalence. In the United States, *Klebsiella pneumoniae* carbapenemases (KPCs), which are usually found in strains of *Escherichia coli* and *K. pneumoniae*, are most widespread, but New Delhi metallo-β-lactamases (NDM carbapenemases), which were found initially on the Indian subcontinent, have now appeared in several areas in the United States, as has an OXA group carbapenemase, OXA-48. In some cases, high levels of expression of an ESBL or an AmpC enzyme (see below), together with reduced porin diffusion channels, can also result in resistance to carbapenems. In *Pseudomonas aeruginosa*, resistance to carbapenems can occur by mutations that cause reductions in the OprD diffusion channel for imipenem or increased expression of efflux pumps that can remove meropenem from the bacterial cell.

The chromosomal β-lactamase of *K. pneumoniae* preferentially degrades penicillins but not cephalosporins. In contrast, the chromosomal β-lactamase of *Enterobacter* and related genera, AmpC, can degrade almost all cephalosporins but is normally expressed in only small amounts. Mutations in regulatory genes that cause increased amounts of AmpC to be produced confer full resistance to penicillins and cephalosporins; the exceptions are cefoxitin and cefepime, which are relatively stable to AmpC. Resistance to cefepime can develop, however, through the combined effects of mutations that cause increased AmpC production and decreased porin diffusion channels. Genes encoding AmpC have also been found on plasmids but are less common than plasmid-encoded ESBLs. A recent novel cephalosporin,

cefiderocol, has enhanced stability to β-lactamases and, due to a catechol side group, is actively taken up into the bacterial cell by siderophore iron uptake pathways, rather than diffusing passively through porin channels. It is active against many gram-negative bacteria that are resistant to other β-lactams, including carbapenems. Reduced susceptibility has been reported to occur in strains with mutations in multiple iron transport genes.

Inhibitors of β-lactamases such as clavulanate, sulbactam, tazobactam, avibactam, and vaborbactam have been developed and paired with amoxicillin and ticarcillin (clavulanate), ampicillin (sulbactam), piperacillin and ceftolozane (tazobactam), ceftazidime (avibactam), meropenem (vaborbactam), or imipenem (relebactam). These inhibitors have little or no antibacterial activity of their own but inhibit plasmid-mediated β-lactamases, including ESBLs. Only avibactam, vaborbactam, and relebactam inhibit AmpC enzymes and some carbapenemases (KPCs but not metallo-carbapenemases, such as NDM).

Resistance to β-lactams also occurs through alterations in the drugs' target transpeptidase enzymes (PBPs) involved in cross-linking of the bacterial cell-wall peptidoglycan structure. In *S. pneumoniae*, *N. gonorrhoeae*, and *Neisseria meningitidis*, resistance to penicillin occurs by recombination of transformed DNA from related species that results in mosaic PBPs with lower affinity for penicillin. A combination of increased expression of an efflux pump and a porin mutation also causes penicillin resistance in *N. gonorrhoeae*. In staphylococci, resistance to methicillin and other β-lactams occurs by acquisition of the *mec* gene, which encodes PBP2a with reduced drug affinity. PBP2a is a bypass target that can function in the presence of β-lactams, bypassing their effect on other PBPs. Ceftaroline is the only β-lactam that has an affinity for PBP2a and is thus active against methicillin-resistant staphylococcal strains. Resistance to ceftaroline can occur, however, by mutations in the gene encoding PBP2a that reduce its affinity for the drug.

Glycopeptides and Lipoglycopeptides Glycopeptides and lipoglycopeptides inhibit bacterial cell-wall synthesis by binding to the terminal two D-alanine amino acids on the cell-wall peptidoglycan stem peptides, which are involved in peptidoglycan cross-links. In doing so, these drugs block the transpeptidase cross-linking enzymes and glycosyl transferases necessary for cell-wall synthesis. Resistance to vancomycin in enterococci is due to the acquisition of a set of *van* genes that result in (1) the production of D-alanine-D-lactate—instead of the normal D-alanine-D-alanine—at the end of the peptidoglycan stem peptide and (2) the reduction of existing D-alanine-D-alanine–terminated peptides. Vancomycin binds D-alanine-D-lactate with a 1000-fold lower affinity than D-alanine-D-alanine. The *van* genes originated in the organisms that naturally produce vancomycin and have been mobilized and reorganized in transposon mobile genetic elements and onto plasmids, which can be transferred between enterococci. In rare cases, the *van* gene cassettes have been transferred from enterococci to *S. aureus*, with the consequent generation of full vancomycin resistance. In *S. aureus*, intermediate resistance to vancomycin is more common than full vancomycin resistance and is due to a different mechanism that results from a series of several chromosomal mutations leading to a thickened and poorly cross-linked cell wall. This modified cell wall contains additional D-alanine-D-alanine–terminated stem peptides that bind vancomycin at a site distant from the cell membrane, adjacent to which new peptidoglycan is synthesized and where vancomycin binding blocks transpeptidase and transglycosylase enzymes. Thus, vancomycin's binding to these distant termini impedes its access to the proximal binding sites that result in inhibition of peptidoglycan synthesis. This intermediate-resistance phenotype was first recognized in patients receiving prolonged courses of vancomycin that created an opportunity for selection of the multiple mutations needed to produce the modified cell wall. Because of the energy costs of a thickened cell wall, this intermediate-resistance phenotype may be unstable, with strains returning to susceptibility in the absence of vancomycin selection pressure. Susceptibility to telavancin, dalbavancin, and oritavancin is also reduced in strains that exhibit resistance or intermediate susceptibility to vancomycin, although in some cases, the drugs remain sufficiently active that the strains may still be classified as susceptible on the basis of standard clinical laboratory interpretive criteria.

Aminoglycosides Aminoglycosides are one of several classes of antimicrobials that inhibit protein synthesis by binding to either the 30S or the 50S bacterial ribosomal subunit (both of which differ from eukaryotic ribosomal subunits), with consequent selective antibacterial activity. The aminoglycosides bind to the 30S subunit of the bacterial ribosome. The most common mechanism of resistance to aminoglycosides in gram-negative bacteria is due to acquisition of plasmid genes encoding transferase enzymes that modify aminoglycosides by the addition of acetyl, adenyl, or phosphate groups; these added groups decrease the drugs' binding affinity to their ribosomal target site. Transferases differ in which aminoglycosides they modify, and amikacin resistance occurs less often than resistance to gentamicin or tobramycin by these mechanisms. Plazomicin, a recently developed aminoglycoside, is distinctive in that it remains active and is not modified by most transferases. Another mechanism of plasmid-mediated aminoglycoside resistance is due to methylase enzymes that can methylate the site of aminoglycoside binding on the 16S ribosomal RNA of the 30S ribosomal subunit and reduce drug binding to its ribosome target, resulting in resistance to all aminoglycosides, including plazomicin. For streptomycin, a single ribosomal protein mutation may also cause resistance. In *P. aeruginosa*, resistance can occur through mutations in regulatory genes causing increased expression of a chromosomally encoded efflux pump, MexXY, which reduces intracellular drug concentrations.

Tetracyclines These antibiotics bind the 16S ribosomal RNA of the 30S ribosomal subunit at a site distinct from the binding site of the aminoglycosides and inhibit bacterial protein synthesis. For tetracyclines, including doxycycline and minocycline, resistance is often plasmid-mediated and due either to active efflux pumps, which are generally specific for tetracyclines, or to proteins that protect the ribosome from tetracycline action. A number of broad-spectrum, chromosomally encoded efflux pumps may also include tetracyclines among their substrates, and regulatory mutations that cause pump overexpression may confer tetracycline resistance together with resistance to other agents. There have been recent derivatives of the tetracyclines, including the glycylcycline, tigecycline, the fluorocycline, eravacycline, and the aminomethylcycline, omadacycline, which have modifications on the core tetracycline ring structure rendering them less affected or unaffected by the common tetracycline resistance mechanisms. Resistance to the newer tetracyclines can occur, however, through mutations that cause overexpression of some broad-spectrum efflux pumps, particularly in *Proteus* species. An uncommon plasmid-encoded tetracycline modification mechanism can also cause resistance to the newer agents.

Macrolides, Ketolides, Lincosamides, and Streptogramins These antibiotics are also inhibitors of bacterial protein synthesis, in this case through their binding to the 23S RNA of the 50S ribosomal subunit. They are generally active against gram-positive bacteria. Resistance to macrolides, clindamycin, and quinupristin is most often due to acquired Erm methylases that modify the drug-binding site on the ribosome, reducing drug binding. Resistance to quinupristin by this mechanism renders the quinupristin-dalfopristin combination bacteriostatic rather than bactericidal. Telithromycin, a ketolide structurally related to macrolides, has an additional binding site on the ribosome and remains active in the presence of some methylases. Methylase gene expression can be induced by exposure to most macrolides but generally not ketolides (e.g., telithromycin); however, bacterial strains constitutively expressing methylase genes can display resistance to both macrolides and ketolides. Acquired genes encoding active efflux pumps also can contribute to resistance to macrolides in streptococci and to resistance to macrolides, clindamycin, and dalfopristin in staphylococci. Plasmid-acquired, drug-modifying enzymes

in staphylococci can also cause resistance to quinupristin and dalfopristin. Macrolide resistance due to 23S rRNA mutations at the site of drug binding is uncommon in staphylococci and streptococci because of the multiple copies of the rRNA genes on the chromosomes of these species; such resistance may occur more frequently, however, in mycobacteria, *Helicobacter pylori*, and *Treponema* species, which have only one or two chromosomal copies of these rRNA genes. Among gram-negative bacteria, many of which are not susceptible to current macrolides because of inadequate drug permeation, some strains with acquired genes for macrolide-modifying enzymes have been described.

Chloramphenicol Chloramphenicol inhibits bacterial protein synthesis by binding to the 23S rRNA of the 50S subunit at a site that overlaps the macrolide-binding site. Chloramphenicol is uncommonly used in human medicine because of infrequent but potentially severe bone marrow toxicity. Resistance to chloramphenicol is most often due to plasmid-encoded, drug-modifying acetyltransferases that have been found in both gram-positive and gram-negative bacteria and whose expression can be induced by drug exposure. Among staphylococci, some resistant strains have been found to have a plasmid-encoded ribosomal methylase that confers resistance to chloramphenicol, clindamycin, and oxazolidinones. As is the case for macrolides, ribosomal mutations causing resistance to chloramphenicol are uncommon because of multiple copies of rRNA genes in most human pathogens. Plasmid-encoded efflux pumps affecting chloramphenicol specifically have been found in gram-negative bacteria, and other pumps affecting chloramphenicol and oxazolidinones have been found in gram-positive bacteria.

Oxazolidinones Linezolid and tedizolid are the only members of the oxazolidinone class of antimicrobials in clinical use, and both are active against gram-positive bacteria only; lack of sufficient activity in gram-negative bacteria results from the ability of native efflux pumps in these bacteria to limit drug access to their cytoplasmic ribosome targets. Oxazolidinones target the bacterial ribosome and inhibit protein synthesis by binding to 23S rRNA of the 50S subunit at a distinct site that overlaps with the chloramphenicol-binding site. Resistance has been seen in enterococci more often than in staphylococci and, in both organisms, is most often due to mutations in multiple copies of the 23S rRNA genes that reduce drug binding to the ribosome. A plasmid-acquired ribosomal methylase gene that enables ribosomal alteration at a site that confers resistance to both linezolid and chloramphenicol has also been found in some strains of both *S. aureus* and coagulase-negative staphylococci but is not yet widespread. A plasmid-encoded active efflux pump conferring resistance to oxazolidinones (both linezolid and tedizolid) and chloramphenicol has been described in animal isolates and a small number of human isolates of *Enterococcus faecalis*.

Pleuromutilins Lefamulin was recently approved and is the only systemic pleuromutilin in clinical use. Retapamulin has been available for topical use in skin infections. Pleuromutilins inhibit bacterial protein synthesis by binding to the peptidyl transferase center in the 50S ribosomal subunit, and lefamulin is generally active against gram-positive bacteria, *Haemophilus influenzae*, *Moraxella catarrhalis,* and atypical respiratory pathogens such a *Mycoplasma pneumoniae* and *Legionella* spp. Although there is partial overlap in the site of binding of lefamulin and those of other antibacterials binding the 50S ribosomal subunit, cross-resistance with macrolides, oxazolidinones, lincosamides, and streptogramins is uncommon. Resistance to lefamulin can occur by mutations in L3 and L4 proteins of the 50S subunit that alter the lefamulin binding site. In addition, the plasmid-encoded Cfr methylase, which confers resistance to chloramphenicol and oxazolidinones, can also cause resistance to lefamulin by disrupting its binding site. Vga transporters, which cause resistance to lincosamides and streptogramins, also affect pleuromutilins.

Mupirocin Mupirocin is used only in topical formulations, most often for elimination of nasal carriage of *S. aureus*. It targets bacterial leucyl-tRNA synthetase and inhibits protein synthesis. Resistance to mupirocin occurs by either mutation in the target leucyl-tRNA synthetase (low-level resistance) or the acquisition of a plasmid-encoded resistant tRNA synthetase (high-level resistance), which bypasses drug inhibition of the native, sensitive synthetase.

Sulfonamides and Trimethoprim These agents inhibit the folate biosynthesis pathway at different steps. Sulfonamides are structurally similar to *para*-aminobenzoic acid (PABA) and competitively inhibit dihydropteroate synthetase, which, in an early step in the pathway, uses PABA to synthesize dihydropteroate, a precursor of dihydrofolate. Trimethoprim inhibits dihydrofolate reductase at a later step in the pathway that generates tetrahydrofolate. Clinical use of folate pathway inhibitors most often consists of the combination of sulfamethoxazole and trimethoprim; on occasion, however, trimethoprim or various sulfonamides are used individually. Resistance to both of these antimetabolites can result from mutation in their target enzymes or can be due to plasmid-acquired genes encoding resistant enzymes that bypass the inhibition of the native sensitive enzymes—a resistant dihydropteroate synthetase in the case of sulfonamides and a resistant dihydrofolate reductase in the case of trimethoprim. Resistance to the combination of sulfamethoxazole and trimethoprim requires that the bacterial strain have resistance mechanisms for both agents and yet is not uncommon. Resistance due to drug efflux or drug modification has been limited for both sulfonamides and trimethoprim.

Quinolones Quinolones are synthetic inhibitors of bacterial DNA synthesis. They bind to two enzymes required for DNA synthesis: DNA gyrase and DNA topoisomerase IV, which alter DNA conformation and the interlinking of replicated molecules. In addition to inhibiting the enzymes' catalytic functions of altering DNA topology, they stabilize enzyme–DNA complexes that form a barrier to the DNA replication machinery and are a precursor to lethal double-strand DNA breaks. Although related topoisomerase enzymes are involved in mammalian DNA synthesis, the mammalian and bacterial enzymes are sufficiently different from each other for quinolones to have selective activity against bacteria. Resistance to quinolones is most often due either to chromosomal mutations altering the target enzymes DNA gyrase and DNA topoisomerase IV, with consequent reduction in drug binding, or to mutations that increase the expression of native broad-spectrum efflux pumps for which quinolones (among other compounds) are substrates. In addition, three types of acquired genes can confer reduced susceptibility or low-level resistance by protecting the target enzymes, modifying some quinolones (particularly ciprofloxacin and norfloxacin) to reduce their activity, or generating an efflux of quinolones. These genes are usually located on multidrug-resistance plasmids that have spread worldwide. Their presence can promote higher levels of quinolone resistance by enhancing selection of the mutations in chromosomal target genes with exposure to quinolones and can then link quinolone resistance to resistance to other antibacterial drugs that are encoded by the same plasmid.

Rifampin and Rifabutin Antimicrobials of the rifamycin class target bacterial RNA polymerase and thereby inhibit transcription of messenger RNA and gene expression. Their activity is generally limited to gram-positive bacteria because native efflux pumps in most gram-negative bacteria reduce drug access to the cytoplasmic enzyme target. Single mutations in the β subunit of RNA polymerase constitute the principal mechanism of acquired rifampin resistance, which is high level. Thus, rifampin and other rifamycins are used for treatment of infections only in combination with other antibacterial drugs in order to reduce the likelihood of selection of high-level resistance.

Metronidazole Metronidazole is actively taken up by most anaerobic bacteria and then converted to reactive drug derivatives that nonspecifically damage cytoplasmic proteins and nucleic acids. Thus, metronidazole lacks a specific cellular target. Acquired resistance to metronidazole in *Bacteroides* species is rare. Such resistance has been reported in strains that lack the endogenous activating nitroreductase or that have acquired *nim* genes responsible for further reduction of

DNA-damaging nitroso intermediates to an inactive derivative. Active efflux and enhanced DNA repair mechanisms also have been associated with resistance.

Nitrofurantoin Nitrofurantoin is used only for treatment of lower urinary tract infections because adequate drug concentrations are found only in urine. Its mechanism of action is not fully understood but is thought to involve generation of reactive derivative molecules (as occurs with metronidazole) that damage DNA and ribosomes. Resistance to nitrofurantoin in *E. coli* can emerge through a series of mutations that progressively decrease the nitroreductase activity required for generating active nitrofuran metabolites. These mutants are also impaired in growth; this impairment possibly explains the infrequent occurrence of resistance with clinical use of nitrofurantoin.

Polymyxins Because of emerging multidrug resistance in gram-negative bacteria, colistin and polymyxin B are being used increasingly for infections due to resistant Enterobacterales, *P. aeruginosa*, and *Acinetobacter* species. Polymyxins are cationic cyclic peptide molecules that bind negatively charged lipopolysaccharides on the gram-negative bacterial outer membrane, with subsequent disruption and permeabilization of both outer-membrane and cytoplasmic-membrane structure. Thus, the polymyxins are bactericidal. Resistance is so far uncommon but can emerge during therapy through mutations that cause reductions in the negative charge of the gram-negative bacterial cell surface, thereby reducing binding of the positively charged colistin. Recently transferable plasmid-mediated colistin resistance has also been found to be due to *mcr-1*, a gene encoding a phosphoethanolamine transferase that also reduces the negative charge on the cell surface. *mcr-1*-containing enteric bacteria have now been identified in Asia, Europe, and the United States.

Daptomycin Daptomycin is active against gram-positive bacteria and interacts with and disrupts the cytoplasmic membrane in a calcium-dependent manner, resulting in bactericidal activity. The mechanisms of resistance to daptomycin are complex and involve mutations in several genes that can alter cell membrane charge and structure and reduce daptomycin binding. Resistance to daptomycin is relatively infrequent but has emerged in some *S. aureus* strains with intermediate vancomycin susceptibility from patients treated with vancomycin and not exposed to daptomycin. In some strains of methicillin-resistant *S. aureus*, daptomycin resistance has been linked to acquired susceptibility to β-lactams; combinations of daptomycin with nafcillin or ceftaroline have been successful for treatment of patients infected with resistant strains when daptomycin alone or in combination with other agents has failed. The mechanism of this effect is not yet clear but may involve alteration in surface charge and increased daptomycin binding in the presence of β-lactams. Daptomycin resistance has also been reported in enterococci.

EPIDEMIOLOGY OF RESISTANCE AND REDUCTION OF ITS OCCURRENCE

Multidrug resistance in human bacterial infections has been increasing overall in recent years, substantially limiting the number of antibiotics that can be used to treat some infections. The prevalence of resistance to various antimicrobials among human pathogens can, however, vary greatly in different geographic areas and even at different institutions in the same area. Thus, specific local data on the occurrence of various types of resistance are an important component of the choice of antimicrobials for empirical treatment of infection until the responsible pathogen is identified and its specific susceptibilities are determined by the clinical microbiology laboratory. Prompt adjustment of the initially chosen antimicrobial on the basis of species and susceptibility data to best target therapy is equally important. These principles emphasize the importance of obtaining appropriate samples for culture or other diagnostic modalities and susceptibility testing—whenever possible, prior to administration of antimicrobials. They also highlight the importance of rapid and sensitive diagnostic methods and the prompt communication of their results to clinicians to inform best choices of antimicrobials.

The overall prevalence of resistance can be affected by a number of factors, including (1) the extent of resistance reservoirs in the patient population; (2) the selection pressures from use of antimicrobials that favor resistant strains over susceptible ones; and (3) the extent by which resistance is amplified by transmission of resistant strains to patients from their environment or other persons, either directly or indirectly via the contaminated hands of health care workers when hand hygiene and other infection control practices are inadequately followed. The likelihood that an individual patient will be infected with a resistant pathogen is likewise affected by his or her history. Studies have shown that prior antibiotic treatment, prior infection with resistant pathogens, and prior hospitalizations all increase this likelihood.

These factors emphasize the importance of the appropriate use of antimicrobials (particularly, the avoidance of their use in clinical conditions in which they are not needed), the use of the shortest courses of therapy sufficient for a successful clinical outcome, and the implementation of antimicrobial stewardship programs **(Chap. 144)** as well as careful and consistent infection control practices in short- and long-term-care institutions. Antimicrobial agents are distinct among drug classes in human medicine in that—despite their clear clinical value when used appropriately—the extent of their use can compromise their future utility because of resistance. The remarkable ability of pathogens to acquire resistance is inherent in their biology and emphasizes the necessity for clinicians and institutions to pay careful attention to those factors that can be controlled through judicious antimicrobial use and rigorous infection control and prevention practices.

Efforts to address the problems caused by resistance are now being made worldwide. The U.S. Centers for Disease Control and Prevention (CDC) has recently estimated that >2.8 million resistant bacterial infections occur in the United States each year, with 35,900 deaths, and has identified particular resistant pathogens that are of greatest concern because of their overall effects on public health **(Table 145-2)**. Enteric bacteria (such as *E. coli*, *K. pneumoniae*, and *Enterobacter* spp.) and

Acinetobacter spp. that are resistant to carbapenems are included in the "urgent" category because of their increasing occurrence worldwide and because they are often highly resistant to multiple drugs, with few if any active antimicrobials available for treatment. Resistant *N. gonorrhoeae* is included in this category as well because of the ease with which gonorrhea can be spread from person to person and because few active agents are now available. Other resistances are common and also affect clinical care, often requiring use of alternatives to first-line agents that can be less effective and less well tolerated. Also affecting clinical care and considered urgent are infections due to *Clostridioides difficile*. Although not directly due to acquired resistance, *C. difficile* disease, like resistant bacterial infections, is linked to antibacterial use (by the disruption of the normal microbiome of the gastrointestinal tract rather than direct resistance selection) and to its ability as a spore-forming bacterium to be spread in health care environments. To address the problems posed by resistance and *C. difficile* disease, the CDC has emphasized a set of five core actions. (1) *Infection prevention and control:* These efforts focus on implementation of evidence-based activities to reduce the risks and incidence of device-related infections overall and on improvement of compliance with infection control practices that prevent transmission of resistant pathogens from one person to another, such as hand hygiene and isolation precautions in health care and long-term care settings. (2) *Tracking and data:* Efforts aim to increase the reporting and sharing of the occurrence of resistance to enhance epidemiologic data and inform targeting of preventive interventions. (3) *Antibiotic use and access:* Antimicrobial stewardship programs with specific components to track usage and educate clinicians on appropriate use have become required in hospitals, and the CDC has implemented efforts to reduce inappropriate use in outpatient settings, with particular attention to upper respiratory illnesses that often do not require antimicrobials because of their common self-limited viral causes. (4) *Vaccines, therapeutics, and diagnostics:* The U.S. Congress and the U.S. Food and Drug Administration, as well as agencies in other countries, have recently developed incentives and enhanced regulatory pathways for drug approval that pharmaceutical companies can use for development of antimicrobials that specifically address particular resistant pathogens. Both small and large companies have undertaken efforts in this area. New technologies for rapid detection of resistance and susceptibility are also being developed by multiple diagnostics companies in order to facilitate the appropriate choice of antimicrobials earlier in the course of illness, providing an important tool for antimicrobial stewardship programs. (5) *Environment and sanitation:* Reservoirs of resistant bacteria and resistance genes on mobile genetic elements can exist in agriculture and food production and domestic animals and have the potential for introduction into humans. Thus, antibiotic use in these environments can amplify resistance reservoirs and increase the chance of human exposure. Therefore, public health interventions addressing these issues in a One Health approach (*https://www.cdc.gov/onehealth/index.html*) are an important component of managing resistance risks.

Section 5 Diseases Caused by Gram-Positive Bacteria

146 Pneumococcal Infections

David Goldblatt, Katherine L. O'Brien

In the late nineteenth century, pairs of micrococci were first recognized in the blood of rabbits injected with human saliva by both Louis Pasteur, working in France, and George Sternberg, an American army physician. The important role of these micrococci in human disease was not appreciated at that time. By 1886, when the organism was designated "pneumokokkus" and *Diplococcus pneumoniae*, it had been isolated by many independent investigators, and its role in the etiology of pneumonia was well known. In the 1930s, pneumonia was the third leading cause of death in the United States (after heart disease and cancer) and was responsible for ~7% of all deaths both in the United States and in Europe. While pneumonia was caused by a host of pathogens, lobar pneumonia—a pattern more likely to be caused by the pneumococcus—accounted for approximately one-half of all pneumonia deaths in the United States in 1929. In 1974, the organism was reclassified as *Streptococcus pneumoniae*.

MICROBIOLOGY

Etiologic Agent Pneumococci are spherical gram-positive bacteria of the genus *Streptococcus*. Within this genus, cell division occurs along a single axis, and bacteria grow in chains or pairs—hence the name *Streptococcus*, from the Greek *streptos*, meaning "twisted," and *kokkos*, meaning "berry." At least 22 streptococcal species are recognized and are divided further into groups based on their hemolytic properties. *S. pneumoniae* belongs to the α-hemolytic group that characteristically produces a greenish color on blood agar because of the reduction of iron in hemoglobin (Fig. 146-1). The bacteria are fastidious and grow

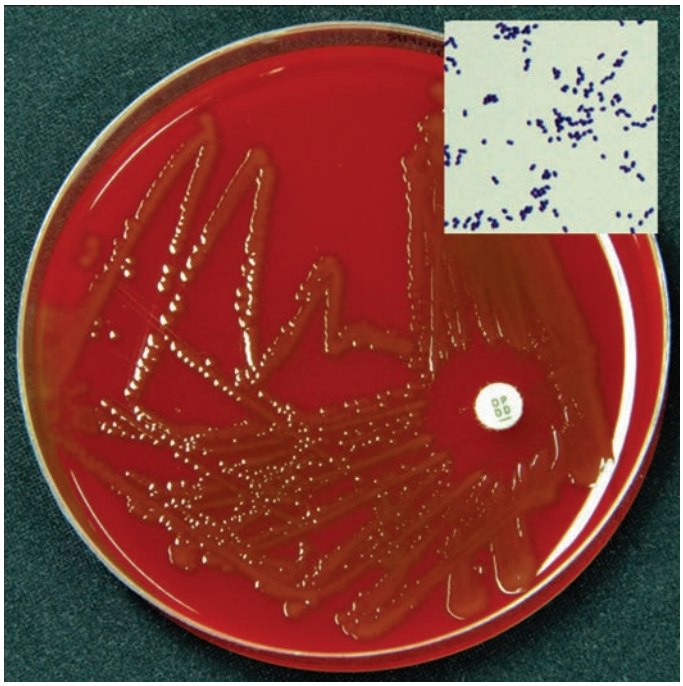

FIGURE 146-1 Pneumococci growing on blood agar, illustrating α hemolysis and optochin sensitivity (zone around optochin disk). *Inset:* Gram's stain, illustrating gram-positive diplococci. *(Photographs courtesy of Paul Turner, University of Oxford, United Kingdom.)*

best in 5% CO_2 but require a source of catalase (e.g., blood) for growth on agar plates, where they develop mucoid (smooth/shiny) colonies. Pneumococci without a capsule produce colonies with a rough surface. Unlike that of other α-hemolytic streptococci, their growth is inhibited in the presence of optochin (ethylhydrocupreine hydrochloride), and they are bile soluble.

In common with other gram-positive bacteria, pneumococci have a cell membrane beneath a cell wall, which in turn is covered by a polysaccharide capsule. Pneumococci are divided into serogroups or serotypes based on capsular polysaccharide structure, as distinguished with rabbit polyclonal antisera; capsules swell in the presence of specific antiserum (the Quellung reaction). The most recently discovered serotypes—6C, 6D, 6F, 6G, 6H, 11E, 20A, 20B and 35D—have been identified with monoclonal antibodies and by serologic, genetic, and biochemical means. The currently recognized 98 serotypes fall into 21 serogroups, and each serogroup contains two to eight serotypes with closely related capsules. Detailed genetic analysis of the locus coding for the polysaccharide capsule, the *cps* locus, continues to reveal putative novel capsular polysaccharides, variants within existing serogroups and designated with an "X." In the absence of type-specific antibody, the capsule protects the bacteria from phagocytosis by host cells and is arguably the most important determinant of pneumococcal virulence. Unencapsulated variants are occasionally identified in cases of invasive pneumococcal disease; however, when their genotype is assessed, they often contain capsular genes. Thus it is likely that they were encapsulated in vivo and have stopped producing capsule during the laboratory steps of pathogen isolation.

Virulence Factors Within the cytoplasm, cell membrane, and cell wall, many molecules that may play a role in pneumococcal pathogenesis and virulence have been identified **(Fig. 146-2)**. These proteins are often involved in direct interactions with host tissues or in concealment of the bacterial surface from host defense mechanisms. Pneumolysin (PLY) is a secreted cytotoxin thought to result in cytolysis of cells and tissues, and LytA enhances pathogenesis. A number of cell wall proteins interfere with the complement pathway, thus inhibiting complement deposition and preventing lysis and/or opsonophagocytosis. The pneumococcal H inhibitor (Hic) impedes the formation of C3 convertase, while pneumococcal surface protein C (PspC), also known as choline-binding protein A (CbpA), binds factor H and is thought to accelerate the breakdown of C3. PspA and CbpA inhibit the deposition of or degrade C3b. To avoid clearance by the mucus, pneumococci utilize the matrix metalloprotease ZmpA, which cleaves mucosal IgA to evade complement activation, preventing agglutination and thus clearance by the mucociliary flow.

The numerous pneumococcal proteins thought to be involved in adhesion include pneumococcal surface adhesin A (PsaA) and the exoglycosidases such as neuraminidase (NanA), β-galactosidase (BgaA), and β-N-Acetylglucosaminidase (StrH), which deglycosylate host glycoproteins releasing sugars as a nutrient source and exposing hidden receptors for adhesion. Once through the epithelial barrier, pneumococci utilize PLY and Mannose receptor C type lectin 1 (MRC-1/CD206) on the surface of dendritic cells and macrophages to enter cells, where they may survive intracellularly in vacuoles thus facilitating spread. To outcompete the other co-colonizing bacteria, the pneumococcus produces bacteriocins called pneumocins that mediate intraspecific competition. Some of the antigens mentioned above are potential vaccine candidates (see "Prevention," below). Biofilm production by pneumococci is now well recognized and is likely to be an important mechanism aiding survival of pneumococci in the upper respiratory tract and contributing to local disease manifestations such as otitis media.

Although the capsule surrounding the cell wall of *S. pneumoniae* is the basis for categorization by serotype, the disease potential of a

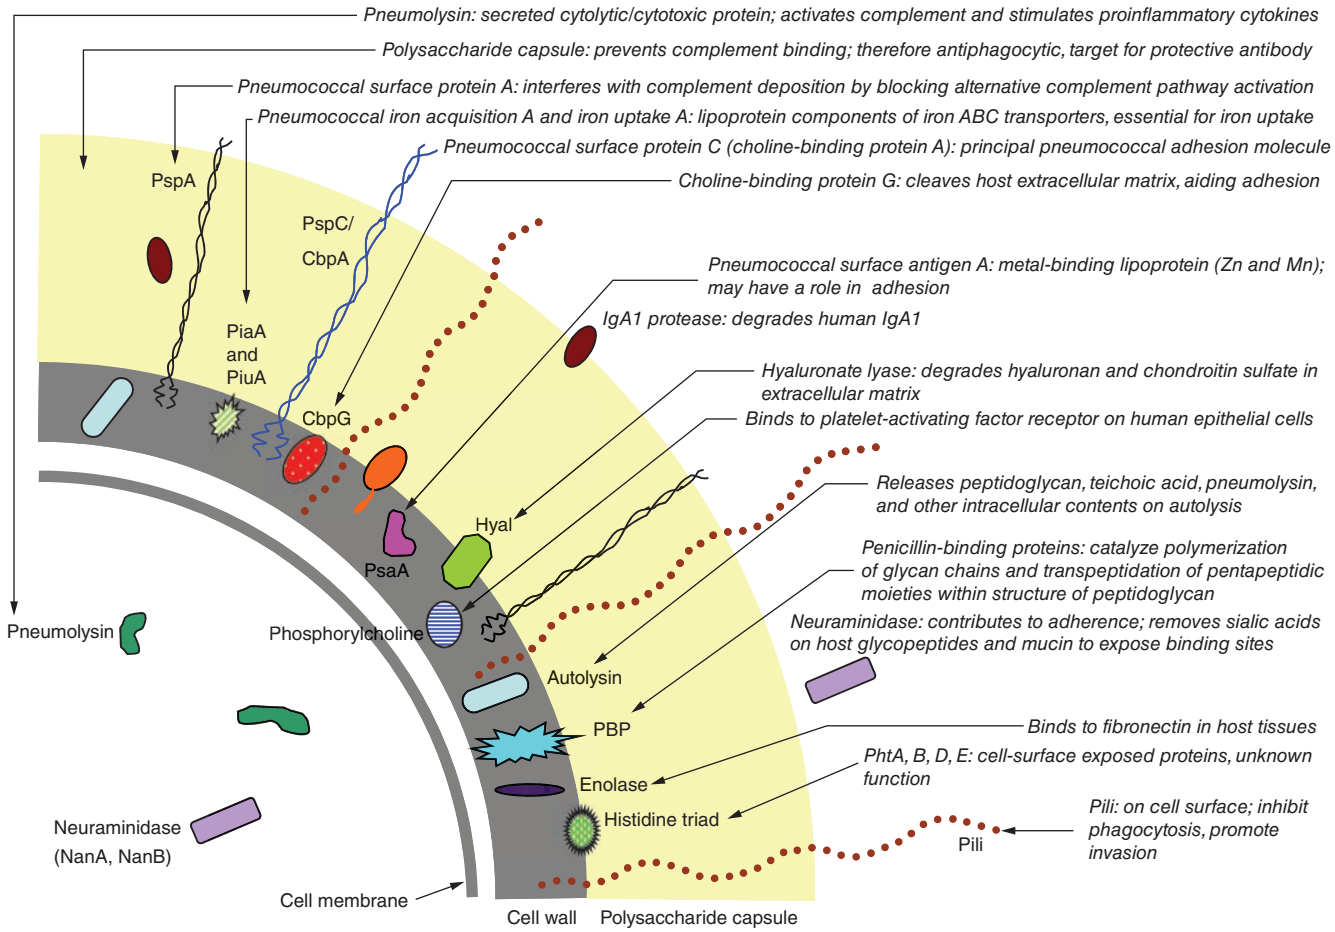

FIGURE 146-2 Schematic diagram of the pneumococcal cell surface, with key antigens and their roles highlighted.

serotype is also related to the genetic composition of the strain. Molecular genotyping and epidemiology are therefore essential, and the gold-standard technique for epidemiologic analyses is the sequencing of housekeeping genes by multilocus sequence typing (MLST). For *S. pneumoniae*, alleles at each of seven loci (*aroE*, *gdh*, *gki*, *recP*, *spi*, *xpt*, and *ddl)* are sequenced and compared with all of the known alleles at that locus. The combination of seven alleles confers the unique sequence type (ST). The pneumococcal MLST website (*pubmlst.org/spneumoniae/*) facilitates the assignment of allele and ST data. Users from nearly all countries of the world and from all major public health and reference laboratories submit their data to the PubMLST site for assignment and curation. Sequence-based MLST genotyping thus provides an unambiguous nomenclature for epidemiologic investigations.

The first pneumococcal genome (a serotype 4 strain known as TIGR4) was sequenced nearly 20 years ago. With the recent advent of high-throughput and relatively inexpensive sequencing techniques, whole-genome sequencing has facilitated even more precise molecular epidemiology: seven-locus STs are simple to define, and enhanced genomic epidemiology can be performed using ribosomal MLST (rMLST; >50 ribosomal genes) and core genome MLST (cgMLST; >1300 core genes), also via the PubMLST website. The pneumococcal database currently contains nearly 50,000 isolates, more than 275,000 alleles, and nearly 15,000 genomes. This includes the PubMLST Pneumococcal Genome Library of curated, published, assembled genomes and isolate provenance data (*pubmlst.org/spneumoniae/pgl/*). All PubMLST data are publicly available and free to access. In recent years, genome sequence analyses have made major contributions to the understanding of pneumococcal molecular epidemiology, biology, diversity, pathogenicity, and vaccine impact.

EPIDEMIOLOGY

(See also "Global Health," below.) Pneumococcal infections remain a significant global cause of morbidity and death, particularly among children and the elderly. Rapid and dramatic changes in the epidemiology of this disease during the past 20 years in several developed countries followed the licensure and routine childhood administration of pneumococcal polysaccharide–protein conjugate vaccine (PCV). With PCV introduction in low and middle-income countries (LMIC), additional profound changes in pneumococcal ecology and disease epidemiology are occurring. The disease burden and serotype distribution in the PCV era are influenced not only by the reduction in disease caused by serotypes included in PCV but also by serotype replacement as a result of reductions in vaccine serotypes, concomitant secular trends in pneumococcal strains unrelated to vaccine use, the impact of antibiotic use on pneumococcal strain ecology, and surveillance system attributes that can themselves affect analysis of epidemiologic features of pneumococcal strains and disease.

Serotype Distribution Not all pneumococcal serotypes are equally likely to cause disease; observed serotype distributions vary by age category, disease syndrome, and geography. Geographic differences may be driven by variations in the relative prevalence of syndromes causing disease rather than by true serotype distribution differences, as certain serotypes are more common causes of some syndromes than others (e.g., pneumonia and meningitis). Most data on serotype distribution come from pediatric invasive pneumococcal disease (IPD, defined as infection of a normally sterile site); much less information on global or regional serotype distributions is available for disease in adults. In the era before PCV use, five to seven serotypes caused >60% of IPD cases among children <5 years of age in most parts of the world; seven serotypes (1, 5, 6A, 6B, 14, 19F, and 23F) accounted for ~60% of such cases in all areas of the world, but in any given region these seven serotypes may not all rank as the most common disease strains. Some serotypes (e.g., types 1 and 5) not only tend to cause disease in areas with a high disease burden but also cause waves of disease in lower-burden areas (e.g., Europe) or outbreaks (e.g., in military barracks; meningitis in sub-Saharan Africa). The widespread use of pneumococcal conjugate vaccines has significantly altered serotype-specific epidemiology, with some of the serotypes identified above now causing little invasive disease in countries with mature vaccine programs and emerging serotypes, not prominent in the pre-conjugate vaccine era, appearing as important causes of invasive disease. These include serotypes such as 15BC, 22F, 10A, 23B, 12F, 33F, 15A, 8, and 24F, while some serotypes included in PCVs such as 3 and 19A continue to cause IPD.

Nasopharyngeal Carriage Pneumococci are intermittent inhabitants of the healthy human nasopharynx and are transmitted by respiratory droplets. In children, pneumococcal nasopharyngeal ecology varies by geographic region, socioeconomic status, climate, degree of crowding, and particularly intensity of exposure to other children, with children in day-care settings having higher rates of colonization. In developed-world settings, children serve as the major vectors of pneumococcal transmission. By 1 year of age, ~50% of children have had at least one episode of pneumococcal colonization. Cross-sectional prevalence data show rates of pneumococcal carriage ranging from 20% to 50% among children <5 years of age and from 5% to 15% among young and middle-aged adults; **Fig. 146-3** shows relevant data from the United Kingdom. Data on colonization rates among healthy elderly individuals are limited. In LMICs, pneumococcal acquisition occurs much earlier, sometimes within the first few days after birth, and nearly all infants have had at least one episode of colonization by 2 months of age. Cross-sectional studies show that up to the age of 5 years, 70–90% of children carry *S. pneumoniae* in the nasopharynx, and a significant proportion of adults (sometimes >40%) also are colonized. Their high rates of colonization make adults an important source of transmission and may affect community transmission dynamics.

Invasive Disease and Pneumonia IPD develops when *S. pneumoniae* invades the bloodstream and seeds other organs or directly reaches the cerebrospinal fluid (CSF) by local extension. Pneumonia may follow aspiration of pneumococci, although only 10–30% of pneumococcal pneumonia cases are associated with a positive blood culture (and thus contribute to the measured burden of IPD). The substantial variation of IPD rates with age is illustrated by data from the United States for 1998–1999, a period prior to PCV introduction. Rates of IPD were highest among children <2 years of age and among adults ≥65 years of age (188 and 60 cases/100,000, respectively; **Fig. 146-4**). Since the introduction of PCV, IPD rates among infants and children in the United States have fallen by >75%, a decrease driven by the near elimination of vaccine-serotype IPD. A similar impact of PCV on vaccine-serotype IPD rates has been consistently observed in countries where PCV has been introduced into the routine pediatric vaccination schedule. However, the magnitudes of change in the non-vaccine-serotype IPD rate in various countries have been heterogeneous; the interpretation of this heterogeneity is a complex issue. In the United States, Canada, and Australia, rates of non-vaccine-serotype IPD have increased but the magnitude of the increase is

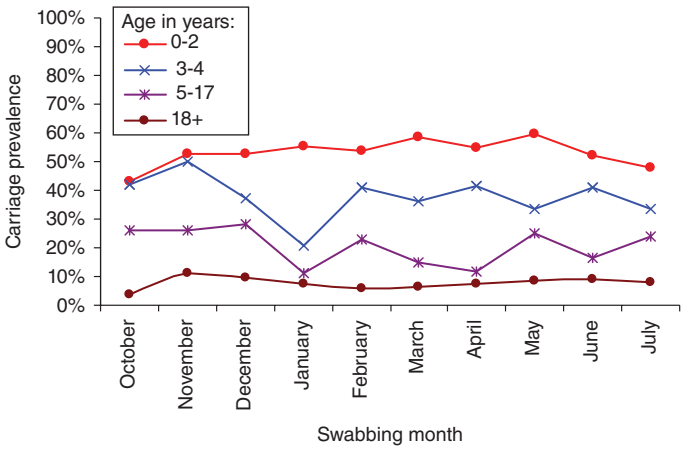

FIGURE 146-3 Prevalence of pneumococcal carriage in adults and children resident in the United Kingdom who had nasopharyngeal swabs collected monthly for 10 months (no seasonal trend; *t* test trend, >.05). *(Data adapted from D Goldblatt et al: J Infect Dis 192:387, 2005.)*

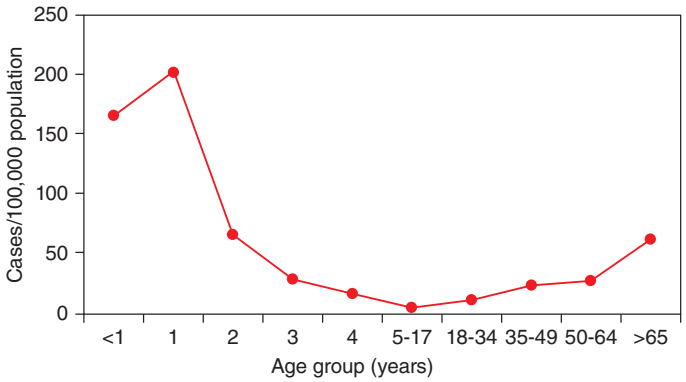

FIGURE 146-4 Rates of invasive pneumococcal disease before the introduction of pneumococcal conjugate vaccine, by age group: United States, 1998. *(Source: CDC, Active Bacterial Core Surveillance/Emerging Infectious Program Network, 2000. Data adapted from MMWR 49[RR-9], 2000.)*

generally small relative to the substantial reductions in vaccine-serotype IPD. In contrast, in other settings (e.g., Alaska Native communities and adults in the United Kingdom), the reduction in vaccine-serotype IPD has been offset by notable increases in rates of disease caused by non-vaccine serotypes. Explanations for the heterogeneity of findings include replacement disease resulting from vaccine pressure, changes in clinical case investigation, secular trends unrelated to PCV use, antibiotic pressure selecting for resistant organisms, changes in surveillance or reporting systems, rapidity of PCV introduction, and inclusion of a catch-up campaign. Serotype replacement in IPD follows the use of PCV7, PCV10, and PCV13, but the magnitude of this phenomenon is small relative to the reduction in disease from vaccine serotypes in vaccinated populations. In adults in the UK, however, where rates of IPD due to vaccine serotypes fell following PCV introduction, the increase in IPD secondary to non-vaccine serotypes is eroding the original impact of PCV. Furthermore, not all vaccine serotypes have declined and persistent disease due to serotypes 3 and 19A bas been noted in many settings.

Pneumonia is the most common of the serious pneumococcal disease syndromes and poses special challenges from a clinical and public health perspective. Most cases of pneumococcal pneumonia are not associated with bacteremia, and in these cases a definitive etiologic diagnosis is difficult or impossible. As a result, estimates of disease burden focus primarily on IPD rates and fail to include the major portion of the burden of serious pneumococcal disease. Among children, PCV trials designed to collect efficacy data on syndrome-based outcomes (e.g., radiographically confirmed pneumonia, clinically diagnosed pneumonia) have revealed the burden of culture-negative pneumococcal pneumonia. These trials have provided the means to infer that only ~5–20% of pneumococcal pneumonia cases result in bacteremia. An important randomized controlled trial of PCV among the elderly in the Netherlands (the CAPiTA trial) has revealed the small fraction of adult pneumococcal pneumonia patients who also have bacteremia. Use of high-quality sputum specimens and, in the case of adults with a low likelihood of colonization absent disease, urine antigen detection both contribute to the diagnosis of nonbacteremic pneumococcal pneumonia. Furthermore, accruing evidence continues to indicate that pneumococcal pneumonia events are often the result of co-infection with viral or other bacterial pathogens. Thus a pneumonia case resulting from a pulmonary infection with a single pathogen is probably an uncommon event; rather, most cases of pneumonia likely result from the sequential or contemporaneous co-infection of a host with multiple pathogens, often both viruses and bacteria.

The case–fatality ratios (CFRs) for pneumococcal pneumonia and IPD vary by age, underlying medical condition, and access to care. In addition, the CFR for pneumococcal pneumonia varies with the severity of disease at presentation (rather than according to whether the pneumonia episode is associated with bacteremia) and with the patient's age (from <5% among hospitalized patients 18–44 years old to >12% among those >65 years old, even when appropriate and timely management is available). Notably, the likelihood of death in the first 24 h of hospitalization did not change substantially with the introduction of antibiotics; this surprising observation highlights the fact that the pathophysiology of severe pneumococcal pneumonia among adults reflects a rapidly progressive cascade of events that often unfolds irrespective of antibiotic administration. Management in an intensive care unit can provide critical support for the patient through the acute period, with lower CFRs, while antibiotics address the underlying infection.

Rates of pneumococcal disease vary by season, with higher rates in colder than in warmer months in temperate climates; by sex, with males more often affected than females; and by risk group, with risk factors including underlying medical conditions, behavioral issues (e.g., smoking), and ethnic group. In the United States, some Native American populations (including Alaska Natives) and African Americans have higher rates of disease than the general population; the increased risk is probably attributable to socioeconomic conditions and the prevalence of underlying risk factors for pneumococcal disease. Medical conditions that increase the risk of pneumococcal infection are listed in Table 146-1. Outbreaks of disease are well recognized in crowded settings with susceptible individuals, such as infant day-care facilities, military barracks, and nursing homes. Furthermore, there is a clear association between preceding viral respiratory disease (especially but not exclusively influenza) and risk of secondary pneumococcal infections. The significant role of pneumococcal pneumonia in the morbidity and mortality associated with seasonal and pandemic influenza is increasingly well recognized.

Antibiotic Resistance Reduced pneumococcal susceptibility to penicillin was first noted in 1967, but not until the 1990s did reduced antibiotic susceptibility emerge as a significant clinical and public health issue, with an increasing prevalence of pneumococcal isolates resistant to single or multiple classes of antibiotics and a rising absolute

TABLE 146-1 Clinical Risk Groups for Pneumococcal Infection

CLINICAL RISK GROUP	EXAMPLES
Asplenia or splenic dysfunction	Sickle cell disease and other hemoglobinopathies, celiac disease
Chronic respiratory disease	Chronic obstructive pulmonary disease, bronchiectasis, cystic fibrosis, interstitial lung fibrosis, pneumoconiosis, bronchopulmonary dysplasia, aspiration risk, neuromuscular disease (e.g., cerebral palsy), severe asthma
Chronic heart disease	Ischemic heart disease, congenital heart disease, hypertension with cardiac complications, chronic heart failure
Chronic kidney disease	Nephrotic syndrome, chronic renal failure, renal transplantation
Chronic liver disease	Cirrhosis, biliary atresia, chronic hepatitis
Diabetes mellitus	Diabetes mellitus requiring insulin or oral hypoglycemic drugs
Immunocompromise/ immunosuppression	HIV infection, primary immunodeficiency including B-cell, T-cell, complement and some phagocytic disorders, leukemia, lymphoma, Hodgkin's disease, multiple myeloma, generalized malignancy, chemotherapy, organ or bone marrow transplantation, systemic glucocorticoid treatment for >1 month at a dose equivalent to ≥20 mg/d (children, ≥1 mg/kg per day)
Cochlear implants	…
Cerebrospinal fluid leaks	…
Miscellaneous	Infancy and old age; prior hospitalization; alcoholism; malnutrition; cigarette smoking; day-care center attendance; residence in military training camps, prisons, homeless shelters

Note: Groups for whom pneumococcal vaccines are recommended by the Advisory Committee on Immunization Practices can be found at *www.cdc.gov/vaccines/schedules/*.

magnitude of minimal inhibitory concentrations (MICs). Strains with reduced susceptibility to penicillin G, cefotaxime, ceftriaxone, macrolides, and other antibiotics are now found worldwide and account for a significant proportion of disease-causing strains in many locations, especially among children. Vancomycin resistance has not yet been observed in clinical pneumococcal strains. Lack of antimicrobial susceptibility is clearly related to a subset of serotypes, many of which disproportionately cause disease among children. Resistance phenotypes are based on a diverse array of mutational events and inter- and intraspecies gene-transfer phenomena carried out by several types of mobile genetic elements, with consequent dissemination of successful resistant clones. The vicious cycle of antibiotic exposure, selection of resistant organisms in the nasopharynx, and transmission of these organisms within the community, leading to difficult-to-treat infections and increased antibiotic exposure, has been interrupted to some extent by the introduction and routine use of PCV. The clinical implications of pneumococcal antimicrobial nonsusceptibility are addressed in "Treatment," below.

PATHOGENESIS

Pneumococci colonize the human nasopharynx from an early age; colonization acquisition events are generally described as asymptomatic, but evidence exists to associate acquisition with mild respiratory symptoms, especially in the very young. Bacteria survive in the nasopharynx protected by a variety of factors, including their bacterial capsule and the formation of a biofilm. From the nasopharynx, the bacteria spread either via the bloodstream to distant sites (e.g., brain, joint, bones, peritoneal cavity) or locally to mucosal surfaces where they can cause otitis media or pneumonia. Direct spread from the nasopharynx to the central nervous system (CNS) can occur in rare cases of skull-base fracture, although most cases of pneumococcal meningitis are secondary to hematogenous spread. The pneumococcus is not a static bacterium; rather, it modifies its expression of capsule in adaptation to the external environment. In the nasopharynx, the pneumococcus downregulates capsular expression, averting protective immunologic mechanisms that recognize capsule; rough colonies are the phenotype on culture. Upon invasion by traversal of the epithelium, the pneumococcus upregulates its capsular expression, transforming its appearance on culture to smooth colonies—a change illustrating the dynamic nature of the organism in response to the local environment. Pneumococci can cause disease in almost any organ or part of the body; however, otitis media, pneumonia, bacteremia, and meningitis are most common. Colonization is a relatively frequent event, yet disease is rare. In the nasopharynx, pneumococci survive in mucus secreted by epithelial cells and in a biofilm they create, where they can avoid local immune factors such as leukocytes and complement. The mucus itself is a component of local defense mechanisms, and the flow of mucus (driven in part by cilia in what is known as the *mucociliary escalator*) effects mechanical clearance of pneumococci. While many colonization episodes are of short duration, longitudinal studies in adults and children have revealed persistent colonization with a specific serotype over many months. Colonization eventually results in the development of capsule- and protein-specific serum IgG antibodies, which are thought to play a role in mediating clearance of bacteria from the nasopharynx. IgG antibodies to surface-exposed cell-wall or secreted proteins also appear in the circulation in an age-dependent fashion or after colonization; these antibodies are likely to have a disease-modifying and/or protective role. Recent acquisition of a new colonizing serotype is more likely to be associated with subsequent invasion, presumably as a result of the absence of type-specific immunity. Intercurrent viral infections make the host more susceptible to pneumococcal colonization, and pneumococcal disease in a colonized individual often follows perturbation of the nasopharyngeal mucosa by such infections. Local cytokine production after a viral infection is thought to upregulate adhesion factors in the respiratory epithelium, allowing pneumococci to adhere via a variety of surface adhesin molecules, including PsaA, PspA, CbpA, PspC, Hyl, pneumolysin, and the neuraminidases (Fig. 146-2). Adhesion coupled with inflammation induced by pneumococcal factors such as peptidoglycans and teichoic acids results in invasion. It is the inflammation induced by various bacterium-derived factors that is responsible for the pathology associated with pneumococcal infection. Pneumococcal cell wall–derived teichoic acids and peptidoglycans induce a variety of cytokines, including the proinflammatory cytokines interleukin (IL) 1, IL-6, and tumor necrosis factor, and activate complement via the alternative pathway. Polymorphonuclear leukocytes are thus attracted, and an intense inflammatory response is initiated. Pneumolysin also is important in local pathology, inducing proinflammatory cytokine production by local monocytes.

The pneumococcal capsule, consisting of polysaccharides with antiphagocytic properties (i.e., the capacity to resist complement deposition in the absence of type-specific antibody), plays an important role in pathogenesis. While most capsular types can cause human disease, certain capsular types are more commonly isolated from sites of infection. The reason for the dominance of some serotypes over others in IPD is unclear.

HOST DEFENSE MECHANISMS

Innate Immunity As described above, intact respiratory epithelium and a host of nonspecific or innate immune factors (e.g., mucus, splenic function, complement, neutrophils, and macrophages) constitute the first line of defense against pneumococci. Physical factors such as the cough reflex and the mucociliary escalator are important in clearing bacteria from the lungs. Immunologic factors are critical as well: C-reactive protein (CRP) binds phosphorylcholine in the pneumococcal cell wall, inducing complement activation and leading to bacterial clearance; Toll-like receptor 2 (TLR2) recognizes pneumococcal-derived lipoproteins. In animal models, the absence of host TLR2 leads to more severe infection and impaired clearance of nasopharyngeal colonization. TLR4 appears to be necessary for the proinflammatory effect of pneumolysin on macrophages. The importance of TLR recognition is underlined by descriptions of an inherited deficiency of human IL-1 receptor–associated kinase 4 (IRAK-4) that manifests as an unusual susceptibility to infection with bacteria, including *S. pneumoniae*. IRAK-4 is essential for the normal functioning of several TLRs. Other factors that interfere with these nonspecific mechanisms (e.g., viral infections, cystic fibrosis, bronchiectasis, complement deficiency, chronic obstructive pulmonary disease) all predispose to the development of pneumococcal pneumonia. Patients who lack a spleen or have abnormal splenic function (e.g., persons with sickle cell disease) are at high risk of developing overwhelming pneumococcal disease.

Acquired Immunity Acquired immunity induced following colonization or through exposure to cross-reactive antigens rests largely on the development of serum IgG antibody specific for the pneumococcal capsular polysaccharide. Nearly all polysaccharides are T-cell–independent antigens; B cells can make antibodies to such antigens without T cell help. However, in children <1–2 years old, such B-cell responses are poorly developed. This delayed ontogeny of capsule-specific IgG in young children is associated with susceptibility to pneumococcal infection (Fig. 146-5). The extremely high risk of pneumococcal infection in the absence of serum immunoglobulin (i.e., in conditions such as agammaglobulinemia) highlights the important role of capsular antibody in protection against disease. Each serotype's capsule is chemically distinct, even though for some serotypes the chemical distinction from another type may be a minor one; thus immunity tends to be serotype specific, although some cross-immunity exists. For example, conjugate vaccine–induced antibodies to serotype 6B prevent infection due to serotype 6A. However, cross-protection against serotypes within serogroups is not universal; for instance, antibodies to serotype 19F induced by some vaccines do not appear to confer protection against disease caused by serotype 19A. Antibodies to surface-exposed or secreted pneumococcal proteins (such as pneumolysin, PsaA, and PspA) also appear in the circulation with increasing age of the host and are likely to contribute to protection. Data from murine models suggest that CD4+ T cells may play a role in preventing pneumococcal colonization and disease, and experimental data derived from humans suggest that IL-17-secreting CD4+ T cells may be relevant.

APPROACH TO THE PATIENT

Pneumococcal Infections

There is no pathognomonic presentation of pneumococcal disease; patients may present with one or more clinical syndromes (e.g., pneumonia, meningitis, sepsis). *S. pneumoniae* can infect nearly any body tissue, manifesting as disease ranging in severity from mild and self-limited to life-threatening. The differential diagnosis of common clinical syndromes such as pneumonia, otitis media, fever of unknown origin, and meningitis should always include pneumococcal infection. A microbiologically confirmed diagnosis is made in only a minority of pneumococcal cases since, in most circumstances (and especially in pneumonia and otitis media), fluid from the site of infection is not available for etiologic determination, and infection of body fluids distant from the site of infection (e.g., blood in the case of pneumonia) occurs in only a minority of true pneumococcal cases. Empirical therapy that includes appropriate treatment for *S. pneumoniae* is often indicated.

Algorithms for assessment and management of ill children (Integrated Management of Childhood Illness; IMCI) have been developed for use in the developing world or in other settings where evaluation by a trained physician may not be feasible. No such algorithms for the management of adults with suspected disease exist. Children who present with signs associated with increased risk of serious disease, such as an inability to drink, convulsions, lethargy, and severe malnutrition, are categorized as having very severe disease without further evaluation by the community health care worker; are given antibiotics; and are immediately referred to a hospital for diagnosis and management. Children who present with cough and tachypnea (the latter defined according to specific age strata) are further stratified into severity categories based on the presence or absence of lower chest wall indrawing and are managed accordingly either with antibiotics alone or with antibiotics and referral to a hospital facility. Children with cough but no tachypnea are categorized as having a nonpneumonia respiratory illness.

CLINICAL MANIFESTATIONS

The clinical manifestations of pneumococcal disease depend on the site of infection and the duration of illness. Clinical syndromes are classified as noninvasive (e.g., otitis media) or invasive (e.g., bacteremic pneumonia, meningitis) according to whether a normally sterile site is infected. The pathogenesis of noninvasive illness involves contiguous spread from the nasopharynx or skin; invasive disease involves infection of a normally sterile body fluid or follows bacteremia. Regardless of the mechanism, all pneumococcal infections result from nasopharyngeal acquisition of the organism.

Pneumonia Pneumonia is the most common serious pneumococcal syndrome and is considered invasive when associated with a positive blood culture. Whether to categorize nonbacteremic pneumococcal pneumonia as invasive or noninvasive remains debatable.

Pneumococcal pneumonia can present as a mild community-acquired infection at one extreme and as a life-threatening disease requiring intubation and intensive support at the other.

PRESENTING MANIFESTATIONS The presentation of pneumococcal pneumonia does not reliably distinguish it from pneumonia of other etiologies. In a subset of cases, pneumococcal pneumonia is recognized at the outset as associated with a viral upper respiratory infection and is characterized by the abrupt onset of cough and dyspnea accompanied by fever, shaking chills, and myalgias. The cough evolves from nonpurulent to productive of sputum that is purulent and sometimes tinged with blood. Patients may describe stabbing pleuritic chest pain and significant dyspnea indicating involvement of the parietal pleura. Among the elderly, the presenting clinical symptoms may be less specific, with confusion or malaise but without fever or cough. In such cases, a high index of suspicion is required because failure to treat pneumococcal pneumonia promptly in an elderly patient is likely to result in rapid evolution of the infection, with increased severity, morbidity, and risk of death.

FINDINGS ON PHYSICAL EXAMINATION The clinical signs associated with pneumococcal pneumonia among adults include tachypnea (defined as >20 breaths/min) and tachycardia, hypotension in severe cases, and fever in most cases (although not in all elderly patients). Respiratory signs are varied, including dullness to percussion in areas of the chest with significant consolidation, crackles on auscultation, reduced expansion of the chest in some cases as a result of splinting to reduce pain, bronchial breathing in a minority of cases, pleural rub in occasional cases, and cyanosis in cases with significant hypoxemia. Among infants with severe pneumonia, chest wall indrawing and nasal flaring are common. Nonrespiratory findings can include upper abdominal pain if the diaphragmatic pleura is involved as well as mental status changes, particularly confusion in elderly patients.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of pneumococcal pneumonia includes cardiac conditions such as myocardial infarction and heart failure with atypical pulmonary edema; pulmonary conditions such as atelectasis; and pneumonia caused by viral pathogens, mycoplasmas, *Haemophilus influenzae*, *Klebsiella pneumoniae*, *Staphylococcus aureus*, *Legionella*, or (in HIV-infected and otherwise immunocompromised hosts) *Pneumocystis jirovecii*. In cases with abdominal symptoms, the differential diagnosis includes cholecystitis, appendicitis, perforated peptic ulcer disease, and subphrenic abscesses. The challenge in cases with abdominal symptoms is to remember to include pneumococcal pneumonia—a nonabdominal process—in the differential diagnosis.

DIAGNOSIS Some authorities advocate treating uncomplicated, nonsevere, community-acquired pneumonia without determining the microbiologic etiology, given that this information is unlikely to alter clinical management. However, efforts to identify the cause of pneumonia are important when the disease is more severe and when the diagnosis of pneumonia is not clearly established. The gold standard for etiologic diagnosis of pneumococcal pneumonia is pathologic examination of lung tissue. In lieu of that procedure, evidence of an infiltrate on chest radiography warrants a diagnosis of pneumonia. However, cases of pneumonia without radiographic evidence do occur. An infiltrate can be absent either early in the course of the illness or with dehydration; upon rehydration, an infiltrate usually appears. The radiographic appearance of pneumococcal pneumonia is varied; it classically consists of lobar or segmental consolidation **(Fig. 146-5)** but in some cases is patchy. More than one lobe is involved in ~30% of cases. Consolidation may be associated with a small pleural effusion or empyema in complicated cases. In children, "round pneumonia," a distinctly spherical consolidation on chest radiography, is associated with a pneumococcal etiology. Round pneumonia is uncommon in adults. *S. pneumoniae* is not the only cause of such lesions; other causes, especially cancer, should be considered.

Blood drawn from patients with suspected pneumococcal pneumonia can be used for supportive or definitive diagnostic tests. Blood cultures are positive for pneumococci in a minority (<30%) of cases of pneumococcal pneumonia, as evidenced especially by vaccine clinical trials, which provide an independent method to reveal the contribution of the pneumococcus to pneumonia cases. Nonspecific findings include an elevated polymorphonuclear leukocyte count (>15,000/μL in most cases and upward of 40,000/μL in some), leukopenia in <10% of cases (a poor prognostic sign associated with a fatal outcome), and elevated values in liver function tests (e.g., both conjugated and unconjugated hyperbilirubinemia). Anemia, low serum albumin levels, hyponatremia, and elevated serum creatinine levels are all found in ~20–30% of patients.

Urinary pneumococcal antigen assays, based on identifying a ubiquitous common cell wall polysaccharide, have facilitated etiologic diagnosis, but the application of the results is confounded by the fact that nasopharyngeal colonization with the pneumococcus, in the absence of disease, also results in a positive test. In adults, therefore, a positive pneumococcal urinary antigen test has a predictive value for etiologic attribution of pneumonia because the prevalence of pneumococcal nasopharyngeal colonization is relatively low. In communities, particularly those in low-income countries, where colonization rates

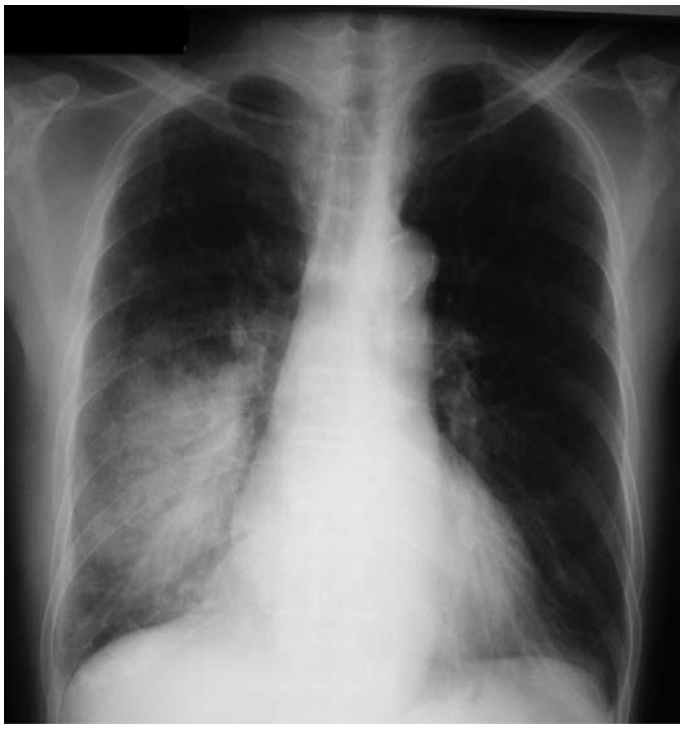

FIGURE 146-5 Chest radiograph depicting classic lobar pneumococcal pneumonia in the right lower lobe of an elderly patient's lung.

among adults are high, urine antigen assays may be less useful. The same issue holds for children, in whom a positive urinary antigen test is usually uninformative for etiologic attribution of their pneumonia illness because colonization rates are generally high. A recent advance is the development of quantitative serotype-specific urinary antigen detection assays; their application for adults and children holds promise, especially in detecting serotypes that are rarely identified in asymptomatic carriage (e.g., serotype 1), even among children.

Most cases of pneumococcal pneumonia in adults are diagnosed by Gram's staining and culture of sputum. The utility of a sputum specimen is directly related to its quality and the patient's antibiotic treatment status.

COMPLICATIONS Empyema is the most common focal complication of pneumococcal pneumonia, occurring in <5% of cases. When fluid in the pleural space is accompanied by fever and leukocytosis (even low-grade) after 4–5 days of appropriate antibiotic treatment for pneumococcal pneumonia, empyema should be considered. Parapneumonic effusions are more common than empyema, representing a self-limited inflammatory response to pneumonia. Pleural fluid with frank pus, bacteria (detected by microscopic examination), or a pH of ≤7.1 indicates empyema and demands aggressive and complete drainage, usually through chest tube insertion.

Meningitis Pneumococcal meningitis usually presents as a pyogenic condition that is clinically indistinguishable from meningitis of other bacterial etiologies. Meningitis can be the primary presenting pneumococcal syndrome or a complication of other conditions such as skull fracture, otitis media, bacteremia, or mastoiditis. Now that *H. influenzae* type b vaccine is routinely used in children, *S. pneumoniae* and *Neisseria meningitidis* are the most common bacterial causes of meningitis in both adults and children. Pyogenic meningitis, including that due to *S. pneumoniae*, is associated clinically with findings that include severe, generalized, gradual-onset headache, fever, and nausea as well as specific CNS manifestations such as stiff neck, photophobia, seizures, and confusion. Clinical signs include a toxic appearance, altered consciousness, bradycardia, and hypertension indicative of increased intracranial pressure. A small proportion of adult patients have Kernig's or Brudzinski's sign or cranial nerve palsies (particularly of the third and sixth cranial nerves).

A definitive diagnosis of pneumococcal meningitis rests on the examination of CSF for (1) evidence of turbidity (visual inspection); (2) elevated protein level, elevated white blood cell count, and reduced glucose concentration (quantitative measurement); and (3) specific identification of the etiologic agent (culture, Gram's staining, antigen testing, or polymerase chain reaction [PCR]). A blood culture positive for *S. pneumoniae* in conjunction with clinical manifestations of meningitis also is considered confirmatory. As discussed in "Pneumonia," above, detection of pneumococcal antigen in urine is considered highly specific among adults because of the low prevalence of nasopharyngeal colonization in this age group.

The mortality rate for pneumococcal meningitis is ~20%. In addition, up to 50% of survivors experience acute or chronic complications, including deafness, hydrocephalus, and mental retardation in children and diffuse brain swelling, subarachnoid bleeding, hydrocephalus, cerebrovascular complications, and hearing loss in adults.

Other Invasive Syndromes *S. pneumoniae* can cause other invasive syndromes involving virtually any body site. These syndromes include primary bacteremia without other sites of infection (bacteremia without a source; occult bacteremia), osteomyelitis, septic arthritis, endocarditis, pericarditis, and peritonitis. The essential diagnostic approach is collection of fluid from the site of infection by sterile technique and examination by Gram's staining, culture, and—when relevant—capsular antigen assay or PCR. Hemolytic-uremic syndrome can complicate invasive pneumococcal disease.

Noninvasive Syndromes The major noninvasive syndromes caused by *S. pneumoniae* are sinusitis, bacterial bronchitis, and otitis media; the latter is the most common pneumococcal syndrome and most often affects young children. The manifestations of otitis media include the acute onset of severe pain, fever, deafness, and tinnitus, most frequently in the setting of a recent upper respiratory tract infection. Clinical signs include a red, swollen, often bulging tympanic membrane with reduced movement on insufflation or tympanography. Redness of the tympanic membrane is not sufficient for the diagnosis of otitis media.

Pneumococcal sinusitis is also a complication of upper respiratory tract infections and presents with facial pain, congestion, fever, and—in many cases—persistent nighttime cough. A definitive diagnosis is made by aspiration and culture of sinus material; however, presumptive treatment is most commonly initiated after application of a strict set of clinical diagnostic criteria. Pneumococcal bronchitis is usually seen in the context of pre-existing lung conditions such as bronchiectasis or chronic obstructive pulmonary disease (COPD) and may be caused by non-typeable strains.

TREATMENT

Pneumococcal Infections

Historically, the activity of penicillin against pneumococci made parenteral penicillin G the drug of choice for disease caused by susceptible organisms, including community-acquired pneumonia. Today, parenteral β-lactam drugs such as ampicillin, cefotaxime, ceftriaxone, and cefuroxime are often used as first-line agents for community-acquired infections. Macrolides and cephalosporins are alternatives for penicillin-allergic patients. While agents such as clindamycin, tetracycline, and trimethoprim-sulfamethoxazole exhibit some activity against pneumococci, resistance to these agents is frequently encountered in different parts of the world.

Penicillin-resistant pneumococci were first described in the mid-1960s, at which point tetracycline- and macrolide-resistant strains had already been reported. Multidrug-resistant strains were first described in the 1970s, but it was during the 1990s that pneumococcal drug resistance reached pandemic proportions. The use of antibiotics selects for resistant pneumococci, and strains resistant to β-lactam agents and to multiple drugs are now found all over the world. The emergence of high rates of macrolide and

fluoroquinolone resistance also has been described. Drug-resistant pneumococci are considered a serious threat by the Centers for Disease Control and Prevention.

The molecular basis of penicillin resistance in *S. pneumoniae* is the alteration of penicillin-binding protein (PBP) genes by transformation and horizontal transfer of DNA from related streptococcal species. Such alteration of PBPs results in lower affinity for penicillins. Depending on the specific PBP(s) and the number of PBPs altered, the level of resistance ranges from intermediate to high. For many years, penicillin susceptibility breakpoints have been defined by MICs as follows: susceptible, ≤0.06 μg/mL and resistant, ≥2.0 μg/mL. However, in vitro results often were not predictive of the response of a patient to treatment for pneumococcal diseases other than meningitis. Revised recommendations have been based on the penicillin G breakpoints established in 2008 by the Clinical and Laboratory Standards Institute. For IV treatment of meningitis with at least 24 million units per day in 8 divided doses, the susceptibility breakpoint remains ≤0.06 μg/mL, and MICs of ≥0.12 μg/mL indicate resistance. For IV treatment of nonmeningeal infections with 12 million units per day in 6 divided doses, the breakpoints are ≤2 μg/mL for susceptible organisms and ≥8 μg/mL for resistant organisms; a dosage of 18–24 million units per day is recommended for strains with MICs in the intermediate category.

Although guidelines for antibiotic therapy should be driven in part by local patterns of resistance, guidelines from national organizations in many countries (e.g., the Infectious Diseases Society of America/American Thoracic Society, the British Thoracic Society, the European Respiratory Society) lay out evidence-based approaches. The following guidelines for the treatment of individual sepsis syndromes are based on those advocated by the American Academy of Pediatrics and published in the 2018 *Red Book*.

MENINGITIS LIKELY OR PROVEN TO BE DUE TO *S. PNEUMONIAE*

In areas of the world with an increased prevalence of resistant pneumococci, first-line therapy for persons ≥1 month of age is a combination of vancomycin (adults, 30–60 mg/kg per day; infants and children, 60 mg/kg per day) and cefotaxime (adults, 8–12 g/d in 4–6 divided doses; children, 225–300 mg/kg per day in 1 dose or 2 divided doses) or ceftriaxone (adults, 4 g/d in 1 dose or 2 divided doses; children, 100 mg/kg per day in 1 dose or 2 divided doses). In low-prevalence areas and where the patient has not recently traveled, vancomycin is not included in first-line therapy. If children are hypersensitive to β-lactam agents (penicillins and cephalosporins), rifampin (adults, 600 mg/d; children, 20 mg/d in 1 dose or 2 divided doses) can be substituted for cefotaxime or ceftriaxone and added as a second agent. A repeat lumbar puncture should be considered after 48 h if the organism is not susceptible to penicillin and information on cephalosporin sensitivity is not yet available, if the patient's clinical condition does not improve or deteriorates, or if dexamethasone has been administered interfering with the ability to interpret clinical responses in the deteriorating patient. When antibiotic sensitivity data become available, treatment should be modified accordingly. If the isolate is sensitive to penicillin, vancomycin can be discontinued and penicillin can replace the cephalosporin, or cefotaxime or ceftriaxone can be continued alone. If the isolate displays any resistance to penicillin but is susceptible to the cephalosporins, vancomycin can be discontinued and cefotaxime or ceftriaxone continued. If the isolate exhibits any resistance to penicillin and is not susceptible to cefotaxime and ceftriaxone, vancomycin and high-dose cefotaxime or ceftriaxone can be continued and rifampin may be added. Data support the use of corticosteroids in high-income countries but do not appear to have a beneficial effect in low-income countries. This discrepancy in the efficacy of corticosteroids may be related to differences in availability of appropriate and timely medical care. Glucocorticoids significantly reduce rates of mortality, severe hearing loss, and neurologic sequelae in adults and should be administered to those with community-acquired bacterial meningitis. If dexamethasone is given to either adults or children, it should be administered before or in conjunction with the first antibiotic dose.

SEPSIS (EXCLUDING MENINGITIS)

In previously well children with noncritical illness, therapy with a recommended antibiotic should be instigated at the usually recommended dosages: ampicillin 200 mg/kg/day (doses 6h apart), cefotaxime, 75–225 mg/kg/day (doses 8 h apart), ceftriaxone, 50–75 mg/kg/day (doses 12–24 h apart) or penicillin G, 250,000–400,000 units/kg per day (in divided doses 4–6 h apart). For critically ill children, including those who have myocarditis or multilobular pneumonia with hypoxia or hypotension, vancomycin may be added if the isolate may possibly be resistant to β-lactam drugs, with its use reviewed once susceptibility data become available. If the organism is resistant to β-lactam agents, therapy should be modified on the basis of clinical response and susceptibility to other antibiotics. Clindamycin or vancomycin can be used as a first-line agent for children with severe β-lactam hypersensitivity, but vancomycin should not be continued if the organism is shown to be sensitive to other non-β-lactam antibiotics.

For outpatient management, oral amoxicillin (45–90 mg/kg/day, doses 8 h apart) provides effective treatment for virtually all cases of pneumococcal pneumonia. Cephalosporins, which are far more expensive, offer no advantages over amoxicillin. Levofloxacin (500–750 mg/d as a single dose) and moxifloxacin (400 mg/d as a single dose) also are highly likely to be effective in the United States except in patients who come from closed populations where these drugs are used widely or who have themselves been treated recently with a quinolone. Clindamycin (600–1200 mg/d every 6 h) is effective in 90% of cases and azithromycin (500 mg on day 1 followed by 250–500 mg/d) or clarithromycin (500–750 mg/d as a single dose) in 80% of cases. Treatment failure resulting in bacteremic disease due to macrolide-resistant isolates has been amply documented in patients given azithromycin empirically. As noted above, rates of resistance to all these antibiotics are relatively low in some countries and much higher in others; high-dose amoxicillin remains the best option worldwide.

The optimal duration of treatment for pneumococcal pneumonia is uncertain, but its continuation for at least 5 days once the patient becomes afebrile appears to be a prudent approach—although in adults, 5 days in total will usually suffice. Cases with a second focus of infection (e.g., empyema or septic arthritis) require longer therapy.

ACUTE OTITIS MEDIA

Amoxicillin (80–90 mg/kg per day) is recommended for infants <6 months of age and those 6–23 months of age with bilateral disease. Observation and symptom-based treatment without antibiotics are advocated for nonsevere illness and an uncertain diagnosis in children 6 months to 2 years of age and nonsevere illness (even if the diagnosis seems certain) in children >2 years of age. Although the optimal duration of therapy has not been conclusively established, a 10-day course is recommended for younger children and for children with severe disease at any age. For children >6 years old who have mild or moderate disease, a course of 5–7 days is considered adequate. Patients whose illness fails to respond should be reassessed at 48–72 h. If acute otitis media is confirmed and antibiotic treatment has not been started, administration of amoxicillin should be commenced. If antibiotic therapy fails, a change is indicated. Failure to respond to second-line antibiotics (such as high-dose amoxicillin-clavulanate) as well indicates that myringotomy or tympanocentesis may need to be undertaken in order to obtain samples for culture.

The above recommendations can also be followed for the treatment of sinusitis. Detailed information on the further management of these conditions in children has been published by the American Academy of Pediatrics, the American Academy of Family Physicians, the Pediatric Infectious Diseases Society, and the Infectious Diseases Society of America.

PREVENTION

Measures to prevent pneumococcal disease include vaccination against *S. pneumoniae* and influenza viruses, reduction of comorbidities that increase the risk of pneumococcal disease, and prevention of antibiotic overuse, which fuels pneumococcal resistance.

Capsular Polysaccharide Vaccines The 23-valent pneumococcal polysaccharide vaccine (PPSV23), containing 25 μg of each capsular polysaccharide, has been licensed for use since 1983. Recommendations for its use vary by country. The U.S. Advisory Committee on Immunization Practices (ACIP) recommends PPSV23 for all persons ≥65 years of age and for those 2–64 years of age who have underlying medical conditions that put them at increased risk for pneumococcal disease or, if infected, disease of increased severity (Table 146-1; see also *www.cdc.gov/vaccines/schedules*). The committee updated their recommendations to include the combined use of pneumococcal conjugate vaccine followed by PPSV23 in at-risk individuals (see "Polysaccharide–Protein Conjugate Vaccines," below). Revaccination 5 years after the first dose is recommended for persons >2 years of age who have underlying medical conditions but not routinely for those whose only indication is an age of ≥65 years. PPSV23 does not induce an anamnestic response, and antibody concentrations wane over time; thus revaccination is particularly important for individuals with conditions resulting in loss of antibody. Concerns about repeated revaccination have focused on safety (i.e., local reactions) and the induction of immune hyporesponsiveness. Neither the clinical relevance nor the biologic basis of hyporesponsiveness is clear, but, given the possibility of its occurrence, more than one revaccination has not been recommended.

The effectiveness of PPSV23 against IPD, pneumococcal pneumonia, all-cause pneumonia, and death is controversial, with wide variation in observations. The many published meta-analyses of PPSV efficacy have often reached opposing conclusions with regard to a given clinical entity. Generally, observational studies cite greater effectiveness than do controlled clinical trials. The consensus is that PPSV is effective against IPD but is less effective against nonbacteremic pneumococcal pneumonia. However, the results of some published trials, observational studies, and meta-analyses contradict this view. Effectiveness is often lower in the elderly and in immunodeficient patients whose condition is associated with reduced antibody responses to vaccines than in younger, healthier populations. When PPSV is effective, the duration of protection following a single dose of vaccine is estimated to be ~5 years.

What is not disputed is that improved pneumococcal vaccines are needed for adults. Even in the setting of routine pneumococcal conjugate vaccination of infants (which indirectly protects adults from vaccine-serotype strains), disease caused by serotypes not represented in the conjugate vaccine continues to be a significant burden among adults.

Polysaccharide–Protein Conjugate Vaccines Infants and young children respond poorly to PPSV, which contains T cell–independent antigens. Consequently, another class of pneumococcal vaccines, the PCVs, were developed specifically for infants and young children. The first product, a 7-valent PCV, was licensed in 2000 in the United States. Two PCV products—containing 10 and 13 serotypes, respectively—are commercially available as of 2020. The serotypes included in these PCV formulations are important causes of IPD and antibiotic resistance among young children. Randomized controlled trials have demonstrated a high degree of efficacy of PCVs against vaccine-serotype IPD as well as efficacy against pneumonia, otitis media, nasopharyngeal colonization, and all-cause mortality. PCVs are recommended by the World Health Organization for inclusion in routine childhood immunization schedules worldwide, especially in countries with high infant mortality rates. To date 144 countries have PCV in their National Immunization program, 16 are planning introduction, and 34 have no national decision.

The introduction of PCV in high-income settings has resulted in a >90% reduction in vaccine-serotype IPD among the whole population. This decline has been noted not only in those age groups immunized but also in adults and is attributable to the near elimination of vaccine-serotype nasopharyngeal colonization in immunized infants, which reduces spread to adults. This protection of unimmunized community members through vaccination of a subset of the community is termed *the indirect effect*. Increases in colonization with—and concomitantly in disease due to—non-vaccine-serotype strains (i.e., replacement colonization and disease) have been seen. The scale of replacement disease has varied geographically with the impact eroding vaccine impact significantly in the elderly in the UK while having relatively little impact in the USA (see "Epidemiology," above). Since vaccine-serotype strains are more commonly resistant to antibiotics than are non-vaccine serotypes, use of PCV has also resulted in substantial declines in the proportion and absolute rates of drug-resistant pneumococcal disease. The ACIP recommendations for the use of conjugate vaccines can be found at *www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/pneumo.html*. PCV has been shown to prevent pneumococcal infection in HIV-infected adults. In the United States, PCV13 followed by a dose of PPSV23 is now recommended for all immunocompromised children and adults. Until 2019 this was also the U.S. recommendation for those ≥65 years of age, but that recommendation has been modified. Shared decision-making with a physician should determine whether PCV13 in addition to PPSV23 is used in otherwise healthy adults ≥65 years of age. Two new extended-valency vaccines containing upwards of 15 serotypes—VAXNEUVANCE (Merck) and PREVNAR 20 (Pfizer)—were licensed in 2021.

Other Prevention Strategies Pneumococcal disease can be averted through the prevention of illnesses that predispose individuals to pneumococcal infections. Relevant measures include smoking cessation and influenza vaccination, as well as improved management and control of diabetes, HIV infection, heart disease, and lung disease. Finally, the reduction of antibiotic misuse is a strategy for the prevention of pneumococcal disease in that antimicrobial resistance directly and indirectly perpetuates organism transmission and disease in the community.

GLOBAL HEALTH

Pneumococcal infections are estimated to cause ~317,000 annual deaths worldwide among children 1–59 months of age, accounting for 9.7 % of the 3.2 million all-cause deaths and 38% of all pneumonia deaths in this age group in 2015. Reliable estimates of adult cases and deaths globally are more difficult to establish because of limited data from parts of the world where most disease occurs. Rates of pneumococcal disease and mortality vary substantially across geographic settings, with the highest rates in selected countries of sub-Saharan Africa and southern Asia, where risk factors for pneumococcal disease—including HIV infection, lack of breast feeding of infants and children, malnutrition, sickle cell disease, and limited access to medical care—are prevalent. Serotypes causing disease exhibit some heterogeneity across geographic settings, but a small number of serotypes universally account for the preponderance of disease in the absence of vaccination; accordingly, vaccine development and vaccination programs are globally relevant. Reductions in disease from pneumococcal infections are anchored in prevention through the inclusion of pneumococcal vaccines in infant immunization programs, timely assessment and appropriate treatment of persons with pneumococcal infections, and reduction of risk factors for pneumococcal disease. The availability of vaccines for the prevention of adult pneumococcal disease, particularly among the elderly, is currently restricted to high-income countries, with virtually no availability in low-income countries where most cases of disease exist.

147 Staphylococcal Infections

Franklin D. Lowy

Staphylococcus aureus, the most virulent of the many (≥40) staphylococcal species, has demonstrated its versatility by remaining a major cause of morbidity and mortality worldwide despite the availability of numerous effective antistaphylococcal antibiotics. *S. aureus* is a pluripotent pathogen, causing disease through both toxin- and non-toxin-mediated mechanisms. It is responsible for numerous nosocomial and community-based infections that range from relatively minor skin and soft tissue infections (SSTIs) to life-threatening systemic infections.

The "other" staphylococci, coagulase-negative staphylococci, are less virulent than *S. aureus* but remain important pathogens in select settings, such as infections that involve prosthetic devices.

MICROBIOLOGY AND TAXONOMY

Staphylococci, gram-positive cocci in the family Micrococcaceae, form grapelike clusters on Gram's stain **(Fig. 147-1)**. These organisms (~1 μm in diameter) are catalase-positive (unlike streptococcal species), nonmotile, aerobic, and facultatively anaerobic. They are capable of prolonged survival on environmental surfaces under varying conditions. Some species have a relatively broad host range, including mammals and birds, whereas the host range for others is quite narrow—i.e., limited to one or two closely related animals.

S. aureus is generally distinguished from other staphylococcal species by coagulase production, a surface enzyme that converts fibrinogen to fibrin. However, several of the "coagulase-negative staphylococci," including *S. pseudintermedius* and *S. argenteus*, are coagulase positive. As a result, description of these other staphylococci as non–*S. aureus* staphylococci (NSaS) is more accurate.

S. aureus ferments mannitol, is positive for protein A, and produces DNAse. On blood agar plates, *S. aureus* forms golden β-hemolytic colonies; in contrast, most NSaS form small white nonhemolytic colonies. Latex kits that detect both protein A and clumping factor can distinguish *S. aureus* from most other staphylococcal species. Point of care tests also are used for the rapid detection of staphylococcal colonization.

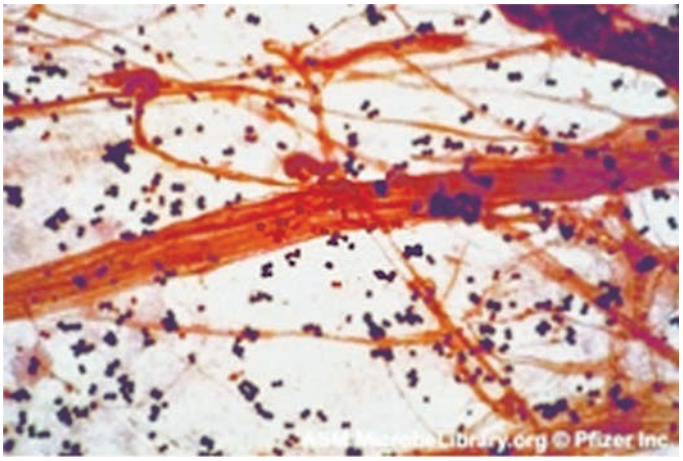

FIGURE 147-1 Gram's stain of *S. aureus* in a sputum sample, illustrating staphylococcal clusters. *(From ASM MicrobeLibrary.org. © Pfizer, Inc.)*

Newer methods such as matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF) are increasingly being used for staphylococcal speciation.

Determining whether multiple staphylococcal isolates from different patients are the same or different is often relevant when there is concern that a nosocomial outbreak of staphylococcal infections is due to a common point source (e.g., a contaminated medical instrument). Molecular typing methods, such as pulsed-field gel electrophoresis and sequence-based techniques (e.g., staphylococcal protein A [SpA] typing), have been used for this purpose. More recently, whole-genome sequencing has emerged as the gold standard for discrimination among different isolates.

S. AUREUS INFECTIONS

EPIDEMIOLOGY

S. aureus is both a commensal and an opportunistic pathogen. Approximately 20–40% of healthy persons are colonized with *S. aureus*, with a smaller percentage (~10%) persistently colonized with the same strain. The rate of colonization is elevated among type 1 diabetics, HIV-infected patients, patients undergoing hemodialysis, injection drug users, and individuals with skin damage. The anterior nares and oropharynx are frequent sites of human colonization, although the skin (especially when damaged), vagina, axilla, and perineum also are often colonized. These colonization sites serve as potential reservoirs for future infections.

Most individuals who develop *S. aureus* infections become infected with a strain that is already a part of their own commensal flora. Breaches of the skin or mucosal membrane allow *S. aureus* to initiate infection. Person-to-person transmission of *S. aureus* also occurs, most frequently from direct personal contact with an infected body site. Spread of staphylococci in aerosols of respiratory or nasal secretions from heavily colonized individuals, although rare, has been reported.

Some diseases increase the risk of *S. aureus* infection; diabetes, for example, combines an increased rate of *S. aureus* colonization and the use of injectable insulin with the possibility of impaired leukocyte function. Individuals with congenital or acquired qualitative or quantitative defects of polymorphonuclear leukocytes (PMNs) are at increased risk of *S. aureus* infections; this group includes neutropenic patients (e.g., those receiving chemotherapeutic agents), those with chronic granulomatous disease, and those with autosomal dominant hyperimmunoglobulin E (Job syndrome) or Chédiak-Higashi syndrome. Other groups at risk include individuals with end-stage renal disease, HIV infection, skin abnormalities, or prosthetic devices.

S. aureus is a leading cause of health care–associated infections **(Chap. 142)**. It is the most common cause of surgical wound infections and is second only to NSaS as a cause of primary bacteremia. These

isolates are often resistant to multiple antibiotics; thus, available therapeutic options may be limited. In the community, *S. aureus* remains an important cause of SSTIs, respiratory infections, and, especially among injection drug users, infective endocarditis. The increasing use of home infusion therapy also poses a risk of community-acquired staphylococcal infections.

In the past three decades, there has been a dramatic change in the epidemiology of infections due to methicillin-resistant *S. aureus* (MRSA). In addition to its major role as a nosocomial pathogen, MRSA has become an established community-based pathogen. Numerous outbreaks of community-associated MRSA (CA-MRSA) infections have been reported in both rural and urban settings in widely separated regions throughout the world.

This trend appears to be due in part to the dramatic increase in MRSA colonization found in the community in different parts of the world. Outbreaks of CA-MRSA infections have occurred among such diverse groups as children, prisoners, athletes, Native Americans, and drug users. Risk factors common to these outbreaks include poor hygienic conditions, close contact, contaminated material, and damaged skin. In some geographic regions of the world, the infections have been caused by a single CA-MRSA strain, while in others a variety of CA-MRSA strains have been responsible. In the United States, strain sequence type 8 (PFGE type USA300) has been the predominant clone **(Fig. 147-2)**. Although the majority of infections caused by these strains have involved the skin and soft tissue, 5–10% have been invasive and potentially life-threatening. CA-MRSA strains have also been responsible for an increasing number of nosocomial infections. Of concern has been the enhanced capacity of CA-MRSA to cause disease in immunocompetent individuals.

PATHOGENESIS

General Concepts *S. aureus* is a pyogenic pathogen known for its capacity to induce abscess formation at both local and distant sites (i.e., metastatic infections). This classic pathologic response to *S. aureus* defines the framework within which the infection will progress. The bacteria elicit an inflammatory response characterized by an initial intense infiltration of PMNs and a subsequent infiltration of macrophages and fibroblasts. Either the host cellular response (including the deposition of fibrin and collagen) contains the infection with the formation of a fibrinous capsule, or infection spreads to the adjoining tissue or into the bloodstream.

In toxin-mediated staphylococcal disease, infection is not invariably present. For example, in staphylococcal food poisoning, once the heat-stable enterotoxin has been released into food, symptoms can develop in the absence of viable bacteria. In staphylococcal toxic shock syndrome (TSS), conditions allowing toxin elaboration at colonization sites (e.g., the presence of a superabsorbent tampon) suffice for initiation of clinical illness.

The *S. aureus* Genome The complete genomes of *S. aureus* strains are now readily available. Among the interesting revelations are (1) the high degree of nucleotide sequence similarity of the core genomes of different strains; (2) the acquisition of a relatively large amount of genetic information by horizontal transfer from other bacterial species; and (3) the presence of unique "pathogenicity" or "genomic" islands—mobile genetic elements that contain clusters of enterotoxin and exotoxin genes and/or antimicrobial resistance determinants. Among the genes in these islands is *mecA*, the gene responsible for methicillin resistance. Methicillin resistance–containing islands have been designated staphylococcal cassette chromosome *mec* (SCC*mec*). There are different *SCCmec* types that range in size from ~20 to 60 kb. Among the more common SCC*mec* types, types 1–3 are traditionally associated with nosocomial MRSA isolates, whereas types 4–6 have been associated with epidemic CA-MRSA strains.

A relatively limited number of MRSA clones have been responsible for most community- and hospital-associated infections worldwide. A comparison of these strains with those from earlier outbreaks (e.g., the phage 80/81 strains from the 1950s) has revealed preservation of the nucleotide sequence over time. This observation suggests that these strains possess determinants that facilitate survival and spread.

Regulation of Virulence Gene Expression In both toxin-mediated and non-toxin-mediated diseases due to *S. aureus*, the expression of virulence determinants associated with infection depends on a series of regulatory genes (e.g., accessory gene regulator [*agr*] and staphylococcal accessory regulator [*sar*]) that coordinately control the expression of many virulence genes. The

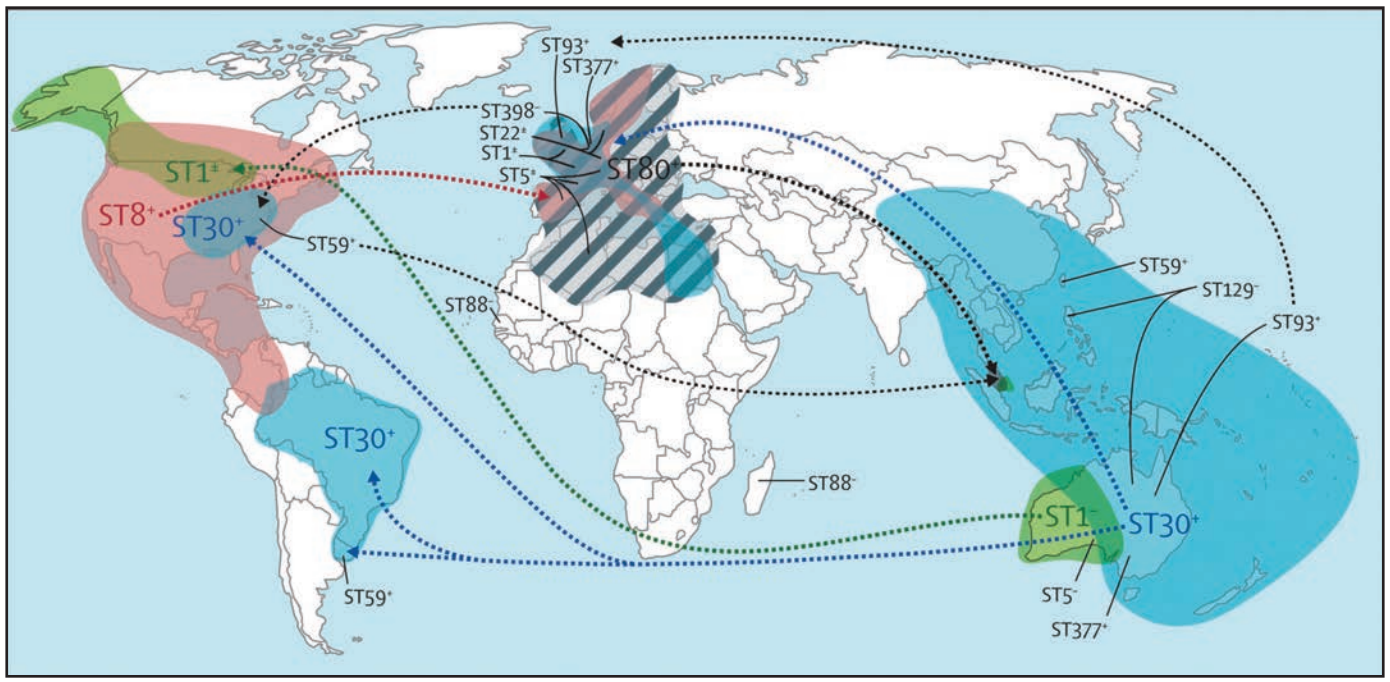

FIGURE 147-2 Global distribution of community-associated MRSA. Dotted lines indicate possible route of dissemination. Estimates of the areas are shown where infection with the main strains—i.e., ST1 *(green)*, ST8 *(red)*, ST30 *(blue)*, and ST80 *(grey hatched)*—have been reported. +, Panton Valentine Leukocidin (PVL)-positive strains; –, PVL-negative strains; ±, PVL-positive and -negative strains. *(Reproduced with permission from FR DeLeo, M Otto, BN Kreiswirth, HF Chambers: Community-associated meticillin-resistant Staphylococcus aureus. Lancet 375:1557, 2010.)*

regulatory gene *agr* is part of a quorum-sensing signal transduction pathway that senses and responds to bacterial density. Staphylococcal surface proteins are synthesized during the bacterial exponential growth phase in vitro. In contrast, many secreted proteins, such as α toxin, the enterotoxins, and assorted enzymes, are released during the post–exponential growth phase in response to transcription of the effector molecule of *agr*, RNAIII.

These regulatory genes appear to serve a similar function in vivo. Successful invasion requires the sequential expression of these different bacterial elements. Bacterial adhesins are needed to initiate colonization of host tissue surfaces. The subsequent release of various enzymes enables the colony to obtain nutritional support and permits bacteria to spread to adjacent tissues. Studies with strains in which these regulatory genes are inactivated show reduced virulence in several animal models of *S. aureus* infection.

Pathogenesis of Invasive *S. aureus* Infection Staphylococci are opportunists. For these organisms to invade the host and cause infection, some or all of the following steps are necessary: contamination and colonization of host tissue surfaces, breach of cutaneous or mucosal barriers, establishment of a localized infection, invasion, evasion of the host response, and metastatic spread. Colonizing strains or strains transferred from other exposures are introduced into damaged skin, a wound, or the bloodstream. Recurrences of *S. aureus* infections are common, apparently because of the capacity of these pathogens to persist in a quiescent state in various tissues, and then to cause recrudescent infections when suitable conditions arise.

***S. AUREUS* COLONIZATION OF BODY SURFACES** The anterior nares and oropharynx are primary sites of staphylococcal colonization. In the nares, colonization appears to involve the attachment of *S. aureus* to keratinized epithelial cells. Other factors that contribute to colonization include the influence of other resident nasal flora and their bacterial density, host factors, and nasal mucosal damage (e.g., that resulting from inhalational drug use). Other colonized body sites, such as damaged skin, the groin, and the oropharynx, may be particularly important reservoirs for CA-MRSA strains.

INOCULATION AND COLONIZATION OF TISSUE SURFACES Staphylococci may be introduced into tissue as a result of minor abrasions (e.g., mosquito bites), administration of medications such as insulin, or establishment of IV access with catheters. After introduction into a tissue site, bacteria replicate and colonize the host tissue surface. A family of structurally related *S. aureus* surface proteins referred to as MSCRAMMs (microbial surface components recognizing adhesive matrix molecules) play an important role as mediators of adherence to these different sites. By adhering to exposed matrix molecules (e.g., fibrinogen, collagen, fibronectin), MSCRAMMs, such as clumping factor and collagen-binding protein, enable the bacteria to colonize different host tissue surfaces; these proteins contribute to the pathogenesis of invasive infections such as endocarditis and septic arthritis by facilitating the adherence of *S. aureus* to surfaces with exposed fibrinogen or collagen.

Although NSaS are classically known for their ability to elaborate biofilms and to colonize prosthetic devices, *S. aureus* also possesses the genes responsible for biofilm formation, such as the intercellular adhesion (*ica*) locus. Binding to these devices occurs in a stepwise fashion, involving staphylococcal adherence to serum constituents that have coated the device surface and subsequent biofilm elaboration. *S. aureus* is thus a frequent cause of biomedical device–related infections.

INVASION After colonization, staphylococci replicate at the initial site of infection, elaborating enzymes that include serine proteases, hyaluronidases, thermonucleases, and lipases. These enzymes facilitate bacterial survival and local spread across tissue surfaces. The lipases may facilitate survival in lipid-rich areas such as the hair follicles, where *S. aureus* infections are often initiated.

Constitutional findings may result from either localized or systemic infections. The staphylococcal cell wall—consisting of alternating *N*-acetyl muramic acid and *N*-acetyl glucosamine units in combination with an additional cell wall component, lipoteichoic acid—can initiate an inflammatory response that includes the sepsis syndrome. Staphylococcal alpha (α) toxin is a critical staphylococcal toxin. It causes pore formation in various eukaryotic cells and can also initiate an inflammatory response with findings suggestive of sepsis. The *S. aureus* toxin Panton-Valentine leukocidin is cytolytic to PMNs, macrophages, and monocytes. Strains elaborating this toxin have been epidemiologically linked with cutaneous and more serious infections (i.e., pneumonia) caused by strains of CA-MRSA.

EVASION OF HOST DEFENSE MECHANISMS Staphylococci have many host immune evasion strategies that are crucial to their survival. They possess an antiphagocytic polysaccharide microcapsule. Most human *S. aureus* infections are due to strains with capsular types 5 and 8. The zwitterionic (both negatively and positively charged) *S. aureus* capsule also plays a critical role in the induction of abscess formation. Protein A, an MSCRAMM unique to *S. aureus*, acts as an Fc receptor, binding the Fc portion of IgG subclasses 1, 2, and 4 and preventing opsonophagocytosis by PMNs. Both chemotaxis inhibitory protein of staphylococci (CHIPS, a secreted protein) and extracellular adherence protein (EAP, a surface protein) interfere with PMN migration to sites of infection. There are a number of cytolytic toxins, including α toxin and Panton Valentine toxin, that are secreted by staphylococci that cause lysis of different host cells and contribute to host tissue damage.

An additional potential mechanism of *S. aureus* evasion is its capacity for intracellular survival. Both professional and nonprofessional phagocytes internalize staphylococci. Internalization by these cells may provide a sanctuary that protects bacteria against the host's defenses. This phenomenon appears to be especially relevant for hepatic Kupffer cells during staphylococcal bacteremias. The intracellular environment favors the phenotypic expression of *S. aureus* small-colony variants, which are found in patients receiving antimicrobial therapy (e.g., with aminoglycosides) and in those with cystic fibrosis or osteomyelitis. These variants, whether intra- or extracellular, may facilitate prolonged staphylococcal survival in different tissue sites and enhance the likelihood of recurrences. Finally, *S. aureus* can survive within PMNs and may use these cells to spread and seed other tissue sites.

PATHOGENESIS OF COMMUNITY-ACQUIRED MRSA INFECTIONS A number of specific virulence determinants contribute to the pathogenesis of CA-MRSA infections. A strong epidemiologic association links the presence of the gene for the Panton-Valentine leukocidin with SSTIs and with necrotizing post-influenza pneumonia. Other determinants that play a role in the pathogenesis of these infections include the arginine catabolic mobile element (ACME), a cluster of unique genes that may facilitate evasion of host defense mechanisms; phenol-soluble modulins, a family of cytolytic peptides; and α toxin.

Host Response to *S. aureus* Infection The primary host response to *S. aureus* infection is the recruitment of PMNs. These cells are attracted to infection sites by bacterial components such as formylated peptides or peptidoglycan as well as by the cytokines tumor necrosis factor (TNF) and interleukins 1 and 6, which are released by activated macrophages and endothelial cells.

Although most individuals have antibodies to staphylococci, it is not clear that antibody levels are qualitatively or quantitatively sufficient to protect against infection. Anticapsular and anti-MSCRAMM antibodies facilitate opsonization in vitro and have been protective against infection in several animal models; however, they have not yet successfully prevented staphylococcal infections in clinical trials.

Pathogenesis of Toxin-Mediated Disease *S. aureus* produces three types of toxin: cytotoxins, pyrogenic toxin superantigens, and exfoliative toxins. Both epidemiologic data and studies in animals suggest that antitoxin antibodies are protective against illness in TSS, staphylococcal food poisoning, and staphylococcal scalded-skin syndrome (SSSS). Illness develops after toxin synthesis and absorption and the subsequent toxin-initiated host response.

ENTEROTOXIN AND TOXIC SHOCK SYNDROME TOXIN 1 (TSST-1) The pyrogenic toxin superantigens are a family of small-molecular-size, structurally similar proteins that are responsible for two diseases: TSS and food poisoning. TSS results from the ability of TSST-1 and

enterotoxins to function as T-cell mitogens. In the normal process of antigen presentation, the antigen is first processed within the cell, and peptides are then presented in the major histocompatibility complex (MHC) class II groove, initiating a measured T-cell response. In contrast, TSST-1 and enterotoxins bind directly to the invariant region of MHC—outside the MHC class II groove. TSST-1 and the enterotoxins can then bind T-cell receptors via the vβ chain; this binding results in a dramatic overexpansion of T-cell clones (up to 20% of the total T-cell population). The consequence of this T-cell expansion is a cytokine storm, with the release of inflammatory mediators that include interferon γ, IL-1, IL-6, TNF-α, and TNF-β. The resulting multisystem disease produces a constellation of findings that mimic those found in endotoxin shock; however, the pathogenic mechanisms differ.

A different region of the enterotoxin molecule is responsible for the symptoms of food poisoning. The enterotoxins are heat stable and can survive conditions that kill the bacteria. Illness results from the ingestion of preformed toxin; as a result, the incubation period is short (1–6 h). The toxin stimulates the vagus nerve and the vomiting center of the brain. It also appears to stimulate intestinal peristaltic activity.

EXFOLIATIVE TOXINS AND SSSS The exfoliative toxins are responsible for SSSS, most commonly seen in newborns. The toxins that produce disease in humans are of two serotypes: ETA and ETB. These toxins are serine proteases that cleave desmosomal cadherins in the superficial layer of the skin, triggering exfoliation. The result is a split in the epidermis at the granular level, which is responsible for the superficial desquamation of the skin that typifies this illness.

DIAGNOSIS

Staphylococcal infections are readily diagnosed by Gram's stain (Fig. 147-1) and microscopic examination of abscess contents or of infected tissue. Routine cultures of infected material usually are positive; blood cultures are sometimes positive even when infections are localized to extravascular sites. *S. aureus* is rarely a blood culture contaminant. Polymerase chain reaction (PCR)–based assays are now often used for the rapid diagnosis of *S. aureus* infection. A number of point-of-care tests are available to screen patients for colonization with MRSA. Determining whether patients with documented *S. aureus* bacteremia also have infective endocarditis or a metastatic focus of infection remains a diagnostic challenge. Uniformly positive cultures of blood collected over time suggest an endovascular infection such as endocarditis (see "Bacteremia, Sepsis, and Infective Endocarditis," below).

CLINICAL SYNDROMES

(Table 147-1)

TABLE 147-1 Common Illnesses Caused by *Staphylococcus aureus*

Skin and Soft Tissue Infections
Folliculitis
Abscess, furuncle, carbuncle
Cellulitis
Impetigo
Mastitis
Surgical wound infections
Musculoskeletal Infections
Septic arthritis
Osteomyelitis (hematogenous or contiguous spread)
Pyomyositis
Psoas abscess
Respiratory Tract Infections
Ventilator-associated or nosocomial pneumonia
Septic pulmonary emboli
Postviral pneumonia (e.g., influenza)
Empyema
Bacteremia and Its Complications
Sepsis, septic shock
Metastatic foci of infection (kidney, joints, bone, lung)
Infective endocarditis
Infective Endocarditis
Injection drug use–associated
Native-valve
Prosthetic-valve
Nosocomial
Device-Related Infections (e.g., intravascular catheters, prosthetic joints)
Toxin-Mediated Illnesses
Toxic shock syndrome
Food poisoning
Staphylococcal scalded-skin syndrome
Invasive Infections Associated with Community-Acquired Methicillin-Resistant *S. aureus*
Necrotizing fasciitis
Waterhouse-Friderichsen syndrome
Necrotizing pneumonia
Purpura fulminans

Skin and Soft Tissue Infections *S. aureus* causes a variety of cutaneous infections. Common factors predisposing to *S. aureus* cutaneous infection include chronic skin conditions (e.g., eczema), skin damage (e.g., insect bites, minor trauma), injections (e.g., in diabetes, injection drug use), and poor personal hygiene. These infections are characterized by the formation of pus-containing blisters, which often begin in hair follicles and spread to adjoining tissues. *Folliculitis* is a superficial infection that involves the hair follicle, with a central area of purulence (pus) surrounded by induration and erythema. *Furuncles* (boils) are more extensive, painful lesions that tend to occur in hairy, moist regions of the body and extend from the hair follicle to become a true abscess with an area of central purulence. *Carbuncles* are most often located in the lower neck and are even more severe and painful, resulting from the coalescence of other lesions that extend to a deeper layer of the subcutaneous tissue. In general, furuncles and carbuncles are readily apparent, with pus often expressible or discharging from the abscess. Other cutaneous *S. aureus* infections include impetigo and cellulitis. *S. aureus* is one of the most common causes of surgical wound infections.

Mastitis develops in 1–3% of nursing mothers. This infection of the breast, which generally presents within 2–3 weeks after delivery, is characterized by findings that range from cellulitis to abscess formation. Systemic signs, such as fever and chills, are often present in more severe cases.

Musculoskeletal Infections *S. aureus* is a common cause of bone infections—both those resulting from hematogenous dissemination and those arising from contiguous spread from a soft tissue site. *Hematogenous osteomyelitis* in children most often involves the long bones. Infections present with fever and bone pain or with a child's reluctance to bear weight. The white blood cell count and erythrocyte sedimentation rate are often elevated. Blood cultures are positive in ~50% of cases. When necessary, bone biopsies for culture and histopathologic examination are usually diagnostic.

In adults, hematogenous osteomyelitis involving the long bones is less common. However, *vertebral osteomyelitis* is among the more common clinical presentations. Vertebral bone infections are most often seen in patients with endocarditis, those undergoing hemodialysis, diabetics, and injection drug users. These infections may present with intense back pain and fever but may also be clinically occult, presenting as chronic back pain with low-grade fever. *S. aureus* is the most common cause of epidural abscess, a complication that can result in neurologic compromise. Patients report difficulty voiding or walking

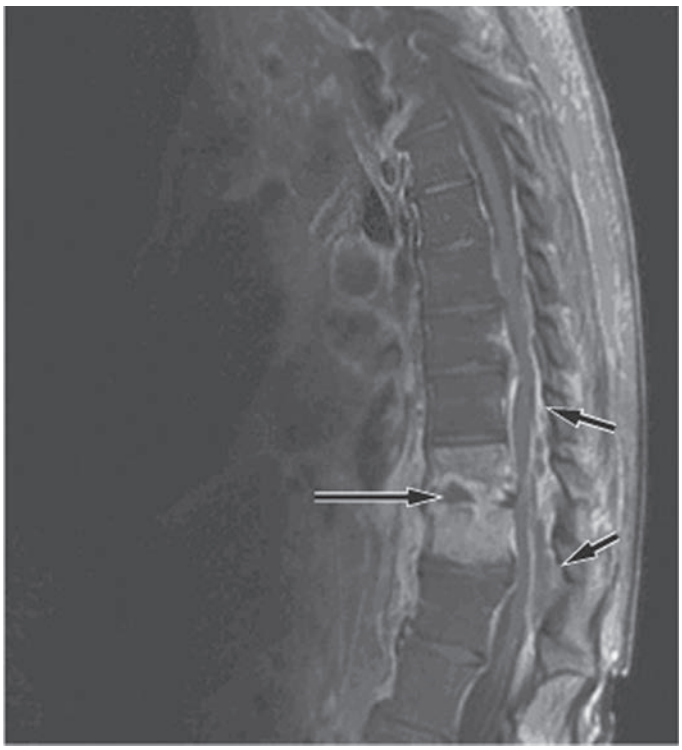

FIGURE 147-3 *S. aureus* vertebral osteomyelitis and epidural abscess involving the thoracic disk between T9 and T10. Sagittal postcontrast MRI of the spine illustrates destruction of the T9–T10 intervertebral space with enhancement (*long arrow*). There is impingement on the thoracic cord and an epidural collection extending from T9 through T11 (*short arrows*).

and radicular pain in addition to the symptoms associated with their osteomyelitis. Surgical intervention in this setting often constitutes a medical emergency.

MRI is the most reliable imaging modality to help establish the diagnosis of osteomyelitis **(Fig. 147-3)**. Routine x-rays are an appropriate first step, but findings may be normal for up to 14 days after the onset of symptoms. If an MRI is not possible, CT is an acceptable alternative.

Bone infections that result from contiguous spread tend to develop from soft tissue infections, such as those associated with diabetic or vascular ulcers, surgery, or trauma. Exposure of bone, a draining fistulous tract, failure to heal, or continued drainage suggests involvement of underlying bone. Bone involvement is established by bone culture and histopathologic examination (revealing evidence of PMN infiltration). Contamination of culture material from adjacent tissue can make the diagnosis of osteomyelitis difficult in the absence of pathologic confirmation. Samples obtained during surgery are the most reliable. An MRI is the most reliable radiologic test to distinguish between osteomyelitis and overlying soft tissue infection with underlying osteitis.

In both children and adults, *S. aureus* is the most common cause of *septic arthritis* in native joints. If left untreated, this infection is rapidly progressive and may be associated with extensive joint destruction. It presents with intense pain on motion of the affected joint, swelling, and fever. Aspiration of the joint reveals turbid fluid, with >50,000 PMNs/μL and gram-positive cocci in clusters seen on Gram's stain (Fig. 147-1). In adults, septic arthritis may result from trauma, surgery, or hematogenous dissemination. The most commonly involved joints include the knees, shoulders, hips, and phalanges. Infection frequently develops in joints previously damaged by osteoarthritis or rheumatoid arthritis. Iatrogenic infections resulting from aspiration or injection of agents into the joint also occur. In these settings, the patient experiences increased pain and swelling in the involved joint in association with fever.

Pyomyositis is an unusual infection of skeletal muscles that is seen primarily in tropical climates but also occurs in immunocompromised (e.g., HIV-infected) patients. It is believed to arise from occult bacteremia. Pyomyositis presents as fever, swelling, and pain overlying the involved muscle. Aspiration of fluid from the involved tissue yields pus. Although a history of trauma may be associated with the infection, its pathogenesis is poorly understood.

Respiratory Tract Infections Respiratory tract infections caused by *S. aureus* occur in selected clinical settings. *S. aureus* is a cause of serious respiratory tract infections in newborns and infants; these infections present with shortness of breath, fever, and respiratory failure. Chest x-ray may reveal pneumatoceles (shaggy, thin-walled cavities). Pneumothorax and empyema are recognized complications.

In adults, nosocomial *S. aureus* pulmonary infections are common among intubated patients in intensive care units. Nasally colonized patients are at increased risk of these infections. The clinical presentation is no different from pulmonary infections caused by other bacterial pathogens. Patients produce increased volumes of purulent sputum and develop respiratory distress, fever, and new pulmonary infiltrates. Distinguishing bacterial pneumonia from respiratory failure or other causes of new pulmonary infiltrates in critically ill patients is difficult and relies on a constellation of clinical, radiologic, and laboratory findings.

Community-acquired respiratory tract infections due to *S. aureus* often follow viral infections—most commonly influenza. Patients may present with fever, bloody sputum production, and midlung-field pneumatoceles or multiple, patchy pulmonary infiltrates. Diagnosis is made by sputum Gram's stain and culture. Blood cultures, although useful, are usually negative.

Bacteremia, Sepsis, and Infective Endocarditis *S. aureus* bacteremia may be complicated by sepsis, endocarditis, vasculitis, or metastatic seeding (establishment of suppurative collections at other tissue sites). Among the more commonly seeded tissue sites are bones, joints, kidneys, and lungs. The frequency of metastatic seeding during bacteremia has been estimated to be as high as 31%. The incidence of these complications increases with the duration of the bacteremia.

Recognition of these complications by clinical criteria alone is challenging. Comorbid conditions that are frequently seen in association with *S. aureus* bacteremia and that increase the risk of complications include diabetes, HIV infection, and renal insufficiency. Other host factors that increase the risk of complications include presentation with community-acquired *S. aureus* bacteremia, lack of an identifiable primary focus of infection, and the presence of prosthetic devices or material.

Clinically, *S. aureus* sepsis presents in a manner similar to that documented for sepsis due to other bacteria. The well-described progression of hemodynamic changes—beginning with respiratory alkalosis and clinical findings of hypotension and fever—is commonly seen. The microbiologic diagnosis is established by positive blood cultures.

The overall incidence of *S. aureus* endocarditis has increased over the past 20 years. *S. aureus* is now the leading cause of endocarditis worldwide, accounting for 25–35% of cases. This increase is due, at least in part, to the increased use of intravascular devices and, more recently, the upsurge in injection drug use. Studies using transesophageal echocardiography found an endocarditis incidence of ~25% among patients with intravascular catheter–associated *S. aureus* bacteremia. Other factors associated with an increased risk of endocarditis are hemodialysis, the presence of intravascular prosthetic devices at the time of bacteremia, and immunosuppression. Patients with implantable cardiac devices (e.g., permanent pacemakers) are at increased risk of endocarditis or device-related infections. Despite the availability of effective antibiotics, mortality rates from these infections continue to range from 20 to 40%, depending on both the host and the nature of the infection. Complications of *S. aureus* endocarditis include cardiac valvular insufficiency, peripheral emboli, metastatic seeding, vasculitis, and central nervous system (CNS) involvement (e.g., mycotic aneurysms, embolic strokes).

S. aureus endocarditis is encountered in four clinical settings: (1) right-sided endocarditis in association with injection drug use; (2) left-sided native-valve endocarditis; (3) prosthetic-valve endocarditis; and

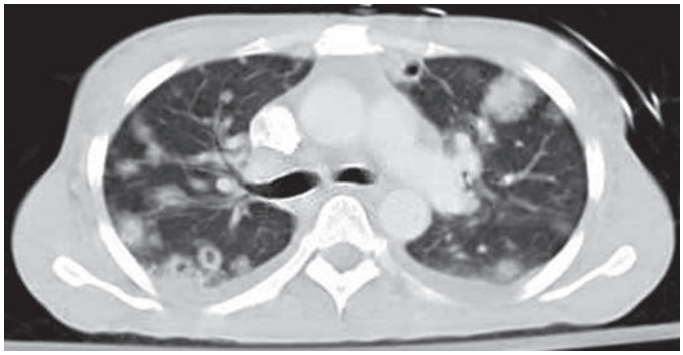

FIGURE 147-4 CT scan illustrating septic pulmonary emboli in a patient with methicillin-resistant *Staphylococcus aureus* bacteremia.

(4) nosocomial endocarditis. In each of these settings, the diagnosis is suspected from the patient's history and the recognition of physical signs suggestive of endocarditis. These findings include cardiac manifestations, such as new or changing cardiac valvular murmurs; cutaneous evidence, such as vasculitic lesions, Osler's nodes, or Janeway lesions; evidence of right- or left-sided embolic disease; and a history suggesting a risk for *S. aureus* bacteremia. In the absence of antecedent antibiotic therapy, blood cultures are almost uniformly positive. Transthoracic echocardiography, while less sensitive than transesophageal echocardiography, is less invasive and often identifies valvular vegetations. The Duke criteria **(Chap. 128)** are commonly used to help establish this diagnosis.

Acute right-sided tricuspid valvular *S. aureus* endocarditis is most often seen in patients who inject drugs. The classic presentation includes a high fever, a toxic clinical appearance, pleuritic chest pain, and the production of purulent, sometimes bloody, sputum. Chest x-rays or CT scans reveal evidence of septic pulmonary emboli (small, peripheral, circular lesions that may cavitate with time) **(Fig. 147-4)**. A high percentage of affected patients have no history of antecedent valvular damage. At the outset of their illness, patients may present with fever alone, without cardiac or other localizing findings. As a result, a high index of clinical suspicion is essential for diagnosis.

Individuals with antecedent cardiac valvular damage more commonly present with left-sided native-valve endocarditis involving the damaged valve. These patients tend to be older than those with right-sided endocarditis, their prognosis is worse, and their incidence of complications (including peripheral emboli, cardiac decompensation, cerebrovascular events and metastatic seeding) is increased.

S. aureus is one of the more common causes of prosthetic-valve endocarditis. This infection is especially fulminant in the early postoperative period and is associated with increased morbidity and mortality. In most instances, medical therapy alone is not sufficient and urgent valve replacement is necessary. Patients are prone to develop valvular insufficiency or myocardial abscesses originating from the region of valve implantation.

The increased frequency of nosocomial endocarditis (15–30% of cases, depending on the series) reflects in part the increased use of intravascular devices. This form of endocarditis is most commonly caused by *S. aureus*. These patients are often critically ill, are receiving antibiotics for various other indications, and have comorbid conditions. As a result, blood cultures may be negative and the diagnosis missed.

Prosthetic Device–Related Infections *S. aureus* accounts for a large proportion of prosthetic device–related infections. These infections include intravascular and peritoneal catheters, prosthetic valves, orthopedic devices, pacemakers, left-ventricular-assist devices, or vascular grafts. In contrast with the more indolent presentation of NSaS infections, *S. aureus* device-related infections are often acute, have both local and systemic manifestations, and tend to progress more rapidly. It is relatively common for a pyogenic collection to be present at the device site. Aspiration of these collections and performance of blood cultures are important components in establishing a diagnosis. *S. aureus* infections tend to occur more commonly soon after implantation unless the device is used for access (e.g., intravascular or hemodialysis catheters). In the latter instance, infections can occur at any time. As in most prosthetic-device infections, successful therapy usually involves removal of the device. Left in place, the device serves as a potential nidus for either persistent or recurrent infections.

Urinary Tract Infections Urinary tract infections (UTIs) are infrequently caused by *S. aureus*. The presence of *S. aureus* in the urine often suggests hematogenous dissemination. Ascending *S. aureus* infections occasionally result from instrumentation of the genitourinary tract.

Infections Associated with Community-Acquired MRSA Although skin and soft tissues are by far the most common sites of infection associated with CA-MRSA, 5–10% of these infections are invasive and can be life-threatening. The latter unique infections, including necrotizing fasciitis, necrotizing pneumonia, and sepsis with Waterhouse-Friderichsen syndrome or purpura fulminans, were rarely associated with *S. aureus* prior to the emergence of CA-MRSA. These life-threatening infections reflect the increased virulence of CA-MRSA strains.

Toxin-Mediated Diseases • **FOOD POISONING** *S. aureus* is among the most common causes of foodborne outbreaks in the United States. Staphylococcal food poisoning results from the inoculation of toxin-producing *S. aureus* into food by colonized food handlers. Toxin is then elaborated in such growth-promoting food as custards, potato salad, or processed meats. Even if the bacteria are killed by warming, the heat-stable toxin is not destroyed. The onset of illness is rapid, occurring within 1–6 h of ingestion; it is characterized by nausea and vomiting, although diarrhea, hypotension, and dehydration may occur. The differential diagnosis includes diarrhea of other etiologies, especially that caused by similar toxins (e.g., the toxins elaborated by *Bacillus cereus*). The rapidity of onset, the absence of fever, and the epidemic nature of the presentation (without secondary spread) should arouse suspicion of staphylococcal food poisoning. Symptoms generally resolve within 8–10 h. The diagnosis can be established by the demonstration of bacteria or the documentation of enterotoxin in the implicated food. Treatment is entirely supportive.

TOXIC SHOCK SYNDROME TSS gained attention in the early 1980s, when a nationwide outbreak occurred among young, otherwise healthy, menstruating women. Epidemiologic investigation demonstrated that these cases were associated with the use of a highly absorbent tampon recently introduced to the market. Subsequent studies established the role of TSST-1 in these illnesses. Withdrawal of the tampon from the market resulted in a rapid decline in the incidence of this disease. However, menstrual and nonmenstrual cases continue to be reported. Nonmenstrual cases are seen in patients with surgical or postpartum wound infections, especially when packing of the wound occurs.

The clinical presentation is similar in menstrual and nonmenstrual TSS. Evidence of clinical *S. aureus* infection is not a prerequisite. TSS results from the elaboration of an enterotoxin or the structurally related enterotoxin-like TSST-1. More than 90% of menstrual cases are caused by TSST-1, whereas a high percentage of nonmenstrual cases are caused by enterotoxins (e.g., enterotoxin B). TSS begins with relatively nonspecific flulike symptoms. In menstrual cases, the onset usually comes 2 or 3 days after the start of menstruation. Patients present with fever, hypotension, and erythroderma of variable intensity. Mucosal involvement is common (e.g., conjunctival hyperemia). The illness can rapidly progress to symptoms that include vomiting, diarrhea, confusion, myalgias, and abdominal pain. These symptoms reflect the multisystemic nature of the disease, with involvement of the liver, kidneys, gastrointestinal tract, and/or CNS. Desquamation of the skin occurs during convalescence, usually 1–2 weeks after the onset of illness. Laboratory findings may include azotemia, leukocytosis, hypoalbuminemia, thrombocytopenia, and liver function abnormalities.

Diagnosis of TSS still depends on a constellation of findings rather than one specific finding and on a lack of evidence of other possible infections **(Table 147-2)**. These other diagnoses include drug toxicities,

TABLE 147-2 Case Definition of *Staphylococcus aureus* Toxic Shock Syndrome

Clinical Criteria

An illness with the following clinical manifestations:

- Fever: temperature ≥102.0°F (≥38.9°C)
- Rash: diffuse macular erythroderma
- Desquamation: 1–2 weeks after rash onset
- Hypotension: systolic blood pressure ≤90 mmHg for adults or less than the fifth percentile, by age, for children <16 years old
- Multisystem involvement (≥3 of the following organ systems)
  - Gastrointestinal: vomiting or diarrhea at illness onset
  - Muscular: severe myalgia or creatine phosphokinase level at least twice ULN
  - Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
  - Renal: blood urea nitrogen or creatinine level at least twice ULN for laboratory or urinary sediment with pyuria (≥5 leukocytes per high-power field) in the absence of urinary tract infection
  - Hepatic: total bilirubin or aminotransferase level at least twice ULN for laboratory
  - Hematologic: platelet count $<10^5/\mu L$
  - Central nervous system: disorientation or alterations in consciousness without focal neurologic signs in the absence of fever and hypotension

Laboratory Criteria

Negative results in the following tests, if obtained:

- Blood or cerebrospinal fluid cultures for another pathogen[a]
- Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles

Case Classification

Probable: a case that meets the laboratory criteria and in which four of the five clinical criteria are fulfilled

Confirmed: a case that meets the laboratory criteria and in which all five of the clinical criteria are fulfilled, including desquamation (unless the patient dies before desquamation occurs)

[a]Blood cultures may be positive for *S. aureus*.

Abbreviation: ULN, upper limit of normal.

Source: Centers for Disease Control and Prevention (*www.cdc.gov/nndss/conditions/toxic-shock-syndrome-other-than-streptococcal/case-definition/2011/*).

viral exanthems, Rocky Mountain spotted fever, sepsis, and Kawasaki disease. Illness occurs only in persons who lack antibody to TSST-1. Recurrences are possible if antibody fails to develop after the illness.

STAPHYLOCOCCAL SCALDED-SKIN SYNDROME SSSS primarily affects newborns and children. The illness may vary from a localized blister to exfoliation of much of the skin surface. The skin is usually fragile and often tender, with thin-walled, fluid-filled bullae **(Fig. 147-5)**. Gentle pressure results in rupture of the lesions, leaving denuded underlying skin. The mucous membranes are usually spared. In more generalized infection, there are often constitutional symptoms, including fever, lethargy, and irritability with poor feeding. Significant amounts of fluid can be lost in more extensive cases. Illness usually follows localized infection at one of a number of possible sites. SSSS is much less common among adults but can follow infections caused by exfoliative toxin–producing strains.

FIGURE 147-5 Staphylococcal scalded skin syndrome in a 6-year-old boy. Nikolsky's sign, with separation of the superficial layer of the outer epidermal layer, is visible. *(Adapted from LA Schenfeld: Staphylococcal scalded skin syndrome: N Engl J Med 342:1178, 2000.)*

NON–*S. AUREUS* STAPHYLOCOCCAL INFECTIONS

Although less virulent than *S. aureus*, NSaS are among the most common causes of prosthetic-device infections, including endocarditis. They also are increasingly a cause of native-valve endocarditis and life-threatening bloodstream infections in neonates and in neutropenic patients. Approximately half of the identified NSaS species have been associated with human infections. Of these species, *Staphylococcus epidermidis* is the most common human pathogen. It is part of the normal human flora and is found on the skin (where it is the most abundant bacterial species) as well as in the oropharynx and vagina. *Staphylococcus saprophyticus*, a novobiocin-resistant species, is a common pathogen in UTIs.

PATHOGENESIS

S. epidermidis is the NSaS species most often associated with prosthetic-device infections. Infection is a two-step process, with initial adhesion to the device followed by colonization. *S. epidermidis* is uniquely adapted to colonize these devices because of its capacity to elaborate the extracellular polysaccharide (glycocalyx or slime) that facilitates formation of a protective biofilm on the device surface.

Implanted prosthetic material is rapidly coated with host matrix molecules such as fibrinogen or fibronectin. These molecules serve as potential bridging ligands, facilitating initial bacterial attachment to the device surface. A number of staphylococcal surface-associated proteins, such as autolysin (AtlE), fibrinogen-binding protein, and accumulation-associated protein (AAP), appear to play a role in attachment to either modified or unmodified prosthetic surfaces. The polysaccharide intercellular adhesin facilitates subsequent staphylococcal colonization, aggregation, and accumulation on the device surface. Intercellular adhesin (*ica*) genes are more commonly found in strains of *S. epidermidis* that are associated with device infections than in strains associated with colonization of mucosal surfaces. Biofilm acts as a barrier, protecting bacteria from host defense mechanisms as well as from antibiotics while providing a suitable environment for bacterial maturation, survival, and potential spread to other tissue sites.

Two additional NSaS species, *Staphylococcus lugdunensis* and *Staphylococcus schleiferi*, produce more serious infections (native-valve endocarditis and osteomyelitis) than do other NSaS. The basis for this enhanced virulence is not known, although both species appear to share more virulence determinants with *S. aureus* (e.g., clumping factor and lipase) than do other NSaS.

The capacity of *S. saprophyticus* to cause UTIs in young women appears related to the presence of adhesins that facilitate adherence to uroepithelial cells. A 160-kDa hemagglutinin/adhesin may contribute to this affinity.

DIAGNOSIS

Although the detection of NSaS at sites of infection or in the bloodstream by standard microbiologic culture methods is not difficult, interpretation of these results is frequently problematic. Because these organisms are present in large numbers on the skin, they often contaminate cultures. It has been estimated that only 10–20% of blood cultures positive for NSaS reflect true bacteremia. Similar problems arise with cultures obtained from other sites. Among the clinical findings suggestive of true bacteremia are fever, evidence of local infection (e.g., erythema or purulent drainage at the IV catheter site), leukocytosis, and systemic signs of sepsis. Laboratory findings suggestive of true bacteremia include repeated isolation of the same strain (i.e., the same species with the same antibiogram or with a closely related DNA fingerprint)

from separate cultures, growth of the strain within 48 h, and bacterial growth in both aerobic and anaerobic bottles.

CLINICAL SYNDROMES

NSaS cause a variety of prosthetic device–related infections, including those that involve prosthetic cardiac valves and joints, vascular grafts, intravascular devices, and CNS shunts. In all of these settings, the clinical presentation is similar. The signs of localized infection are often subtle, the rate of disease progression is slow, and the systemic findings are often limited. Signs of infection, such as purulent drainage, pain at the site, or loosening of prosthetic implants, are sometimes evident. Fever is frequently but not always present, and there may be mild leukocytosis. Acute-phase reactant levels, erythrocyte sedimentation rate, and C-reactive protein concentration may be elevated.

Infections that are not associated with prosthetic devices include, as noted, native-valve endocarditis due to NSaS, which accounts for ~5% of cases. Infections in preterm infants and neutropenic patients are often associated with the need for intravascular devices. *S. lugdunensis* appears to be a more aggressive pathogen in this setting, causing greater mortality and rapid valvular destruction with abscess formation than other NSaS.

TREATMENT

Staphylococcal Infections

GENERAL PRINCIPLES OF THERAPY

Source control (e.g., incision and drainage of suppurative collections or removal of infected prosthetic devices), coupled with rapid institution of appropriate antimicrobial therapy, is essential for the management of all staphylococcal infections. The emergence of MRSA as a community-based pathogen has increased the importance of culturing all sites of infection in order to determine antimicrobial susceptibility.

DURATION OF ANTIMICROBIAL THERAPY

Therapy for *S. aureus* bacteremia is generally prolonged (4–6 weeks) because of the high risk of complications (e.g., endocarditis, metastatic foci of infection). Among the findings associated with complicated bacteremias are (1) persistently positive blood cultures 96 h after institution of therapy, (2) acquisition of the infection in the community, (3) failure to promptly remove or drain an identified focus of infection (i.e., an intravascular catheter), and (4) the presence of deep-seated infections. Patients with uncomplicated bacteremias are defined by a removable focus of infection, prompt response to antimicrobial therapy (i.e., no fever or positive blood cultures after 3–4 days), no evidence of metastatic foci of infection, and no implanted prostheses. In these latter infections, short-course therapy (2 weeks) can be given; however, these findings are not always predictive of uncomplicated bacteremias. Transesophageal echocardiography to rule out endocarditis is generally necessary because neither clinical nor laboratory findings can reliably detect cardiac involvement. A thorough radiologic investigation to identify potential metastatic collections is also indicated. All symptomatic body sites must be carefully evaluated.

Recent studies have demonstrated that parenteral therapy is not always necessary to complete a course of treatment for invasive staphylococcal infections such as endocarditis or osteomyelitis.

NSaS treatment is complicated by the possibility that a single isolate may be a contaminant. Therapy for 7–14 days is recommended for documented infections (i.e., blood cultures of the same strain ≥24 hours apart) in the absence of endocarditis or additional sites of infection.

CHOICE OF ANTIMICROBIAL AGENTS

The choice of antimicrobial agents to treat both coagulase-positive and coagulase-negative staphylococcal infections is often difficult because of the prevalence of multidrug-resistant strains and the limited number of clinical trials that have compared the available agents. Staphylococcal resistance to most antibiotic families, including β-lactams, aminoglycosides, fluoroquinolones, and (to a lesser extent) glycopeptides, has increased. This trend is even more apparent with NSaS; >80% of nosocomial isolates are resistant to methicillin, and these methicillin-resistant strains are often resistant to many other antibiotics. Because the selection of antimicrobial agents for *S. aureus* infections is similar to that for NSaS infections, treatment options for these pathogens are discussed together and are summarized in **Table 147-3**.

Few strains of staphylococci (≤5%) remain susceptible to penicillin. This is a result of the widespread dissemination of plasmids containing the enzyme penicillinase. Penicillin-resistant isolates are treated with semisynthetic penicillinase-resistant penicillins (SPRPs), such as oxacillin or nafcillin. Methicillin, the first of the SPRPs, is no longer used. Cephalosporins are alternative therapeutic agents for these infections. Second- and third-generation cephalosporins offer no therapeutic advantage over first-generation cephalosporins for the treatment of staphylococcal infections, and some third-generation cephalosporins (e.g., ceftazidime) have considerably less activity. The carbapenems have excellent activity against methicillin-sensitive *S. aureus* but not against MRSA.

The isolation of MRSA was reported within 1 year of the introduction of methicillin. Since then, the prevalence of MRSA has steadily increased. In many U.S. hospitals, 40–50% of *S. aureus* isolates are resistant to methicillin. Resistance to methicillin indicates resistance to all SPRPs as well as to all cephalosporins (except ceftaroline). Production of a novel penicillin-binding protein (PBP2a) is responsible for methicillin resistance. This protein is synthesized by the *mecA* gene, which (as stated above) is part of a large mobile genetic element—a pathogenicity or genomic island—called SCC*mec*. It is hypothesized that *mecA* was acquired via horizontal transfer from related staphylococcal species. Phenotypic expression of methicillin resistance may be constitutive (i.e., expressed in all cells in a population) or heterogeneous (i.e., displayed by only a proportion of the total cell population). Detection of methicillin resistance is enhanced by growth of cultures at reduced temperatures (≤35°C for 24 h) and with increased concentrations of salt in the medium. Culture techniques are increasingly being replaced by PCR-based or other methods (e.g., latex agglutination) that allow for the rapid detection of methicillin resistance.

Either vancomycin or daptomycin are recommended as the drugs of choice for the treatment of invasive MRSA infections. MRSA susceptibility to vancomycin has decreased in many areas of the world. It is important to note that vancomycin is less effective than SPRPs for the treatment of infections due to methicillin-susceptible strains. In patients with a history of serious β-lactam allergies, alternatives to SPRPs for the treatment of invasive infections should be used only after careful consideration. Desensitization to β-lactams remains an option for life-threatening infections.

Three types of staphylococcal resistance to vancomycin have emerged. (1) Minimal inhibitory concentration (MIC; an in vitro measure of susceptibility) "creep" refers to the incremental increase in vancomycin MICs that has been detected in various geographic areas. Studies suggest that morbidity and mortality may be increased in infections due to *S. aureus* strains with vancomycin MICs of ≥1.5 μg/mL. (2) In 1997, an *S. aureus* strain with reduced susceptibility to vancomycin (vancomycin-intermediate *S. aureus* [VISA]) was reported from Japan. Subsequently, additional VISA clinical isolates were reported. These strains were resistant to methicillin and many other antimicrobial agents. The VISA strains appear to evolve (under vancomycin selective pressure) from strains that are susceptible to vancomycin but are heterogeneous, with a small proportion of the bacterial population expressing the resistance phenotype. The mechanism of VISA resistance is in part due to an abnormally thick cell wall. Vancomycin is trapped by the abnormal peptidoglycan cross-linking and is unable to gain access to its target site. Regulatory genes involved in cell wall metabolism appear to play an important role in this type of resistance. (3) In 2002, the first clinical isolate of fully vancomycin-resistant *S. aureus* (VRSA) was reported. Resistance in this and several additional clinical isolates

TABLE 147-3 Antimicrobial Therapy for Staphylococcal Infections[a]

SENSITIVITY/RESISTANCE OF ISOLATE	DRUG OF CHOICE	ALTERNATIVE(S)	COMMENTS
Parenteral Therapy for Serious Infections			
Sensitive to penicillin	Penicillin G (4 mU q4h)	Nafcillin or oxacillin (2 g q4h), cefazolin (2 g q8h), vancomycin (15–20 mg/kg q8h[b])	Fewer than 5% of isolates are sensitive to penicillin. The clinical microbiology laboratory must verify that the strain is not a β-lactamase producer.
Sensitive to methicillin; Resistant to penicillin	Nafcillin or oxacillin (2 g q4h)	Cefazolin (2 g q8h), daptomycin (6–10 mg/kg IV q24h[b,d]), vancomycin (15–20 mg/kg q8h[b])	Patients with a penicillin allergy can be treated with a cephalosporin if the allergy does not involve an anaphylactic or accelerated reaction; desensitization to β-lactams may be indicated in selected cases of serious infection when maximal bactericidal activity is needed (e.g., prosthetic-valve endocarditis[c]). Vancomycin is a less effective option than a β-lactam.
Resistant to methicillin	Vancomycin (15–20 mg/kg q8–12h[b]), daptomycin (6–10 mg/kg IV q24h[b,d]) for bacteremia, endocarditis, osteomyelitis, and complicated skin infections	Linezolid (600 mg q12h PO or IV), ceftaroline (600 mg IV q8–12h), telavancin (7.5–10 mg/kg IV q24h)[b], TMP-SMX (5 mg [based on TMP]/kg IV q8–12h)[f] Additional agents include tedizolid (200 mg once daily IV), oritavancin (single dose of 1200 mg), dalbavancin (single dose of 1500 mg), delafloxacin (300 mg q 12 h IV), omadacycline 100 mg OD). These drugs are primarily approved for the treatment of skin and soft tissue infections.[g]	Sensitivity testing is necessary before an alternative drug is selected. The efficacy of adjunctive therapy is not well established in many settings. Linezolid, ceftaroline, and telavancin have in vitro activity against most VISA and VRSA strains. See footnote for treatment of prosthetic-valve endocarditis.[c]
Resistant to methicillin with intermediate or complete resistance to vancomycin[e]	Daptomycin (6–10 mg/kg q24h[b,d]) for bacteremia, endocarditis, osteomyelitis, and complicated skin infections	Same as for methicillin-resistant strains (check antibiotic susceptibilities) *or* Ceftaroline (600 mg IV q8–12h) Newer agents include tedizolid (200 mg once daily IV or PO), oritavancin (single dose of 1200 mg), and dalbavancin (single dose of 1500 mg). These drugs are approved only for the treatment of skin and soft tissue infections.	Same as for methicillin-resistant strains; check antibiotic susceptibilities. Ceftaroline is used either alone or in combination with daptomycin.
Not yet known (i.e., empirical therapy)	Vancomycin (15–20 mg/kg q8–12h[b]), daptomycin (6–10 mg/kg q24h[b,d]) for bacteremia, endocarditis, osteomyelitis, and complicated skin infections	—	Empirical therapy is given when the susceptibility of the isolate is not known. Vancomycin with or without a β-lactam is recommended for suspected community- or hospital-acquired *Staphylococcus aureus* infections because of the increased frequency of methicillin-resistant strains in the community. If isolates with an elevated MIC to vancomycin (≥1.5 μg/mL) are common in the community, daptomycin may be preferable.
Oral Therapy for Skin and Soft Tissue Infections			
Sensitive to methicillin	Dicloxacillin (500 mg qid), cephalexin (500 mg qid), or cefadroxil (1 g q12h)	Minocycline or doxycycline (100 mg q12h[b]), TMP-SMX (1 or 2 DS tablets bid), clindamycin (300–450 mg tid), linezolid (600 mg PO q12h), tedizolid (200 mg PO q24h)	It is important to know the antibiotic susceptibility of isolates in the specific geographic region. All collections should be drained, and drainage should be cultured.
Resistant to methicillin	Clindamycin (300–450 mg tid), TMP-SMX (1 or 2 DS tablets bid), minocycline or doxycycline (100 mg q12h[b]), linezolid (600 mg bid), or tedizolid (200 mg once daily)	Delafloxacin 450 mg q 12 h, omadacycline 300 mg OD	It is important to know the antibiotic susceptibility of isolates in the specific geographic region. All collections should be drained, and drainage should be cultured.

[a]Recommended dosages are for adults with normal renal and hepatic function. [b]The dosage must be adjusted for patients with reduced creatinine clearance. [c]For the treatment of prosthetic-valve endocarditis, the addition of gentamicin (1 mg/kg q8h) and rifampin (300 mg PO q8h) is recommended, with adjustment of the gentamicin dosage if the creatinine clearance rate is reduced. [d]Daptomycin cannot be used for the treatment of pneumonia. [e]Vancomycin-resistant *S. aureus* isolates from clinical infections have been reported. [f]TMP-SMX may be less effective than vancomycin. [g]Limited data are available on the efficacy of these drugs for the treatment of invasive infections.

Abbreviations: DS, double-strength; TMP-SMX, trimethoprim-sulfamethoxazole; VISA, vancomycin-intermediate *S. aureus;* VRSA, vancomycin-resistant *S. aureus.*

Source: Modified from C Liu et al: Clin Infect Dis 52:285, 2011; DL Stevens et al: Clin Infect Dis 59:148, 2014; DL Stevens et al: Med Lett Drugs Ther 56:39, 2014; and LM Baddour et al: Circulation 132:1435, 2015.

was due to the presence of *vanA*, the gene responsible for expression of vancomycin resistance in enterococci. This observation suggested that resistance was acquired as a result of horizontal conjugal transfer from a vancomycin-resistant strain of *Enterococcus faecalis*. Several of the patients infected with the VRSA strain had both MRSA and vancomycin-resistant enterococci cultured from infection sites. The *vanA* gene is responsible for the synthesis of the dipeptide D-Ala-D-Lac in place of D-Ala-D-Ala. Vancomycin cannot bind to the altered peptide. While isolates with MICs of ≥1.5 μg/mL have been relatively common in some areas, VISA and VRSA isolates are uncommon.

Daptomycin, a parenteral bactericidal agent with antistaphylococcal activity, is approved for the treatment of bacteremia (including right-sided endocarditis) and complicated skin infections. It is not effective in respiratory infections. This drug has a unique mechanism of action: it disrupts the cytoplasmic membrane. Staphylococcal resistance to daptomycin has been reported. Resistance can emerge during therapy; patients previously treated with vancomycin may have elevated daptomycin MICs. Patients need to be monitored for rhabdomyolysis with creatine phosphokinase measurement and for eosinophilic pneumonia.

Linezolid—the first oxazolidinone—is bacteriostatic against staphylococci; it offers the advantage of comparable bioavailability after oral or parenteral administration. Cross-resistance with other inhibitors of protein synthesis has not been detected. Resistance to linezolid has been increasingly reported. Serious adverse reactions to linezolid include thrombocytopenia, occasional cases of neutropenia, and rare instances of lactic acidosis or peripheral and optic neuropathy. These reactions tend to occur after relatively prolonged courses of therapy.

Tedizolid, a second oxazolidinone, is available as both oral and parenteral preparations. It exhibits enhanced in vitro activity against antibiotic-resistant gram-positive bacteria, including staphylococci. Tedizolid is administered once a day. Data on its efficacy for the treatment of deep-seated infections are limited.

Ceftaroline is a fifth-generation cephalosporin with bactericidal activity against MRSA (including strains with reduced susceptibility to vancomycin and daptomycin). It is generally well tolerated. Ceftaroline is approved for use in nosocomial pneumonias and for SSTIs. It has increasingly been used to treat invasive MRSA infections.

Telavancin is a parenteral lipoglycopeptide derivative of vancomycin that is approved for the treatment of complicated SSTIs and for nosocomial pneumonias. The drug has two targets: the cell wall and the cell membrane. It remains active against VISA strains. Because of its potential nephrotoxicity, telavancin should be avoided in patients with renal disease.

Dalbavancin and oritavancin are long-acting, parenterally administered lipoglycopeptides that have been used to treat complicated SSTIs. Because of their long half-lives, they can be administered on a weekly basis. Both have been used as single-dose regimens for the treatment of SSTIs. Anecdotal data support their use for the treatment of invasive staphylococcal infections.

Although the quinolones are active against staphylococci in vitro, the frequency of staphylococcal resistance to these agents has increased, especially among methicillin-resistant isolates. Of particular concern in MRSA is the possibility of quinolone resistance emerging during therapy. Therefore, quinolones are not recommended for the treatment of MRSA infections. Resistance to the quinolones is most commonly chromosomal and results from mutations of the topoisomerase IV or DNA gyrase genes, although multidrug efflux pumps also may contribute. Although the newer quinolones exhibit increased in vitro activity against staphylococci, it is uncertain whether this increase translates into enhanced in vivo activity. Delafloxacin, a fluoroquinolone with broad-spectrum activity, has excellent activity against MRSA, retaining activity against some isolates resistant to other fluoroquinolones.

Tigecycline, a broad-spectrum minocycline analogue, has bacteriostatic activity against MRSA and is approved for use in SSTIs as well as intraabdominal infections caused by *S. aureus*. It is not recommended for the treatment of invasive infections.

Other older antibiotics, such as minocycline, doxycycline, clindamycin, and trimethoprim-sulfamethoxazole, continue to be successfully used to treat MRSA infections.

The benefit of antistaphylococcal combinations to enhance bactericidal activity in the treatment of deep-seated infections remains controversial. Clinical studies have not documented a therapeutic benefit from the addition of gentamicin or rifampin to single-drug regimens; recent reports have raised concern about the potential nephrotoxicity of gentamicin and adverse reactions from, or drug interactions with, rifampin. As a result, the use of gentamicin in combination with β-lactams or other antimicrobial agents is no longer routinely recommended for the treatment of invasive infections such as native-valve endocarditis. Rifampin continues to be used for the treatment of prosthetic device–related infections and for osteomyelitis.

Omadacycline and eravacycline are broad-spectrum semisynthetic tetracycline derivatives with activity against MRSA. They are currently approved for the treatment of SSTIs.

The use of bacteriophages with activity against staphylococci is now being investigated as adjunctive therapy in invasive infections.

ANTIMICROBIAL THERAPY FOR SELECTED SETTINGS

Empirical Therapy Empirical coverage for MRSA is indicated when antibiotic susceptibility is not known. Vancomycin or daptomycin are generally recommended. It remains uncertain whether daptomycin is preferable when elevated vancomycin MICs (>1.5 μg/mL) are common in a specific locale.

Salvage Therapy Salvage therapy for complicated *S. aureus* infections is sometimes needed when the bacteremia persists (i.e., for more than 3 or 4 days) despite appropriate treatment. The risk of a poor outcome (i.e., increased mortality, metastatic infections) is increased with the duration of bacteremia. There is little high-quality evidence to serve as a guide to salvage therapy. The combination of daptomycin or vancomycin with a β-lactam antibiotic (e.g., ceftaroline) has been successfully used to treat patients with persistent MRSA bacteremia, even those patients with isolates displaying reduced susceptibility to these antimicrobial agents. This combination appears to enhance the bactericidal activity of daptomycin by reducing the bacterial cell-surface charge and thus allowing enhanced daptomycin binding. For vancomycin, the combination may allow more strategic binding to the target site with reduced cell-wall thickness. Other combinations have included trimethoprim-sulfamethoxazole or rifampin combined with daptomycin. Linezolid or ceftaroline have also been used as single alternative agents.

Endocarditis *S. aureus* endocarditis is usually an acute, life-threatening infection. Thus, prompt collection of blood for cultures should be followed by immediate institution of empirical antimicrobial therapy. For native-valve endocarditis, therapy with a β-lactam is recommended. If a MRSA strain is isolated, vancomycin (15–20 mg/kg every 8–12 h, given in equal doses up to a total of 2 g, with the dose adjusted in the case of renal disease) or daptomycin (6–10 mg/kg every 24 h) is recommended. The vancomycin dose should be adjusted on the basis of trough drug levels. Patients are generally treated for 6 weeks. For prosthetic-valve endocarditis, surgery in addition to antibiotic therapy is often necessary. The combination of a β-lactam agent—or, if the isolate is β-lactam-resistant, vancomycin or daptomycin—with an aminoglycoside (gentamicin, 1 mg/kg IV every 8 h) for 2 weeks and rifampin (300 mg orally or IV every 8 h) for ≥6 weeks is recommended.

Bone and Joint Infections For hematogenous osteomyelitis or septic arthritis in children, a 4-week course of therapy is usually adequate. In adults, treatment is often more prolonged. For chronic forms of osteomyelitis, surgical debridement is necessary in combination with antimicrobial therapy. For joint infections, a critical component of therapy is the repeated aspiration or arthroscopy of

the affected joint to prevent damage from leukocytes. The combination of rifampin with ciprofloxacin has been used successfully to treat or suppress prosthetic-joint infections, especially when the device cannot be removed. The efficacy of this combination may reflect enhanced activity against staphylococci in biofilms as well as the attainment of effective intracellular concentrations.

Skin and Soft Tissue Infections The increase in SSTIs caused by CA-MRSA has drawn attention to the need for initiation of appropriate empirical therapy. Even small abscesses appear to benefit from antibiotic therapy in addition to incision and drainage. Antibiotics are selected depending on local antibiotic susceptibility data; a number of oral agents have been used to treat these infections, including clindamycin, trimethoprim-sulfamethoxazole, doxycycline, linezolid, and tedizolid. Parenteral therapy is reserved for more complicated infections.

Toxic Shock Syndrome Treatment of shock is the mainstay of therapy for TSS. Both fluids and pressors may be necessary. Tampons or other packing material should be promptly removed. Some investigators recommend therapy with a combination of clindamycin and a semisynthetic penicillin or (if the isolate is resistant to methicillin) vancomycin. Clindamycin is advocated because, as a protein synthesis inhibitor, it reduces toxin production. Linezolid also appears to be effective. A semisynthetic penicillin or a glycopeptide is recommended to eliminate any potential focus of infection as well as to eradicate persistent carriage that might increase the possibility of recurrence. Intravenous immunoglobulin to treat TSS is of uncertain benefit. Glucocorticoids are not recommended for the treatment of this disease.

Other Toxin-Mediated Diseases Therapy for staphylococcal food poisoning is entirely supportive. For SSSS, antistaphylococcal therapy targets the primary site of infection.

NONTRADITIONAL APPROACHES TO ANTI-STAPHYLOCOCCAL THERAPY

In addition to the development of new antibiotics, new and nontraditional approaches to therapy are currently being investigated. These include the use of phages or phage-derived peptides, as well as probiotics and anti-virulence strategies that target selected virulence determinants.

PREVENTION

Primary prevention of *S. aureus* infections in the hospital setting involves hand washing and careful attention to appropriate isolation procedures. Through careful screening for MRSA carriage and strict isolation practices, several Scandinavian countries have been remarkably successful at preventing the introduction and dissemination of MRSA in hospitals.

Decolonization strategies, using both universal and targeted approaches with topical agents (e.g., mupirocin) to eliminate nasal colonization and/or chlorhexidine to eliminate colonization of additional body sites with *S. aureus*, have been successful in some clinical settings where the risk of infection is high (e.g., intensive care units). An analysis of clinical trials suggests that decolonization can reduce the incidence of postsurgical infections among people nasally colonized with *S. aureus*. The risk of recurrent admissions among patients with *S. aureus* bacteremia following discharge is high (approximately 22% within 30 days). Decolonization following discharge with mupirocin and chlorhexidine can lower the incidence of recurrent infections.

"Bundling" (the application of selected medical interventions in a sequence of prescribed steps) has reduced rates of nosocomial infections related to procedures such as the insertion of intravenous catheters, in which staphylococci are among the most common pathogens **(see Table 142-1)**. A number of immunization strategies to prevent *S. aureus* infections—both active (e.g., capsular polysaccharide–protein conjugate vaccine) and passive (e.g., clumping factor antibody)—have been investigated. However, to date, none has been successful for either prophylaxis or therapy in clinical trials.

Strategies to prevent recurrent *S. aureus* infections in the community have had limited success. Decolonization with intranasal mupirocin and chlorhexidine washes of the infected individual and the additional decolonization of household members combined with environmental cleaning of surfaces and personal items have all been studied. For individuals with extensive skin disease and recurrent infections, the use of bleach baths (e.g., one-half cup of household bleach in a half-filled bathtub) 15 minutes three times weekly may be useful.

148 Streptococcal Infections

Michael R. Wessels

Many varieties of streptococci are found as part of the normal flora colonizing the human respiratory, gastrointestinal, and genitourinary tracts. Several species are important causes of human disease. Group A *Streptococcus* (GAS, *Streptococcus pyogenes*) is responsible for streptococcal pharyngitis, one of the most common bacterial infections of school-age children, and for the postinfectious syndromes of acute rheumatic fever (ARF) and poststreptococcal glomerulonephritis (PSGN). Group B *Streptococcus* (GBS, *Streptococcus agalactiae*) is the leading cause of bacterial sepsis and meningitis in newborns and a major cause of endometritis and fever in parturient women. Viridans streptococci are the most common cause of bacterial endocarditis. Enterococci, which are morphologically similar to streptococci, are now considered a separate genus on the basis of DNA homology studies. Thus, the species previously designated as *Streptococcus faecalis* and *Streptococcus faecium* have been renamed *Enterococcus faecalis* and *Enterococcus faecium*, respectively. **The enterococci are discussed in Chap. 149.**

Streptococci are gram-positive, spherical to ovoid bacteria that characteristically form chains when grown in liquid media. Most streptococci that cause human infections are facultative anaerobes, although some are strict anaerobes. Streptococci are relatively fastidious organisms, requiring enriched media for growth in the laboratory. Clinicians and clinical microbiologists identify streptococci by several classification systems, including hemolytic pattern, Lancefield group, species name, and common or trivial name. Many streptococci associated with human infection produce a zone of complete (β) hemolysis around the bacterial colony when cultured on blood agar. The β-hemolytic streptococci that form large (≥0.5-mm) colonies on blood agar can be classified by the Lancefield system, a serologic grouping based on the reaction of specific antisera with bacterial cell-wall carbohydrate antigens. With rare exceptions, organisms belonging to Lancefield groups A, B, C, and G are all β-hemolytic, and each

TABLE 148-1 Classification of Streptococci

LANCEFIELD GROUP	REPRESENTATIVE SPECIES	HEMOLYTIC PATTERN	TYPICAL INFECTIONS
A	*S. pyogenes*	β	Pharyngitis, impetigo, cellulitis, scarlet fever
B	*S. agalactiae*	β	Neonatal sepsis and meningitis, puerperal infection, urinary tract infection, diabetic ulcer infection, endocarditis
C, G	*S. dysgalactiae* subsp. *equisimilis*	β	Cellulitis, bacteremia, endocarditis
D	Enterococci[a]: *E. faecalis, E. faecium*	Usually nonhemolytic	Urinary tract infection, nosocomial bacteremia, endocarditis
	Nonenterococci: *S. gallolyticus* (formerly *S. bovis*)	Usually nonhemolytic	Bacteremia, endocarditis
Variable or nongroupable	Viridans streptococci: *S. sanguis, S. mitis*	α	Endocarditis, dental abscess, brain abscess
	Intermedius or *milleri* group: *S. intermedius, S. anginosus, S. constellatus*	Variable	Brain abscess, visceral abscess
	Anaerobic streptococci[b]: *Peptostreptococcus magnus*	Usually nonhemolytic	Sinusitis, pneumonia, empyema, brain abscess, liver abscess

[a]See Chap. 149. [b]See Chap. 177.

is associated with characteristic patterns of human infection. Other streptococci produce a zone of partial (α) hemolysis, often imparting a greenish appearance to the agar. These α-hemolytic streptococci are further identified by biochemical testing and include *Streptococcus pneumoniae* **(Chap. 146)**, an important cause of pneumonia, meningitis, and other infections, and the several species referred to collectively as the *viridans streptococci*, which are part of the normal oral flora and are important agents of subacute bacterial endocarditis. Finally, some streptococci are nonhemolytic, a pattern sometimes called γ *hemolysis*. Among the organisms classified serologically as group D streptococci, the enterococci are assigned to a distinct genus **(Chap. 149)**. The classification of the major streptococcal groups causing human infections is outlined in **Table 148-1**.

GROUP A STREPTOCOCCI

Lancefield group A consists of a single species, *S. pyogenes*. As its species name implies, this organism is associated with a variety of suppurative infections. In addition, GAS can trigger the postinfectious syndromes of ARF (which is uniquely associated with *S. pyogenes* infection; **Chap. 359**) and PSGN **(Chap. 314)**.

Worldwide, GAS infections and their postinfectious sequelae (primarily ARF and rheumatic heart disease) account for an estimated 500,000 deaths per year. Although data are incomplete, the incidence of all forms of GAS infection and that of rheumatic heart disease are thought to be tenfold higher in resource-limited countries than in developed countries **(Fig. 148-1)**.

PATHOGENESIS

GAS elaborates a number of cell-surface components and extracellular products important in both the pathogenesis of infection and the human immune response. The cell wall contains a carbohydrate antigen that may be released by acid treatment. The reaction of such acid extracts with group A–specific antiserum is the basis for definitive identification of a streptococcal strain as *S. pyogenes*. Rarely, the group A antigen may be present on isolates of *S. dysgalactiae ssp. equisimilis*, which usually express the group C or G antigen (see "Streptococci of Groups C and G," below). The major surface protein of GAS is M protein, which is the basis for the serotyping of strains with specific antisera. The M protein molecules are fibrillar structures anchored in the cell wall of the organism that extend as hairlike projections away from the cell surface. The amino acid sequence of the distal or amino-terminal portion of the M protein molecule is variable, accounting for the antigenic variation of the different M types, while more proximal regions of the protein are relatively conserved. Traditional M-typing by serologic methods has been largely supplanted by a newer technique for assignment of M type to GAS isolates by use of the polymerase chain reaction to amplify the variable region of the *emm* gene, which encodes M protein. DNA sequence analysis of the amplified gene segment can be compared with an extensive database (developed at the Centers for Disease Control and Prevention [CDC]) for assignment of *emm* type. Use of *emm* typing has increased the number of identified *emm* types to more than 200. This method eliminates the need for typing sera, which are available in only a few reference laboratories.

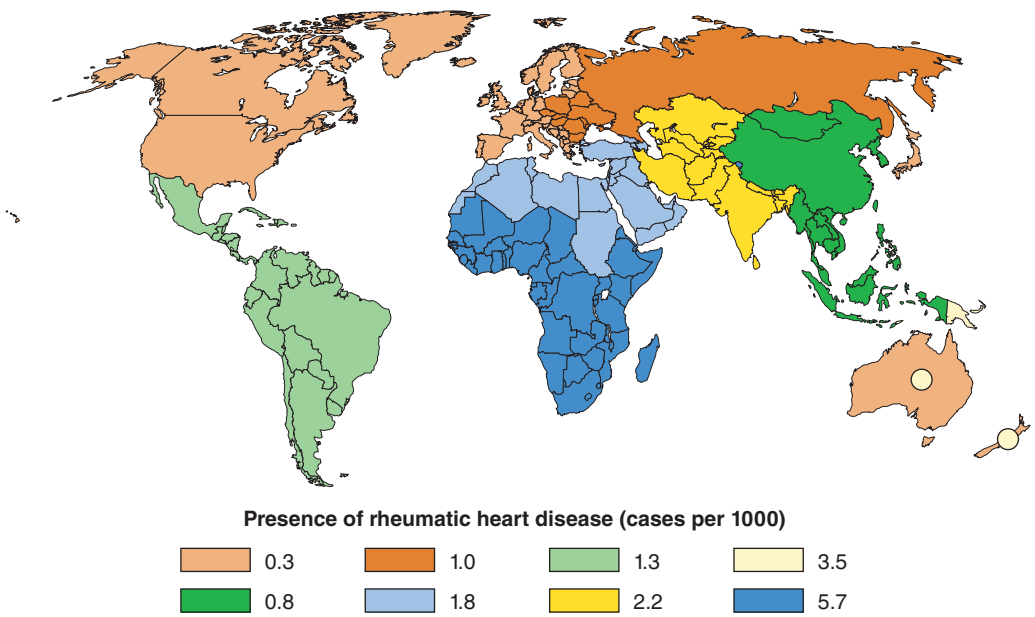

FIGURE 148-1 Prevalence of rheumatic heart disease in children 5–14 years old. The *circles* within Australia and New Zealand represent indigenous populations (and also Pacific Islanders in New Zealand). *(Reproduced with permission from JR Carapetis et al: The global burden of group A streptococcal diseases. Lancet Infect Dis 5:685, 2005.)*

The presence of M protein on a GAS isolate correlates with its capacity to resist phagocytic killing in fresh human blood. This phenomenon appears to be due, at least in part, to the binding of plasma fibrinogen to M protein molecules on the streptococcal surface, which interferes with complement activation and deposition of opsonic complement fragments on the bacterial cell. This resistance to phagocytosis may be overcome by M protein–specific antibodies; thus, individuals with antibodies to a given M type acquired as a result of prior infection are protected against subsequent infection with organisms of the same M type but not against that with different M types.

GAS also elaborates, to varying degrees, a polysaccharide capsule composed of hyaluronic acid. While most clinical isolates of GAS produce a hyaluronic acid capsule, strains of M type 4 or 22 lack a capsule, as do some isolates of M type 89. The fact that acapsular strains have been associated with pharyngitis and invasive infection implies that the capsule is not essential for virulence. The production of large amounts of capsule by certain strains imparts a characteristic mucoid appearance to the colonies. The capsular polysaccharide plays an important role in protecting GAS from ingestion and killing by phagocytes. In contrast to M protein, the hyaluronic acid capsule is a weak immunogen, and antibodies to hyaluronate have not been shown to be important in protective immunity. The presumed explanation is the apparent structural identity between streptococcal hyaluronic acid and the hyaluronic acid of mammalian connective tissues. The capsular polysaccharide may also play a role in GAS colonization of the pharynx by binding to CD44, a hyaluronic acid–binding protein expressed on human pharyngeal epithelial cells.

GAS produces a large number of extracellular products that may be important in local and systemic toxicity and in the spread of infection through tissues. These products include streptolysins S and O, toxins that damage cell membranes and account for the hemolysis produced by the organisms; streptokinase; DNAses; SpyCEP, a serine protease that cleaves and inactivates the chemoattractant cytokine interleukin 8, thereby inhibiting neutrophil recruitment to the site of infection; and several pyrogenic exotoxins. Previously known as erythrogenic toxins, the pyrogenic exotoxins cause the rash of scarlet fever. Since the mid-1980s, pyrogenic exotoxin–producing strains of GAS have been linked to unusually severe invasive infections, including necrotizing fasciitis and the streptococcal toxic shock syndrome (TSS). Several extracellular products stimulate specific antibody responses useful for serodiagnosis of recent streptococcal infection. Tests for antibodies to streptolysin O and DNase B are used most commonly for detection of preceding streptococcal infection in cases of suspected ARF or PSGN.

CLINICAL MANIFESTATIONS

Pharyngitis Although seen in patients of all ages, GAS pharyngitis is one of the most common bacterial infections of childhood, accounting for 20–40% of all cases of exudative pharyngitis in children; it is rare among those under the age of 3. Younger children may manifest streptococcal infection with a syndrome of fever, malaise, and lymphadenopathy without exudative pharyngitis. Infection is acquired through contact with another individual carrying the organism. Respiratory droplets are the usual mechanism of spread, although other routes, including food-borne outbreaks, have been well described. The incubation period is 1–4 days. Symptoms include sore throat, fever and chills, malaise, and sometimes abdominal complaints and vomiting, particularly in children. Both symptoms and signs are quite variable, ranging from mild throat discomfort with minimal physical findings to high fever and severe sore throat associated with intense erythema and swelling of the pharyngeal mucosa and the presence of purulent exudate over the posterior pharyngeal wall and tonsillar pillars. Enlarged, tender anterior cervical lymph nodes commonly accompany exudative pharyngitis.

The differential diagnosis of streptococcal pharyngitis includes the many other bacterial and viral etiologies (Table 148-2). Streptococcal infection is an unlikely cause when symptoms and signs suggestive of viral infection are prominent (conjunctivitis, coryza, cough, hoarseness, or discrete ulcerative lesions of the buccal or pharyngeal mucosa). Because of the range of clinical presentations of streptococcal pharyngitis and the large number of other agents that can produce the same clinical picture, diagnosis of streptococcal pharyngitis on clinical grounds alone is not reliable. The throat culture remains the diagnostic gold standard. Culture of a throat specimen that is properly collected (i.e., by vigorous rubbing of a sterile swab over both tonsillar pillars) and properly processed is the most sensitive and specific means of definitive diagnosis. A rapid diagnostic test for latex agglutination or enzyme immunoassay of swab specimens is a useful adjunct to throat culture. While precise figures on sensitivity and specificity vary, rapid diagnostic tests generally are >95% specific. Thus, a positive result can be relied upon for definitive diagnosis and eliminates the need for throat culture. In settings in which the incidence of rheumatic fever is low, a confirmatory throat culture is not recommended for routine evaluation of most adults with a negative rapid test. However, because rapid diagnostic tests are less sensitive than throat culture (relative sensitivity in comparative studies, 70–90%), a negative result should be confirmed by throat culture for individuals at higher risk such as those with a history of rheumatic fever or immunocompromise or a family member with such a history; patients living in congregate settings of young adults such as dormitories or military facilities where the incidence of GAS pharyngitis may be elevated; individuals with household exposure to someone with proven GAS infection; and those living in an area in which rheumatic fever is endemic.

TABLE 148-2 Infectious Etiologies of Acute Pharyngitis

ORGANISM	ASSOCIATED CLINICAL SYNDROME(S)
Viruses	
Rhinovirus	Common cold
Coronavirus	Common cold, COVID-19
Adenovirus	Pharyngoconjunctival fever
Influenza virus	Influenza
Parainfluenza virus	Cold, croup
Coxsackievirus	Herpangina, hand-foot-and-mouth disease
Herpes simplex virus	Gingivostomatitis (primary infection)
Epstein-Barr virus	Infectious mononucleosis
Cytomegalovirus	Mononucleosis-like syndrome
HIV	Acute (primary) infection syndrome
Bacteria	
Group A streptococci	Pharyngitis, scarlet fever
Group C or G streptococci	Pharyngitis
Mixed anaerobes	Vincent's angina
Arcanobacterium haemolyticum	Pharyngitis, scarlatiniform rash
Neisseria gonorrhoeae	Pharyngitis
Treponema pallidum	Secondary syphilis
Francisella tularensis	Pharyngeal tularemia
Corynebacterium diphtheriae	Diphtheria
Yersinia enterocolitica	Pharyngitis, enterocolitis
Yersinia pestis	Plague
Chlamydiae	
Chlamydia pneumoniae	Bronchitis, pneumonia
Chlamydia psittaci	Psittacosis
Mycoplasmas	
Mycoplasma pneumoniae	Bronchitis, pneumonia

TREATMENT

GAS Pharyngitis

In the usual course of uncomplicated streptococcal pharyngitis, symptoms resolve after 3–5 days. The course is shortened little by treatment, which is given primarily to prevent suppurative complications and ARF. Prevention of ARF depends on eradication of the organism from the pharynx, not simply on resolution of symptoms, and requires 10 days of penicillin treatment (Table 148-3). A first-generation cephalosporin, such as cephalexin or cefadroxil,

TABLE 148-3 Treatment of Group A Streptococcal Infections

INFECTION	TREATMENT[a]
Pharyngitis	Benzathine penicillin G (1.2 mU IM) *or* penicillin V (250 mg PO tid or 500 mg PO bid) × 10 days (Children <27 kg: Benzathine penicillin G [600,000 units IM] *or* penicillin V [250 mg PO bid or tid] × 10 days)
Impetigo	Same as pharyngitis
Erysipelas/cellulitis	Severe: Penicillin G (1–2 mU IV q4h) Mild to moderate: Procaine penicillin (1.2 mU IM bid)
Necrotizing fasciitis/ myositis	Surgical debridement *plus* penicillin G (2–4 mU IV q4h) *plus* clindamycin[b] (600–900 mg IV q8h)
Pneumonia/empyema	Penicillin G (2–4 mU IV q4h) *plus* drainage of empyema
Streptococcal toxic shock syndrome	Penicillin G (2–4 mU IV q4h) *plus* clindamycin[b] (600–900 mg IV q8h) *plus* IV immunoglobulin[b] (2 g/kg as a single dose)

[a]Penicillin allergy: A first-generation cephalosporin, such as cephalexin or cefadroxil, may be substituted for penicillin in cases of penicillin allergy if the nature of the allergy is not an immediate hypersensitivity reaction (anaphylaxis or urticaria) or another potentially life-threatening manifestation (e.g., severe rash and fever). Alternative agents for oral therapy are erythromycin (10 mg/kg PO qid, up to a maximum of 250 mg per dose) and azithromycin (a 5-day course at a dose of 12 mg/kg once daily, up to a maximum of 500 mg/d). Vancomycin is an alternative for parenteral therapy. [b]Efficacy unproven, but recommended by several experts. See text for discussion.

may be substituted for penicillin in cases of penicillin allergy if the nature of the allergy is not an immediate hypersensitivity reaction (anaphylaxis or urticaria) or another potentially life-threatening manifestation (e.g., severe rash and fever).

Alternative agents are erythromycin and azithromycin. Azithromycin offers the advantages of better gastrointestinal tolerability, once-daily dosing, and a 5-day treatment course. Resistance to erythromycin and other macrolides is common among isolates from several countries, including Spain, Italy, Finland, Japan, and Korea. Macrolide resistance may be becoming more prevalent elsewhere with the increasing use of this class of antibiotics. In areas with resistance rates exceeding 5–10%, macrolides should be avoided unless results of susceptibility testing are known.

Follow-up culture after treatment is no longer routinely recommended but may be warranted in selected cases, such as those involving patients or families with frequent streptococcal infections or those occurring in situations in which the risk of ARF is thought to be high (e.g., when cases of ARF have recently been reported in the community).

Complications Suppurative complications of streptococcal pharyngitis have become uncommon with the widespread use of antibiotics for most symptomatic cases. These complications result from the spread of infection from the pharyngeal mucosa to deeper tissues by direct extension or by the hematogenous or lymphatic route and may include cervical lymphadenitis, peritonsillar or retropharyngeal abscess, sinusitis, otitis media, meningitis, bacteremia, endocarditis, and pneumonia. Local complications, such as peritonsillar or parapharyngeal abscess formation, should be considered in a patient with unusually severe or prolonged symptoms or localized pain associated with high fever and a toxic appearance. Nonsuppurative complications include ARF **(Chap. 358)** and PSGN **(Chap. 314)**, both of which are thought to result from immune responses to streptococcal infection. Penicillin treatment of streptococcal pharyngitis reduces the likelihood of ARF but not that of PSGN.

BACTERIOLOGIC TREATMENT FAILURE AND THE ASYMPTOMATIC CARRIER STATE

Surveillance cultures have shown that up to 20% of individuals in certain populations may have asymptomatic pharyngeal colonization with GAS. There are no definitive guidelines for management of these asymptomatic carriers or of asymptomatic patients who still have a positive throat culture after a full course of treatment for symptomatic pharyngitis. A reasonable course of action is to give a single 10-day course of penicillin for symptomatic pharyngitis and, if positive cultures persist, not to re-treat unless symptoms recur. Studies of the natural history of streptococcal carriage and infection have shown that the risk both of developing ARF and of transmitting infection to others is substantially lower among asymptomatic carriers than among individuals with symptomatic pharyngitis. Therefore, aggressive attempts to eradicate carriage probably are not justified under most circumstances. An exception is the situation in which an asymptomatic carrier is a potential source of infection to others. Outbreaks of food-borne infection and nosocomial puerperal infection have been traced to asymptomatic carriers who may harbor the organisms in the throat, vagina, or anus or on the skin.

TREATMENT

Asymptomatic Pharyngeal Colonization with GAS

When a carrier is transmitting infection to others, attempts to eradicate carriage are warranted. Data are limited on the best regimen to clear GAS after penicillin alone has failed. Regimens reported to have efficacy superior to that of penicillin alone for eradication of carriage include (1) a first-generation cephalosporin such as cephalexin (30 mg/kg; 500 mg maximum) twice daily for 10 days or (2) oral clindamycin (7 mg/kg; 300 mg maximum) three times daily for 10 days. A 10-day course of oral vancomycin (250 mg four times daily) and rifampin (600 mg twice daily) has eradicated rectal colonization. Single-dose azithromycin (20 mg/kg; 1000 mg maximum) has been used for mass prophylaxis/eradication of colonization in outbreak situations.

Scarlet Fever Scarlet fever consists of streptococcal infection, usually pharyngitis, accompanied by a characteristic rash **(Fig. 148-2)**. The rash arises from the effects of one of several toxins, currently designated *streptococcal pyrogenic exotoxins* and previously known as *erythrogenic* or *scarlet fever toxins*. In the past, scarlet fever was thought to reflect infection of an individual lacking toxin-specific immunity with a toxin-producing strain of GAS. Susceptibility to scarlet fever was correlated with results of the Dick test, in which a small amount of erythrogenic toxin injected intradermally produced local erythema in susceptible individuals but elicited no reaction in those with specific immunity. Subsequent studies have suggested that development of the scarlet fever rash may reflect a hypersensitivity reaction requiring prior exposure to the toxin. For reasons that are not clear, scarlet fever has become less common in recent years, although large outbreaks have

FIGURE 148-2 Scarlet fever exanthem. Finely punctate erythema has become confluent (scarlatiniform); petechiae can occur and have a linear configuration within the exanthem in body folds (Pastia's lines). *(From TB Fitzpatrick, RA Johnson, K Wolff: Color Atlas and Synopsis of Clinical Dermatology, 4th ed, New York, McGraw-Hill, 2001, with permission.)*

occurred recently in China and the United Kingdom. The symptoms of scarlet fever are the same as those of pharyngitis alone. The rash typically begins on the first or second day of illness over the upper trunk, spreading to involve the extremities but sparing the palms and soles. The rash is made up of minute papules, giving a characteristic "sandpaper" feel to the skin. Associated findings include circumoral pallor, "strawberry tongue" (enlarged papillae on a coated tongue, which later may become denuded), and accentuation of the rash in skinfolds (*Pastia's lines*). Subsidence of the rash in 6–9 days is followed after several days by desquamation of the palms and soles. The differential diagnosis of scarlet fever includes other causes of fever and generalized rash, such as measles and other viral exanthems, Kawasaki disease, TSS, and systemic allergic reactions (e.g., drug eruptions).

Skin and Soft Tissue Infections GAS—and occasionally other streptococcal species—can cause a variety of infections involving the skin, subcutaneous tissues, muscles, and fascia. While several clinical syndromes offer a useful means for classification of these infections, not all cases fit exactly into one category. The classic syndromes are general guides to predicting the level of tissue involvement in a particular patient, the probable clinical course, and the likelihood that surgical intervention or aggressive life support will be required.

IMPETIGO (PYODERMA)

Impetigo, a superficial infection of the skin, is caused primarily by GAS and occasionally by other streptococci or *Staphylococcus aureus*. Impetigo is seen most often in young children, tends to occur during warmer months, and is more common in semitropical or tropical climates than in cooler regions. Infection is more common among children living under conditions of poor hygiene. Prospective studies have shown that colonization of unbroken skin with GAS precedes clinical infection. Minor trauma, such as a scratch or an insect bite, may then serve to inoculate organisms into the skin. Impetigo is best prevented, therefore, by attention to adequate hygiene. The usual sites of involvement are the face (particularly around the nose and mouth) and the legs, although lesions may occur at other locations. Individual lesions begin as red papules, which evolve quickly into vesicular and then pustular lesions that break down and coalesce to form characteristic honeycomb-like crusts **(Fig. 148-3)**. Lesions generally are not painful, and patients do not appear ill. Fever is not a feature of impetigo and, if present, suggests either infection extending to deeper tissues or another diagnosis. The classic presentation of impetigo usually poses little diagnostic difficulty. Cultures of impetiginous lesions often yield *S. aureus* as well as GAS. In almost all cases, streptococci are isolated initially, and staphylococci appear later, presumably as secondary colonizing flora. In the past, penicillin was nearly always effective against these infections. However, an increasing frequency of penicillin treatment failure suggests that *S. aureus* may have become more prominent as a cause of impetigo. *Bullous impetigo* due to *S. aureus* is distinguished from typical streptococcal infection by more extensive, bullous lesions that break down and leave thin paper-like crusts instead of the thick amber crusts of streptococcal impetigo. Other skin lesions that may be confused with impetigo include herpetic lesions—either those of orolabial herpes simplex or those of chickenpox or zoster. Herpetic lesions can generally be distinguished by their appearance as more discrete, grouped vesicles and by a positive Tzanck test or by herpes simplex virus- or varicella-zoster virus-specific PCR. In difficult cases, cultures of vesicular fluid should yield GAS (or *Staphylococcus aureus*) in impetigo and the responsible virus in herpesvirus infections.

FIGURE 148-3 Impetigo is a superficial streptococcal or *Staphylococcus aureus* infection consisting of honey-colored crusts and erythematous weeping erosions. Occasionally, bullous lesions may be seen. *(Courtesy of Mary Spraker, MD; with permission.)*

TREATMENT

Streptococcal Impetigo

Treatment of streptococcal impetigo is the same as that for streptococcal pharyngitis. In view of evidence that *S. aureus* has become a relatively frequent cause of impetigo, empirical regimens should cover both streptococci and *S. aureus*. For example, either dicloxacillin or cephalexin can be given at a dose of 250 mg four times daily for 10 days. Topical mupirocin ointment also is effective. Culture may be indicated to rule out methicillin-resistant *S. aureus*, especially if the response to empirical treatment is unsatisfactory. In most areas of the world, ARF is not a sequela to streptococcal skin infections, although PSGN may follow either skin or throat infection. The reason for this difference is not known. One hypothesis is that the immune response necessary for development of ARF occurs only after infection of the pharyngeal mucosa. In addition, the strains of GAS that cause pharyngitis are generally of different M protein types than those associated with skin infections; thus the strains that cause pharyngitis may have rheumatogenic potential, while the skin-infecting strains may not. An exception to this general rule may occur among indigenous people in northern Australia and in certain Pacific island groups. Acute rheumatic fever and rheumatic heart disease are prevalent in these populations as is streptococcal impetigo/pyoderma, but not pharyngitis. This epidemiologic pattern has led investigators to suggest that skin infection may trigger acute rheumatic fever in this setting.

CELLULITIS

Inoculation of organisms into the skin may lead to *cellulitis*: infection involving the skin and subcutaneous tissues. The portal of entry may be a traumatic or surgical wound, an insect bite, or any other break in skin integrity. Often, no entry site is apparent. One form of streptococcal cellulitis, *erysipelas*, is characterized by a bright red appearance of the involved skin, which forms a plateau sharply demarcated from surrounding normal skin **(Fig. 148-4)**. The lesion is warm to the touch, may be tender, and appears shiny and swollen. The skin often has a *peau d'orange* texture, which is thought to reflect involvement of superficial lymphatics; superficial blebs or bullae may form, usually 2–3 days after onset. The lesion typically develops over a few hours and is associated with fever and chills. Erysipelas tends to occur on the malar area of the face (often with extension over the bridge of the nose to the contralateral malar region) or on the lower extremities. After one episode, recurrence at the same site—sometimes years later—is not uncommon. Classic cases of erysipelas, with typical features, are almost always due to β-hemolytic streptococci, usually GAS and occasionally group C or G. Often, however, the appearance of streptococcal cellulitis is not sufficiently distinctive to permit a specific diagnosis on clinical grounds. The anatomic area involved may not be typical for erysipelas, the lesion may be less intensely red than usual and may fade into surrounding skin, and/or the patient

FIGURE 148-4 Erysipelas is a streptococcal infection of the superficial dermis and consists of well-demarcated, erythematous, edematous, warm plaques.

may appear only mildly ill. In such cases, it is prudent to broaden the spectrum of empirical antimicrobial therapy to include other pathogens, particularly *S. aureus*, that can produce cellulitis with the same appearance. Staphylococcal infection should be suspected if cellulitis develops around a wound or an ulcer.

Streptococcal cellulitis tends to develop at anatomic sites in which normal lymphatic drainage has been disrupted, such as sites of prior cellulitis, the arm ipsilateral to a mastectomy and axillary lymph node dissection, a lower extremity previously involved in deep venous thrombosis or chronic lymphedema, or the leg from which a saphenous vein has been harvested for coronary artery bypass grafting. The organism may enter via a dermal breach some distance from the eventual site of clinical cellulitis. For example, some patients with recurrent leg cellulitis following saphenous vein removal stop having recurrent episodes only after treatment of tinea pedis on the affected extremity. Fissures in the skin presumably serve as a portal of entry for streptococci, which then produce infection more proximally in the leg at the site of previous injury. Streptococcal cellulitis may also involve recent surgical wounds. GAS is among the few bacterial pathogens that typically produce signs of wound infection and surrounding cellulitis within the first 24 h after surgery. These wound infections are usually associated with a thin exudate and may spread rapidly, either as cellulitis in the skin and subcutaneous tissue or as a deeper tissue infection (see below). Streptococcal wound infection or localized cellulitis may also be associated with *lymphangitis*, manifested by red streaks extending proximally along superficial lymphatics from the infection site.

TREATMENT

Streptococcal Cellulitis

See Table 148-3 and Chap. 129.

DEEP SOFT-TISSUE INFECTIONS

Necrotizing fasciitis (*hemolytic streptococcal gangrene*) involves the superficial and/or deep fascia investing the muscles of an extremity or the trunk. The source of the infection is either the skin, with organisms introduced into tissue through trauma (sometimes trivial), or the bowel flora, with organisms released during abdominal surgery or from an occult enteric source, such as a diverticular or appendiceal abscess. The inoculation site may be inapparent and is often some distance from the site of clinical involvement; e.g., the introduction of organisms via minor trauma to the hand may be associated with clinical infection of the tissues overlying the shoulder or chest. Cases associated with the bowel flora are usually polymicrobial, involving a mixture of anaerobic bacteria (such as *Bacteroides fragilis* or anaerobic streptococci) and facultative organisms (usually gram-negative bacilli). Cases unrelated to contamination from bowel organisms are most commonly caused by GAS alone or in combination with other organisms (most often *S. aureus*). Overall, GAS is implicated in ~60% of cases of necrotizing fasciitis. The onset of symptoms is usually quite acute and is marked by severe pain at the site of involvement, malaise, fever, chills, and a toxic appearance. The physical findings, particularly early on, may not be striking, with only minimal erythema of the overlying skin. Pain and tenderness are usually severe. In contrast, in more superficial cellulitis, the skin appearance is more abnormal, but pain and tenderness are only mild or moderate. As the infection progresses (often over several hours), the severity and extent of symptoms worsen, and skin changes become more evident, with the appearance of dusky or mottled erythema and edema. The marked tenderness of the involved area may evolve into anesthesia as the spreading inflammatory process produces infarction of cutaneous nerves.

Although myositis is more commonly due to *S. aureus* infection, GAS occasionally produces abscesses in skeletal muscles (*streptococcal myositis*), with little or no involvement of the surrounding fascia or overlying skin. The presentation is usually subacute, but a fulminant form has been described in association with severe systemic toxicity, bacteremia, and a high mortality rate. The fulminant form may reflect the same basic disease process seen in necrotizing fasciitis, but with the necrotizing inflammatory process extending into the muscles themselves rather than remaining limited to the fascial layers.

TREATMENT

Deep Soft-Tissue Streptococcal Infections

Once necrotizing fasciitis is suspected, early surgical exploration is both diagnostically and therapeutically indicated. Surgery reveals necrosis and inflammatory fluid tracking along the fascial planes above and between muscle groups, without involvement of the muscles themselves. The process usually extends beyond the area of clinical involvement, and extensive debridement is required. Drainage and debridement are central to the management of necrotizing fasciitis; antibiotic treatment is a useful adjunct (Table 148-3), but surgery is life-saving. Treatment for streptococcal myositis consists of surgical drainage—usually by an open procedure that permits evaluation of the extent of infection and ensures adequate debridement of involved tissues—and high-dose penicillin (Table 148-3).

Pneumonia and Empyema GAS is an occasional cause of pneumonia, generally in previously healthy individuals. The onset of symptoms may be abrupt or gradual. Pleuritic chest pain, fever, chills, and dyspnea are the characteristic manifestations. Cough is usually present but may not be prominent. Approximately one-half of patients with GAS pneumonia have an accompanying pleural effusion. In contrast to the sterile parapneumonic effusions typical of pneumococcal pneumonia, those complicating streptococcal pneumonia are almost always infected. The empyema fluid is usually visible by chest radiography on initial presentation, and its volume may increase rapidly. These pleural collections should be drained early, as they tend to become loculated rapidly, resulting in a chronic fibrotic reaction that may require thoracotomy for removal.

Bacteremia, Puerperal Sepsis, and Streptococcal Toxic Shock Syndrome In adults, GAS bacteremia is usually associated with an identifiable local infection, whereas children may have bacteremia without an associated focal infection. Bacteremia occurs rarely with otherwise uncomplicated pharyngitis, occasionally with cellulitis or pneumonia, and relatively frequently with necrotizing fasciitis. Bacteremia without an identified source raises the possibility of endocarditis, an occult abscess, or osteomyelitis. A variety of focal infections may arise secondarily from streptococcal bacteremia, including endocarditis, meningitis, septic arthritis, osteomyelitis, peritonitis, and visceral abscesses. GAS is occasionally implicated in infectious complications

of childbirth, usually endometritis and associated bacteremia. In the preantibiotic era, puerperal sepsis was commonly caused by GAS; currently, it is more often caused by GBS. Several nosocomial outbreaks of puerperal GAS infection have been traced to an asymptomatic carrier, usually someone present at delivery. The site of carriage may be the skin, throat, anus, or vagina.

Beginning in the late 1980s, several reports described patients with GAS infections associated with shock and multisystem organ failure. This syndrome was called *streptococcal toxic shock syndrome* (*TSS*) because it shares certain features with staphylococcal TSS. In 1993, a case definition for streptococcal TSS was formulated **(Table 148-4)**. The general features of the illness include fever, hypotension, renal impairment, and respiratory distress syndrome. Various types of rash have been described, but rash usually does not develop. Laboratory abnormalities include a marked shift to the left in the white blood cell differential, with many immature granulocytes; hypocalcemia; hypoalbuminemia; and thrombocytopenia, which usually becomes more pronounced on the second or third day of illness. In contrast to patients with staphylococcal TSS, the majority with streptococcal TSS are bacteremic. The most common associated infection is a soft tissue infection—necrotizing fasciitis, myositis, or cellulitis—although a variety of other associated local infections have been described, including pneumonia, peritonitis, osteomyelitis, and myometritis. Streptococcal TSS is associated with a mortality rate of ≥30%, with most deaths secondary to shock and respiratory failure. Because of its rapidly progressive and lethal course, early recognition of the syndrome is essential. Patients should receive aggressive supportive care (fluid resuscitation, pressors, and mechanical ventilation) in addition to antimicrobial therapy and, in cases associated with necrotizing fasciitis, should undergo surgical debridement. Exactly why certain patients develop this fulminant syndrome is not known. Early studies of the streptococcal strains isolated from these patients demonstrated a strong association with the production of pyrogenic exotoxin A. This association has been inconsistent in subsequent case series. Pyrogenic exotoxin A and several other streptococcal exotoxins act as superantigens to trigger release of inflammatory cytokines from T lymphocytes. Fever, shock, and organ dysfunction in streptococcal TSS may reflect, in part, the systemic effects of superantigen-mediated cytokine release.

TREATMENT

Streptococcal Toxic Shock Syndrome

In light of the possible role of pyrogenic exotoxins or other streptococcal toxins in streptococcal TSS, treatment with clindamycin has been advocated by some authorities (Table 148-3), who argue that, through its direct action on protein synthesis, clindamycin is more effective in rapidly terminating toxin production than is penicillin—a cell-wall agent. Support for this view comes from studies of an experimental model of streptococcal myositis, in which mice given clindamycin had a higher rate of survival than those given penicillin. Comparable data on the treatment of human infections are not available, although retrospective analysis has suggested a better outcome when patients with invasive soft-tissue infection are treated with clindamycin rather than with cell wall–active antibiotics. Although clindamycin resistance in GAS is uncommon among U.S. isolates (<2%), resistance rates as high as 23% have been documented in Finland. Thus, if clindamycin is used for initial treatment of a critically ill patient, penicillin should be given as well until the antibiotic susceptibility of the streptococcal isolate is known. IV immunoglobulin has been used as adjunctive therapy for streptococcal TSS (Table 148-3). Pooled immunoglobulin preparations contain antibodies capable of neutralizing the effects of streptococcal toxins. Anecdotal reports and case series have suggested favorable clinical responses to IV immunoglobulin, but no adequately powered, prospective, controlled trials have been reported. A meta-analysis of five studies of streptococcal TSS patients treated with clindamycin found that IVIG use was associated with a reduction in mortality rate from 33.7% to 15.7%.

TABLE 148-4 Proposed Case Definition for Streptococcal Toxic Shock Syndrome[a]

- I. Isolation of group A streptococci (*Streptococcus pyogenes*)
  - A. From a normally sterile site
  - B. From a nonsterile site
- II. Clinical signs of severity
  - A. Hypotension *and*
  - B. ≥2 of the following signs
    1. Renal impairment
    2. Coagulopathy
    3. Liver function impairment
    4. Adult respiratory distress syndrome
    5. A generalized erythematous macular rash that may desquamate
    6. Soft tissue necrosis, including necrotizing fasciitis or myositis; *or* gangrene

[a]An illness fulfilling criteria IA, IIA, and IIB is defined as a *definite* case. An illness fulfilling criteria IB, IIA, and IIB is defined as a *probable* case if no other etiology for the illness is identified.

PREVENTION

No vaccine against GAS is commercially available. A formulation that consists of recombinant peptides containing epitopes of 26 M-protein types has undergone phase 1 and 2 testing in volunteers. Early results indicate that the vaccine is well tolerated and elicits type-specific antibody responses. Vaccines based on a conserved region of M protein or on a mixture of other conserved GAS protein antigens are in earlier stages of development.

Household contacts of individuals with invasive GAS infection (e.g., bacteremia, necrotizing fasciitis, or streptococcal TSS) are at greater risk of invasive infection than the general population. Asymptomatic pharyngeal colonization with GAS has been detected in up to 25% of persons with >4 h/d of same-room exposure to an index case. However, the CDC does not recommend antibiotic prophylaxis routinely for contacts of patients with invasive disease because such an approach (if effective) would require treatment of hundreds of contacts to prevent a single case. Prophylaxis may be considered for contacts of unusually severe cases or for individuals at increased risk for invasive infection.

STREPTOCOCCI OF GROUPS C AND G

Group C and group G streptococci are β-hemolytic bacteria that occasionally cause human infections similar to those caused by GAS. Strains that form small colonies on blood agar (<0.5 mm) are generally members of the *Streptococcus milleri* group (*Streptococcus intermedius*, *Streptococcus anginosus*; see "Viridans Streptococci," below). Large-colony group C and G streptococci of human origin are now considered a single species, *Streptococcus dysgalactiae* subspecies *equisimilis*. These organisms have been associated with pharyngitis, cellulitis and soft tissue infections, pneumonia, bacteremia, endocarditis, and septic arthritis. Puerperal sepsis, meningitis, epidural abscess, intraabdominal abscess, urinary tract infection, and neonatal sepsis also have been reported. Group C or G streptococcal bacteremia most often affects elderly or chronically ill patients and, in the absence of obvious local infection, is likely to reflect endocarditis. Septic arthritis, sometimes involving multiple joints, may complicate endocarditis or develop in its absence. Distinct streptococcal species of Lancefield group C cause infections in domesticated animals, especially horses and cattle; some human infections are acquired through contact with animals or consumption of unpasteurized milk. These zoonotic organisms include *Streptococcus equi* subspecies *zooepidemicus* and *S. equi* subspecies *equi*.

TREATMENT

Group C or G Streptococcal Infection

Penicillin is the drug of choice for treatment of group C or G streptococcal infections. Antibiotic treatment is the same as for similar syndromes due to GAS (Table 148-3). Patients with bacteremia or

septic arthritis should receive IV penicillin (2–4 mU every 4 h). All group C and G streptococci are sensitive to penicillin; nearly all are inhibited in vitro by concentrations of ≤0.03 μg/mL. Occasional isolates exhibit tolerance: although inhibited by low concentrations of penicillin, they are killed only by significantly higher concentrations. The clinical significance of tolerance is unknown. Because of the poor clinical response of some patients to penicillin alone, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) is recommended by some authorities for treatment of endocarditis or septic arthritis due to group C or G streptococci; however, combination therapy has not been shown to be superior to penicillin treatment alone. Patients with joint infections often require repeated aspiration or open drainage and debridement for cure; the response to treatment may be slow, particularly in debilitated patients and those with involvement of multiple joints. Infection of prosthetic joints almost always requires prosthesis removal in addition to antibiotic therapy.

GROUP B STREPTOCOCCI

Identified first as a cause of mastitis in cows, streptococci belonging to Lancefield group B have since been recognized as a major cause of sepsis and meningitis in human neonates. GBS is also a frequent cause of peripartum fever in women and an occasional cause of serious infection in nonpregnant adults. Since the widespread institution of prenatal screening for GBS in the 1990s, the incidence of neonatal infection per 1000 live births has fallen from ~2–3 cases to ~0.6 case. During the same period, GBS infection in adults with underlying chronic illnesses has become more common; adults now account for a larger proportion of invasive GBS infections than do newborns. Lancefield group B consists of a single species, *S. agalactiae*, which is definitively identified with specific antiserum to the group B cell wall–associated carbohydrate antigen. A streptococcal isolate can be classified presumptively as GBS on the basis of biochemical tests, including hydrolysis of sodium hippurate (in which 99% of isolates are positive), hydrolysis of bile esculin (in which 99–100% are negative), bacitracin susceptibility (in which 92% are resistant), and production of CAMP factor (in which 98–100% are positive). CAMP factor is a phospholipase produced by GBS that causes synergistic hemolysis with β lysin produced by certain strains of *S. aureus*. Its presence can be demonstrated by cross-streaking of the test isolate and an appropriate staphylococcal strain on a blood agar plate. GBS organisms causing human infections are encapsulated by one of ten antigenically distinct polysaccharides. The capsular polysaccharide is an important virulence factor. Antibodies to the capsular polysaccharide afford protection against GBS of the same (but not of a different) capsular type.

INFECTION IN NEONATES

Two general types of GBS infection in infants are defined by the age of the patient at presentation. *Early-onset infections* occur within the first week of life, with a median age of 20 h at onset. Approximately half of these infants have signs of GBS disease at birth. The infection is acquired during or shortly before birth from the colonized maternal genital tract. Surveillance studies have shown that 5–40% of women are vaginal or rectal carriers of GBS. Approximately 50% of infants delivered vaginally by carrier mothers become colonized, although only 1–2% develop clinically evident infection. Prematurity, prolonged labor, obstetric complications, and maternal fever are risk factors for early-onset infection. The presentation of early-onset infection is the same as that of other forms of neonatal sepsis. Typical findings include respiratory distress, lethargy, and hypotension. Essentially all infants with early-onset disease are bacteremic, one-third to one-half have pneumonia and/or respiratory distress syndrome, and one-third have meningitis.

Late-onset infections occur in infants 1 week to 3 months old and, in rare instances, in older infants (mean age at onset, 3–4 weeks). The infecting organism may be acquired during delivery (as in early-onset cases) or during later contact with a colonized mother, nursery personnel, or another source. Meningitis is the most common manifestation of late-onset infection and in most cases is associated with a strain of capsular type III. Infants present with fever, lethargy or irritability, poor feeding, and seizures. The various other types of late-onset infection include bacteremia without an identified source, osteomyelitis, septic arthritis, and facial cellulitis associated with submandibular or preauricular adenitis.

TREATMENT

Group B Streptococcal Infection in Neonates

Penicillin is the agent of choice for all GBS infections. Empirical broad-spectrum therapy for suspected bacterial sepsis, consisting of ampicillin and gentamicin, is generally administered until culture results become available. If cultures yield GBS, many pediatricians continue to administer gentamicin, along with ampicillin or penicillin, for a few days until clinical improvement becomes evident. Infants with bacteremia or soft tissue infection should receive penicillin at a dosage of 200,000 units/kg per day in divided doses. For meningitis, infants ≤7 days of age should receive 250,000–450,000 units/kg per day in three divided doses; infants >7 days of age should receive 450,000–500,000 units/kg per day in four divided doses. Meningitis should be treated for at least 14 days because of the risk of relapse with shorter courses.

Prevention The incidence of GBS infection is unusually high among infants of women with risk factors: preterm delivery, early rupture of membranes (>24 h before delivery), prolonged labor, fever, or chorioamnionitis. Because the usual source of the organisms infecting a neonate is the mother's birth canal, efforts have been made to prevent GBS infections by the identification of high-risk carrier mothers and their treatment with various forms of antibiotic prophylaxis or immunoprophylaxis. Prophylactic administration of ampicillin or penicillin to such patients during delivery reduces the risk of infection in the newborn. This approach has been hampered by logistical difficulties in identifying colonized women before delivery; the results of vaginal cultures early in pregnancy are poor predictors of carrier status at delivery. The CDC recommends screening for anogenital colonization at 35–37 weeks of pregnancy by a swab culture of the lower vagina and anorectum; intrapartum chemoprophylaxis is recommended for culture-positive women and for women who, regardless of culture status, have previously given birth to an infant with GBS infection or have a history of GBS bacteriuria during pregnancy. Women whose culture status is unknown and who develop premature labor (<37 weeks), prolonged rupture of membranes (>18 h), or intrapartum fever or who have a positive intrapartum nucleic acid amplification test for GBS also should receive intrapartum chemoprophylaxis. The recommended regimen for chemoprophylaxis is a loading dose of 5 million units of penicillin G followed by 2.5 million units every 4 h until delivery. Cefazolin is an alternative for women with a history of penicillin allergy who are thought not to be at high risk for anaphylaxis. For women with a history of immediate hypersensitivity, clindamycin may be substituted, but only if the colonizing isolate has been demonstrated to be susceptible. If susceptibility testing results are not available or indicate resistance, vancomycin should be used in this situation.

Treatment of all pregnant women who are colonized or have risk factors for neonatal infection will result in exposure of up to one-third of pregnant women and newborns to antibiotics, with the attendant risks of allergic reactions and selection for resistant organisms. Although still in the developmental stages, a GBS vaccine may ultimately offer a better solution to prevention. Because transplacental passage of maternal antibodies produces protective antibody levels in newborns, efforts are underway to develop a vaccine against GBS that can be given to childbearing-age women before or during pregnancy. Results of phase 1 clinical trials of GBS capsular polysaccharide–protein conjugate vaccines suggest that a multivalent conjugate vaccine would be safe and highly immunogenic.

INFECTION IN ADULTS

The majority of GBS infections in otherwise healthy adults are related to pregnancy and parturition. Peripartum fever, the most common manifestation, is sometimes accompanied by symptoms and signs of endometritis or chorioamnionitis (abdominal distention and uterine or adnexal tenderness). Blood and vaginal swab cultures are often positive. Bacteremia is usually transitory but occasionally results in meningitis or endocarditis. Infections in adults that are not associated with the peripartum period generally involve individuals who are elderly or have an underlying chronic illness, such as diabetes mellitus or a malignancy. Among the infections that develop with some frequency in adults are cellulitis and soft tissue infection (including infected diabetic skin ulcers), urinary tract infection, pneumonia, endocarditis, and septic arthritis. Other reported infections include meningitis, osteomyelitis, and intraabdominal or pelvic abscesses. Relapse or recurrence of invasive infection weeks to months after a first episode is documented in ~4% of cases.

TREATMENT

Group B Streptococcal Infection in Adults

GBS is less sensitive to penicillin than GAS, requiring somewhat higher doses. Adults with serious localized infections (pneumonia, pyelonephritis, abscess) should receive doses of ~12 million units of penicillin G daily; patients with endocarditis or meningitis should receive 18–24 million units per day in divided doses. Vancomycin is an acceptable alternative for penicillin-allergic patients.

NONENTEROCOCCAL GROUP D STREPTOCOCCI

The main nonenterococcal group D streptococci that cause human infections were previously considered a single species, *Streptococcus bovis*. The organisms encompassed by *S. bovis* have been reclassified into two species, each of which has two subspecies: *Streptococcus gallolyticus* subspecies *gallolyticus*, *S. gallolyticus* subspecies *pasteurianus*, *Streptococcus infantarius* subspecies *infantarius*, and *S. infantarius* subspecies *coli*. Endocarditis caused by these organisms is often associated with neoplasms of the gastrointestinal tract—most frequently, a colon carcinoma or polyp—but is also reported in association with other bowel lesions. When occult gastrointestinal lesions are carefully sought, abnormalities are found in >60% of patients with endocarditis due to *S. gallolyticus* or *S. infantarius*. In contrast to the enterococci, nonenterococcal group D streptococci like these organisms are reliably killed by penicillin as a single agent, and penicillin is the agent of choice for the infections they cause.

VIRIDANS AND OTHER STREPTOCOCCI

VIRIDANS STREPTOCOCCI

Consisting of multiple species of α-hemolytic streptococci, the viridans streptococci are a heterogeneous group of organisms that are important agents of bacterial endocarditis **(Chap. 128)**. Several species of viridans streptococci, including *Streptococcus salivarius*, *Streptococcus mitis*, *Streptococcus sanguis*, and *Streptococcus mutans*, are part of the normal flora of the mouth, where they live in close association with the teeth and gingiva. Some species contribute to the development of dental caries.

Previously known as *Streptococcus morbillorum*, *Gemella morbillorum* has been placed in a separate genus, along with *Gemella haemolysans*, on the basis of genetic-relatedness studies. These species resemble viridans streptococci with respect to habitat in the human host and associated infections.

The transient viridans streptococcal bacteremia induced by eating, toothbrushing, flossing, and other sources of minor trauma, together with adherence to biologic surfaces, is thought to account for the predilection of these organisms to cause endocarditis **(see Fig. 128-1)**. Viridans streptococci are also isolated, often as part of a mixed flora, from sites of sinusitis, brain abscess, and liver abscess.

Viridans streptococcal bacteremia occurs relatively frequently in neutropenic patients, particularly after bone marrow transplantation or high-dose chemotherapy for cancer. Some of these patients develop a sepsis syndrome with high fever and shock. Risk factors for viridans streptococcal bacteremia include chemotherapy with high-dose cytosine arabinoside, prior treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone, treatment with antacids or histamine antagonists, mucositis, and profound neutropenia.

The *S. milleri* group (also referred to as the *S. intermedius* or *S. anginosus* group) includes three species that cause human disease: *S. intermedius*, *S. anginosus*, and *Streptococcus constellatus*. These organisms are often considered viridans streptococci, although they differ somewhat from other viridans streptococci in both their hemolytic pattern (they may be α-, β-, or nonhemolytic) and the disease syndromes they cause. This group commonly produces suppurative infections, particularly abscesses of brain and abdominal viscera, and infections related to the oral cavity or respiratory tract, such as peritonsillar abscess, lung abscess, and empyema.

TREATMENT

Infection with Viridans Streptococci

Isolates from neutropenic patients with bacteremia are often resistant to penicillin; thus these patients should be treated presumptively with vancomycin until the results of susceptibility testing become available. Viridans streptococci isolated in other clinical settings usually are sensitive to penicillin. Susceptibility testing should be performed to guide treatment of serious infections.

ABIOTROPHIA AND *GRANULICATELLA* SPECIES (NUTRITIONALLY VARIANT STREPTOCOCCI)

Occasional isolates cultured from the blood of patients with endocarditis fail to grow when subcultured on solid media. These *nutritionally variant streptococci* require supplemental thiol compounds or active forms of vitamin B_6 (pyridoxal or pyridoxamine) for growth in the laboratory. The nutritionally variant streptococci are generally grouped with the viridans streptococci because they cause similar types of infections. However, they have been reclassified on the basis of 16S ribosomal RNA sequence comparisons into two separate genera: *Abiotrophia*, with a single species (*Abiotrophia defectiva*), and *Granulicatella*, with three species associated with human infection (*Granulicatella adiacens*, *Granulicatella para-adiacens*, and *Granulicatella elegans*).

TREATMENT

Infection with Nutritionally Variant Streptococci

Treatment failure and relapse appear to be more common in cases of endocarditis due to nutritionally variant streptococci than in those due to the usual viridans streptococci. Thus, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) to the penicillin regimen is recommended for endocarditis due to the nutritionally variant organisms.

OTHER STREPTOCOCCI

Streptococcus suis is an important pathogen in swine and has been reported to cause meningitis in humans, usually in individuals with occupational exposure to pigs. *S. suis* has been reported to be the most common cause of bacterial meningitis in Vietnam, and it has been responsible for outbreaks in China. Strains of *S. suis* associated with human infections have generally reacted with Lancefield group R typing serum and sometimes with group D typing serum as well. Isolates may be α- or β-hemolytic and are sensitive to penicillin. *Streptococcus iniae*, a pathogen of fish, has been associated with infections in humans who have handled live or freshly killed fish. Cellulitis of the hand is the most common form of human infection, although bacteremia and endocarditis have been reported. *Anaerobic streptococci*, or

peptostreptococci, are part of the normal flora of the oral cavity, bowel, and vagina. **Infections caused by the anaerobic streptococci are discussed in Chap. 177.**

149 Enterococcal Infections

William R. Miller, Cesar A. Arias, Barbara E. Murray

Enterococci have been recognized as potential human pathogens for well over a century, but only in recent years have these organisms acquired prominence as important causes of nosocomial infections. The ability of enterococci to survive and/or disseminate in the hospital environment and to acquire antibiotic resistance determinants makes the treatment of some enterococcal infections in critically ill patients a difficult challenge. Enterococci were first mentioned in the French literature in 1899; the "entérocoque" was found in the human gastrointestinal tract. The first pathologic description of an enterococcal infection dates to the same year. A clinical isolate from a patient who died as a consequence of endocarditis was initially designated *Micrococcus zymogenes*, was later named *Streptococcus faecalis* subspecies *zymogenes*, and would now be classified as *Enterococcus faecalis*. The ability of this isolate to cause severe disease in both rabbits and mice illustrated its potential lethality in the appropriate settings.

MICROBIOLOGY AND TAXONOMY

Enterococci are gram-positive organisms. In clinical specimens, they are usually observed as single cells, diplococci, or short chains **(Fig. 149-1)**, although long chains are noted with some strains. Enterococci were originally classified as streptococci because organisms of the two genera share many morphologic and phenotypic characteristics, including a generally negative catalase reaction. Only DNA hybridization studies and later 16S rRNA sequencing clearly demonstrated that enterococci should be grouped as a genus distinct from the streptococci. Unlike the majority of streptococci, enterococci hydrolyze esculin in the presence of 40% bile salts and grow at high salt concentrations (e.g., 6.5%) and at high temperatures (46°C). Enterococci are usually reported by the clinical laboratory to be nonhemolytic on the basis of their inability to lyse the ovine or bovine red blood cells (RBCs) commonly used in agar plates; however, some strains of *E. faecalis* do lyse RBCs from humans, horses, and rabbits due to the presence of an acquired hemolysin/cytolysin gene. The majority of clinically relevant enterococcal species hydrolyze pyrrolidonyl-β-naphthylamide (PYR); this characteristic is helpful in differentiating enterococci from organisms of the *Streptococcus gallolyticus* group (formerly known as *S. bovis*, which includes *S. gallolyticus*, *S. pasteurianus*, and *S. infantarius*) and from *Leuconostoc* species. Although many species of enterococci have been isolated from human infections, the overwhelming majority of cases are caused by two species, *E. faecalis* and *E. faecium*. Less frequently isolated species include *Enterococcus gallinarum*, *E. durans*, *E. hirae*, and *E. avium*.

PATHOGENESIS

Enterococci are normal inhabitants of the large bowel of human adults, although they usually make up <1% of the culturable intestinal microbiota. In the healthy human host, enterococci are typical symbionts that coexist with other gastrointestinal bacteria; in fact, the utility of certain enterococcal strains as probiotics in the treatment of diarrhea suggests their possible role in maintaining the homeostatic equilibrium of the bowel. These commensals play a role in *colonization resistance*, or the ability of a healthy gastrointestinal microbiota to impede the establishment of a population of drug-resistant bacteria such as vancomycin-resistant enterococci (VRE). Colonization resistance arises from a complex set of metabolic and immunologic interactions between the host, pathogen, and intestinal microbiota, many of which are disrupted in hospitalized or chronically ill patients.

Several studies have shown that a higher level of gastrointestinal colonization is a critical factor in the pathogenesis of enterococcal infections. However, the mechanisms by which enterococci successfully colonize the bowel and gain access to the lymphatics and/or bloodstream remain incompletely understood. Physical factors, such as stomach pH and the mucin layer on the interior of the intestinal lumen, provide a barrier and limit pathogen access to the intestinal epithelium. In the hospital setting, administration of medications that suppress stomach acid secretion, or degradation of the mucin layer by gut commensals during periods of decreased oral intake, can disrupt these protective layers.

One of the most important factors that promotes increased gastrointestinal colonization by enterococci is the administration of antimicrobial agents since enterococci are intrinsically resistant to a variety of commonly used antibacterial drugs. In particular, antibiotics that are excreted in the bile and have broad-spectrum activity (e.g., certain cephalosporins that target gram-negative bacteria or anaerobes) are usually associated with the recovery of higher numbers of enterococci from feces. However, the increased colonization by hospital-associated

strains of *E. faecium* in the presence of antimicrobial agents appears to be due to more than the simple filling of a "biological niche" after the eradication of competing components of the microbiota. Studies of colonization dynamics in mouse intestines suggest the importance of secreted compounds with bactericidal activity against VRE in preventing domination of the intestinal tract. These include host-derived antimicrobial peptides produced by the innate immune system (such as the lectin RegIIIγ) and compounds such as lantibiotics or bacteriocins produced by members of the microbiota itself. Activation of Toll-like receptors by lipopolysaccharide (an important component of the gram-negative cell envelope) leads, in mice, to increased production of RegIIIγ, and loss of this stimulation by antibiotic-induced disruptions of commensal gram-negative bacteria impairs clearance of VRE from the intestines. Similarly, antimicrobial lantibiotics produced by commensal bacteria (such as *Blautia producta*) are active against VRE in vitro, but this organism may require a cooperative partnership with other members of the microbiota to effectively provide colonization resistance. Disruption of these partnerships by antibiotic administration can lead to an environment where VRE can flourish. Another factor that may contribute to enterococcal survival in the gastrointestinal tract is the production of bacteriocins (molecules that kill competing bacteria). Strains of *E. faecalis* harboring pheromone-producing plasmids that code for bacteriocins are capable of outcompeting enterococci lacking such plasmids. Furthermore, in vivo transfer of these plasmids occurs by conjugation, enhancing the survival of the recipients. In the absence of antibiotics, hospital-associated lineages of *E. faecium* seem to be less adapted for survival in the gastrointestinal tract than are commensal *E. faecium* strains. Studies examining the rate of carriage of VRE in patients after discharge from the hospital document a median time to clearance between 2 and 4 months in patients without ongoing risk factors, such as continued antibiotic use, residence in a long-term care facility, or need for hemodialysis.

Several vertebrate, worm, and insect models have been developed to study the role of possible pathogenic determinants in both *E. faecalis* and *E. faecium*. Three main groups of virulence factors may increase the ability of enterococci to colonize the gastrointestinal tract and/or cause disease. The first group, *enterococcal secreted factors*, are molecules released outside the bacterial cell that contribute to the process of infection. The best studied of these molecules include enterococcal hemolysin/cytolysin and two enterococcal proteases (gelatinase and serine protease). Enterococcal cytolysin is a heterodimeric toxin produced by some strains of *E. faecalis* that is capable of lysing human (as well as equine but not ovine) RBCs as well as polymorphonuclear leukocytes and macrophages. *E. faecalis* gelatinase and serine protease are thought to mediate virulence by several mechanisms, including the degradation of host tissues and the modification of critical components of the immune system. Mutants lacking the genes corresponding to these proteins are highly attenuated in experimental animal models of peritonitis, endocarditis, and endophthalmitis.

A second group of virulence factors, *enterococcal surface components*, includes adhesins and is thought to contribute to bacterial attachment to extracellular matrix molecules in the human host. Several molecules on the surface of enterococci have been characterized and shown to play a role in the pathogenesis of enterococcal infections. Among the characterized adhesins is *aggregation substance* of *E. faecalis*, which mediates the attachment of bacterial cells to each other, thereby facilitating conjugative plasmid exchange. Several lines of evidence indicate that aggregation substance and enterococcal cytolysin act synergistically to increase the virulence potential of *E. faecalis* strains in experimental endocarditis. The surface protein adhesin of collagen of *E. faecalis* (Ace) and its *E. faecium* homologue (Acm) are microbial surface components adhering to matrix molecules (MSCRAMMs); they recognize adhesive matrix molecules involved in bacterial attachment to host proteins such as collagen, fibronectin, and fibrinogen. Both Ace and Acm are collagen adhesins that are important in the pathogenesis of experimental endocarditis. Pili of gram-positive bacteria are important mediators of attachment to and invasion of host tissues and are considered potential targets for immunotherapy. Both *E. faecalis* and *E. faecium* have surface pili. Mutants of *E. faecalis* lacking pili are attenuated in biofilm production, experimental endocarditis, and urinary tract infections (UTIs). Other surface proteins that share structural homology with MSCRAMMs and appear to play a role in enterococcal attachment to the host and in virulence include the *E. faecalis* surface protein Esp and its *E. faecium* homologue Esp_{fm}, the second collagen adhesin of *E. faecium* (Scm), the surface proteins of *E. faecium* (Fms), SgrA (which binds to components of the basal lamina), and EcbA (which binds to collagen type V). Additional surface components apparently associated with pathogenicity include the Erl protein (a protein from the WxL family) and polysaccharides, which are thought to interfere with phagocytosis of the organism by host immune cells. Some *E. faecalis* strains appear to harbor at least three distinct classes of capsular polysaccharide; some of these polysaccharides play a role in virulence and are potential targets for immunotherapy. Teichoic acids on the enterococcal surface appear to be immunogenic, and antibodies to these molecules are protective in some animal models.

The third group of virulence factors has not been well characterized but includes the *E. faecalis* stress protein Gls24, which has been associated with enterococcal resistance to bile salts and appears to be important in the pathogenesis of endocarditis, and the hyl_{Efm}-containing plasmids of *E. faecium*, which are transferable between strains and increase gastrointestinal colonization by *E. faecium*. In mouse peritonitis, acquisition of these plasmids increased the lethality of a commensal strain of *E. faecium* and enhanced colonization of the uroepithelium. A gene encoding a regulator of oxidative stress (AsrR) has been identified as an important virulence factor of *E. faecium*.

EPIDEMIOLOGY

According to data collected from 2015 to 2017 by the National Healthcare Safety Network of the Centers for Disease Control and Prevention, enterococci are the second most common isolates (after staphylococci) from hospital-associated infections in the United States. Although *E. faecalis* remains the predominant species recovered from nosocomial infections, the isolation of *E. faecium* has increased substantially in the past 20 years and accounts for approximately one-third of all enterococcal infections identified to the species level. This point is important, since *E. faecium* is by far the most resistant and challenging enterococcal species to treat. More than 90% of *E. faecium* isolates are resistant to ampicillin (historically the most effective β-lactam agent against enterococci), while ampicillin resistance in *E. faecalis* is uncommon. Vancomycin resistance in *E. faecium* isolates ranges from 83% in acute care hospitals in the United States to up to 93% in long-term care facilities. Resistance to vancomycin in *E. faecalis* isolates is less common, with a higher incidence in device-associated infections (7.2%) than surgical-site infections (3.4%).

The dynamics of enterococcal transmission and dissemination in the hospital environment have been extensively studied, with a focus on VRE. These studies have revealed that VRE colonization of the gastrointestinal tract is a critical step in the development of enterococcal disease and that a substantial proportion of patients colonized with VRE remain colonized for prolonged periods (sometimes >1 year) and are more likely than patients without VRE colonization to develop an *Enterococcus*-related illness (e.g., bacteremia). Important factors associated with VRE colonization and persistence in the gut include prolonged hospitalization; long courses of antibiotic therapy; hospitalization in long-term care facilities, surgical units, and/or intensive care units; organ transplantation; renal failure (particularly in patients undergoing hemodialysis) and/or diabetes; high APACHE (Acute Physiology and Chronic Health Evaluation) scores; and physical proximity to patients infected or colonized with VRE or these patients' rooms. Once a patient becomes colonized with VRE, several key factors are involved in the organisms' dissemination in the hospital environment. VRE can survive exposure to heat and certain disinfectants and have been found on numerous inanimate objects in the hospital, including bed rails, medical equipment, doorknobs, gloves, telephones, and computer keyboards. Thus, health care workers and the environment play pivotal roles in enterococcal transmission from patient to patient, and infection control measures are crucial in breaking the chain of transmission. Moreover, two meta-analyses have found that,

independent of the patient's clinical status, VRE infection increases the risk of death over that among individuals infected with a glycopeptide-susceptible enterococcal strain.

The epidemiology of enterococcal disease and the emergence of VRE have followed slightly different trends in other parts of the world than in the United States. In Europe, the emergence of VRE in the mid-1980s was seen primarily in isolates recovered from animals and healthy humans rather than from hospitalized patients. The presence of VRE was associated with the use of the glycopeptide avoparcin as a growth promoter in animal feeds; this association prompted the European Union to ban the use of this compound in animal husbandry in 1996. However, after an initial decrease in the isolation of VRE from animals and humans, the prevalence of hospital-associated VRE infections has slowly increased in certain European countries, with important regional differences. For example, rates of vancomycin resistance among *E. faecium* clinical isolates in Europe are highest in Greece, Ireland, Romania, Hungary, Slovakia, and Poland (25–35%), whereas rates in the Scandinavian countries and the Netherlands are <5%. These regional differences have been attributed in part to the implementation of aggressive "search-and-destroy" infection-control policies in countries such as the Netherlands; these policies have kept the frequency of nosocomial methicillin-resistant *Staphylococcus aureus* (MRSA) and VRE very low. Despite regional differences, Europe has seen a general trend of increasing rates of VRE over the past decade, though these rates continue to be much lower than in the United States. The reasons are not totally understood, although it has been postulated that this difference is related to the higher levels of human antibiotic use in the United States. Recent data have also shown increasing rates of enterococcal resistance to vancomycin in Latin American countries, with 34% of clinical *E. faecium* isolates found to be resistant in a multicenter study including hospitals from Colombia, Venezuela, Ecuador, and Peru. In Asia, rates of vancomycin resistance among enterococci appear to be similar to those in U.S. hospitals.

The ability to sequence bacterial genomes has increased our understanding of bacterial diversity, evolution, pathogenesis, and mechanisms of antibiotic resistance. The genome sequences of >8000 enterococcal strains are currently available, and some have been entirely closed and annotated. This has allowed researchers to trace the evolutionary trajectory of enterococci from their origin to the emergence of hospital-adapted clones. Sequence analysis suggests the genus appeared ~400 million years ago with the advent of terrestrial animals. Several key features aided in this transition, including the ability to recombine large portions of chromosomal DNA from the *core genome* and a malleable *accessory genome* consisting of plasmids, phages, and mobile genetic elements. This genomic plasticity contributes to the rising rates of antibiotic resistance seen within the genus and, in particular, in *E. faecium*.

A large proportion of the genomes available for analysis belong to *E. faecium*, due to its importance as a nosocomial pathogen and the epidemiologic surveillance projects to track the spread of vancomycin-resistant strains. The population can be divided into two large groups, or clades, of organisms: a hospital-associated clade A and a community-associated clade B. The hospital-associated clade appears to be evolving rapidly, and genomic comparisons suggest that this lineage emerged 75–80 years ago—a time point that coincides with the introduction of antimicrobial drugs—and evolved, perhaps continuously, from animal strains, not from human commensal isolates. Strains belonging to clade A are more frequently identified as isolates causing invasive disease and are more likely to carry drug resistance determinants, whereas clade B isolates largely retain a susceptible phenotype.

One reason for the propensity of clade A strains to acquire resistance determinants is that they more frequently lack a functional CRISPR-cas system (short for *c*lustered *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats). These systems serve as a primitive "immune system" and provide a genome defense for bacteria to protect them from foreign DNA, such as phages, but they also serve to reduce the frequency of acquisition of resistance genes borne on mobile genetic elements. Another reason for their survival in the hospital environment is that clade A isolates tend to possess alleles of penicillin-binding protein 5 (PBP5) associated with high-level β-lactam resistance in *E. faecium* and may express higher levels of this enzyme than commensal strains.

A notable feature of the distribution of strains in clade A in some studies is that they share a relatively recent common ancestor with *E. faecium* of livestock origin. Use of antibiotics in animal husbandry as both therapeutics and growth promoters has been linked to resistance in several important contexts, including glycopeptides as mentioned above. This suggests continued surveillance, and an expanding understanding of the population structure of enterococci may help identify potential reservoirs of resistance and inform policy to limit their spread.

CLINICAL SYNDROMES

Urinary Tract Infection and Prostatitis Enterococci are well-known causes of nosocomial UTI—the most common infection caused by these organisms **(Chap. 135)**. Enterococcal UTIs are usually associated with indwelling catheterization, instrumentation, or anatomic abnormalities of the genitourinary tract, and it is often challenging to differentiate between true infection and colonization (particularly in patients with chronic indwelling catheters). Their role as pathogens in otherwise healthy premenopausal woman with acute cystitis is less clear, with data from one study suggesting that enterococci recovered from mid-stream urine cultures were not predictive of bacteriuria in a subsequent catheterized specimen. The presence of leukocytes in the urine in conjunction with systemic manifestations (e.g., fever) or local signs and symptoms of infection with no other explanation and a positive urine culture ($\geq 10^5$ CFU/mL) suggests the diagnosis. Moreover, enterococcal UTIs often occur in critically or chronically ill patients whose comorbidities may obscure the diagnosis. In many cases, removal of the indwelling catheter may suffice to eradicate the organism without specific antimicrobial therapy. In rare circumstances, UTIs caused by enterococci may run a complicated course, with the development of pyelonephritis and perinephric abscesses that may be a portal of entry for bloodstream infections (see below). Enterococci are also known causes of chronic prostatitis, particularly in men whose urinary tract has been manipulated surgically or endoscopically. These infections can be difficult to treat since the agents most potent against enterococci (i.e., aminopenicillins and glycopeptides) penetrate prostatic tissue poorly. Chronic prostatic infection can be a source of recurrent enterococcal bacteremia.

Bacteremia and Endocarditis Bacteremia without endocarditis is another frequently encountered presentation of enterococcal disease. Intravascular catheters and other devices are commonly associated with these bacteremic episodes **(Chap. 142)**. Other well-known sources of enterococcal bacteremia include the gastrointestinal and hepatobiliary tracts; pelvic and intraabdominal foci; and, less frequently, wound infections, UTIs, and bone infections. In the United States, enterococci are ranked second (after staphylococci) as etiologic agents of central line–associated bacteremia. Patients with enterococcal bacteremia usually have comorbidities and have been in the hospital for prolonged periods; they commonly have received several courses of antibiotics. Several studies indicate that the isolation of *E. faecium* from the blood may lead to worse outcomes and higher mortality rates than when other enterococcal species are isolated; this finding may be related to the higher prevalence of vancomycin and ampicillin resistance in *E. faecium* than in other enterococcal species, with the consequent reduction of therapeutic options. In some cases (usually when the gastrointestinal tract is the source), enterococcal bacteremia may be polymicrobial, with gram-negative organisms isolated at the same time. In addition, several cases have been documented in which enterococcal bacteremia was associated with *Strongyloides stercoralis* hyperinfection syndrome in immunocompromised patients.

Enterococci are important causes of community- and health care–associated endocarditis, ranking second after staphylococci in the latter infections. The presumed initial source of bacteremia leading to endocarditis is the gastrointestinal or genitourinary tract—e.g., in patients who have malignant and inflammatory conditions of the gut or have undergone procedures in which these tracts are manipulated.

The affected patients tend to be male and elderly and to have other debilitating diseases and heart conditions. Both prosthetic and native valves can be involved; mitral and aortic valves are affected most often. Community-associated endocarditis (usually caused by *E. faecalis*) also occurs in patients with no apparent risk factors or cardiac abnormalities. Endocarditis in women of childbearing age was well described in the past. The typical presentation of enterococcal endocarditis is a subacute course of fever, weight loss, malaise, and cardiac murmur; typical stigmata of endocarditis (e.g., petechiae, Osler's nodes, Roth's spots) are found in only a minority of patients. Atypical manifestations include arthralgias and manifestations of metastatic disease (splenic abscesses, hiccups, pain in the left flank, pleural effusion, and spondylodiscitis). Embolic complications are variable and can affect the brain. Heart failure is a common complication of enterococcal endocarditis, and valve replacement may be critical in curing this infection, particularly when multidrug-resistant organisms or major complications are involved. Several clinical scoring systems (designated NOVA and DENOVA) have been proposed to help differentiate enterococcal bacteremia from true endocarditis. The duration of therapy is usually 4–6 weeks, with more prolonged courses suggested for multidrug-resistant isolates in the absence of valvular replacement.

Meningitis Enterococcal meningitis is an uncommon disease (accounting for only ~4% of meningitis cases) that is usually associated with neurosurgical interventions and conditions such as shunts, central nervous system (CNS) trauma, and cerebrospinal fluid (CSF) leakage. In some instances—usually in patients with a debilitating condition, such as cardiovascular or congenital heart disease, chronic renal failure, malignancy, receipt of immunosuppressive therapy, or HIV/AIDS—presumed hematogenous seeding of the meninges is seen in infections such as endocarditis or bacteremia. Fever and changes in mental status are common, whereas overt meningeal signs are less so. CSF findings are consistent with bacterial infection—i.e., pleocytosis, with a predominance of polymorphonuclear leukocytes (average, ~500/μL), an elevated serum protein level (usually >100 mg/dL), and a decreased glucose concentration (average, 28 mg/dL). Gram's staining yields a positive result in about half of cases, with a high rate of organism recovery from CSF cultures; the most common species isolated are *E. faecalis* and *E. faecium*. Complications include hydrocephalus, brain abscesses, and stroke. As mentioned before for bacteremia, an association with *Strongyloides* hyperinfection has also been documented.

Intraabdominal, Pelvic, and Soft Tissue Infections As mentioned earlier, enterococci are part of the commensal microbiota of the gastrointestinal tract and can produce spontaneous peritonitis in cirrhotic individuals and in patients undergoing chronic ambulatory peritoneal dialysis **(Chap. 132)**. These organisms are commonly found (usually along with other bacteria, including enteric gram-negative species and anaerobes) in clinical samples from intraabdominal and pelvic collections. The presence of enterococci in intraabdominal infections is sometimes considered to be of little clinical relevance. Several studies have shown that the role of enterococci in intraabdominal infections originating in the community and involving previously healthy patients is minor since surgery and broad-spectrum antimicrobial drugs that do not target enterococci are often sufficient to treat these infections successfully. In the past few decades, however, these organisms have become prominent as a cause of intraabdominal infections in hospitalized patients because of the emergence and spread of vancomycin resistance among enterococci and the increase in rates of nosocomial infections due to multidrug-resistant *E. faecium* isolates. In fact, several studies have now documented treatment failures due to enterococci, with consequently increased rates of postoperative complications and death among patients with intraabdominal infections. Thus, anti-enterococcal therapy is recommended for nosocomial peritonitis in immunocompromised and severely ill patients who have had a prolonged hospital stay, have undergone multiple procedures, have persistent abdominal sepsis and collections, or have risk factors for the development of endocarditis (e.g., prosthetic or damaged heart valves). Conversely, specific treatment for enterococci in the first episode of intraabdominal infection originating in the community and affecting previously healthy patients with no important cardiac risk factors for endocarditis does not appear to be beneficial.

Enterococci are commonly isolated from soft tissue infections **(Chap. 129)**, particularly those involving surgical wounds **(Chap. 142)**. In fact, these organisms rank third as agents of nosocomial surgical-site infections, with *E. faecalis* the most frequently isolated species. The clinical relevance of enterococci in some of these infections—as in intraabdominal infections—is a matter of debate; differentiating between colonization and true infection is sometimes challenging, although in some cases, enterococci have been recovered from lung, liver, and skin abscesses. Diabetic foot and decubitus ulcers are often colonized with enterococci and may be the portal of entry for bone infections.

Other Infections Enterococci are well-known causes of neonatal infections, including sepsis (mostly late-onset), bacteremia, meningitis, pneumonia, and UTI. Outbreaks of enterococcal sepsis in neonatal units have been well documented. Risk factors for enterococcal disease in newborns include prematurity, low birth weight, indwelling devices, and abdominal surgery. Enterococci have also been described as etiologic agents of bone and joint infections, including vertebral osteomyelitis, usually in patients with underlying conditions such as diabetes or endocarditis. Similarly, enterococci have been isolated from bone infections in patients who have undergone arthroplasty or reconstruction of fractures with the placement of hardware. Since enterococci can produce a biofilm that is likely to alter the efficacy of anti-enterococcal agents, treatment of infections that involve foreign material is challenging, and removal of the hardware may be necessary to eradicate the infection. Rare cases of enterococcal pneumonia, lung abscess, and spontaneous empyema have been described.

TREATMENT

Enterococcal Infections

GENERAL PRINCIPLES

Enterococci are intrinsically resistant and/or tolerant to several antimicrobial agents. (*Tolerance* is defined as lack of killing by drug concentrations 32 times higher than the minimal inhibitory concentration [MIC].) Monotherapy for endocarditis with a β-lactam antibiotic (to which many enterococci are tolerant) has produced disappointing results, with high relapse rates after the end of therapy. However, the addition of an aminoglycoside to a cell wall–active agent (a β-lactam or a glycopeptide) increases cure rates and eradicates the organisms; moreover, this combination is synergistic and bactericidal in vitro. Therefore, for many decades, combination therapy with a cell wall–active agent and an aminoglycoside was the standard of care for endovascular infections caused by enterococci. This synergistic effect can be explained, at least in part, by the increased penetration of the aminoglycoside into the bacterial cell, presumably as a result of cell-wall alterations produced by the β-lactam (or glycopeptide). Nonetheless, attaining synergistic bactericidal activity in the treatment of severe enterococcal infections—particularly those caused by *E. faecium*—has become increasingly difficult because of the development of resistance to virtually all antibiotics available for this purpose.

The treatment of *E. faecalis* differs substantially from that of *E. faecium* **(Tables 149-1 and 149-2)**, mainly because of differences in resistance profiles (see below). For example, resistance to ampicillin and vancomycin is rare in *E. faecalis*, whereas these antibiotics are only infrequently useful against current isolates of *E. faecium*. Moreover, as a consequence of the challenges and therapeutic limitations posed by the emergence of drug resistance in enterococci, valve replacement may need to be considered in the treatment of endocarditis caused by multidrug-resistant enterococci. Less severe infections are often related to indwelling intravascular catheters; removal of the catheter increases the likelihood of enterococcal eradication by a subsequent short course of appropriate antimicrobial therapy.

TABLE 149-1 Suggested Regimens for the Management of Infections Caused by *Enterococcus faecalis*

CLINICAL SYNDROME	SUGGESTED THERAPEUTIC OPTIONS[a]
Endovascular infections (including endocarditis)	• Ampicillin[b] (12 g/d IV in divided doses q4h) plus ceftriaxone (2 g IV q12h) • Ampicillin[b] (12 g/d IV in divided doses q4h or by continuous infusion) or penicillin (18–30 mU/d IV in divided doses q4h or by continuous infusion) *plus* an aminoglycoside[c] • Vancomycin[d] (15 mg/kg IV per dose) plus an aminoglycoside[c] • High-dose daptomycin[e] ± another active agent[f] • Ampicillin[b] plus imipenem
Nonendovascular bacteremia[g]	• Ampicillin (12 g/d IV in divided doses q4h) or penicillin (18 mU/d IV in divided doses q4h) ± an aminoglycoside[c] or ceftriaxone • Vancomycin[d] (15 mg/kg IV per dose) • High-dose daptomycin[e] ± another active agent[f] • Linezolid (600 mg IV/PO q12h)
Meningitis	• Ampicillin (20–24 g/d IV in divided doses q4h) or penicillin (24 mU/d IV in divided doses q4h) *plus* an aminoglycoside[c,h] and consider adding ceftriaxone (2 g IV q12h) • Vancomycin (500–750 mg IV q6h)[d] *plus* an aminoglycoside[c] or rifampin • Linezolid • High-dose daptomycin[e] (plus intrathecal daptomycin) ± another active agent[f]
Urinary tract infections (uncomplicated)	• Fosfomycin (3 g PO, one dose)[i] • Ampicillin (500 mg IV or PO q6h) • Nitrofurantoin (100 mg PO q6h)

[a]Authors' preferences are underlined for each category; many of the regimens are off-label. [b]In rare cases, β-lactamase-producing isolates may be present. Because these isolates are not detected by conventional determination of the minimal inhibitory concentration, additional tests (e.g., the nitrocefin disk) are recommended for isolates from endocarditis. The use of ampicillin/sulbactam (12–24 g/d) is suggested in these cases. [c]Only if the organism does not exhibit high-level resistance (HLR) to aminoglycosides. This test is performed by the clinical microbiology laboratory only for gentamicin or streptomycin (growth of enterococci on agar containing gentamicin [500 μg/mL] or streptomycin [2000 μg/mL]). If HLR is documented, the aminoglycoside will not act synergistically with the other agent in the combination. However, HLR to one of these aminoglycosides does not indicate resistance to the other agent (as reported individually). HLR to gentamicin implies lack of synergism with tobramycin and with amikacin. Gentamicin (1–1.5 mg/kg IV q8h) and streptomycin (15 mg/kg per day IV/IM in two divided doses) are the only two recommended aminoglycosides. [d]Vancomycin is recommended only as an alternative to β-lactam agents in cases of allergy or toxicity plus the inability to desensitize. Specific pharmacologic targets for trough concentrations have not been clinically evaluated in enterococcal bacteremia; trough concentrations of 15–20 mg/L have been associated with increased rates of nephrotoxicity. Cerebrospinal fluid (CSF) concentrations in meningitis should be determined. Vancomycin-resistant strains of *E. faecalis* have been reported. [e]Consider doses of 10–12 mg/kg once daily if used in combination and 10–12 mg/kg per day if used alone. Monitoring of creatine phosphokinase levels is recommended throughout therapy because of possible rhabdomyolysis. [f]Potentially active agents may include an aminoglycoside (if HLR is not detected), ampicillin, ceftaroline, tigecycline, or a fluoroquinolone (which, if the isolate is susceptible, may be favored in meningitis). The presence of mutations in *liaFSR* seems to increase susceptibility to ampicillin and ceftaroline, and combinations of daptomycin with these compounds are bactericidal in vitro against such strains. [g]In selected cases of catheter-associated bacteremia, removal of the catheter and a short course of therapy (~5–7 days) may be sufficient. A single positive blood culture that is likely to be associated with a catheter in a patient who is otherwise doing well may not require therapy after removal of the catheter. Patients at high risk for endovascular infections or with severe disease may benefit from synergistic combination therapy. [h]The addition of intrathecal or intraventricular therapy with gentamicin (2–10 mg/d) if the organism does not exhibit HLR or with vancomycin (10–20 mg/d) when the isolate is susceptible has been suggested by some authorities. The addition of systemic rifampin (a good CSF-penetrating agent) may be considered. The combination of ampicillin and ceftriaxone may have clinical benefit (by analogy with endocarditis), but no cases treated with this combination have been reported; the authors would use this combination. [i]Approved by the U.S. Food and Drug Administration only for uncomplicated urinary tract infections caused by vancomycin-susceptible *E. faecalis*.

TABLE 149-2 Suggested Regimens for the Management of Infections Caused by Vancomycin- and Ampicillin-Resistant *Enterococcus faecium*

CLINICAL SYNDROME	SUGGESTED THERAPEUTIC OPTIONS[a]
Endovascular infections (including endocarditis)	• High-dose daptomycin[b] plus another agent[c] ± an aminoglycoside[d] • Linezolid (600 mg IV q12h) • High-dose ampicillin (if MIC is ≤64 μg/mL) ± an aminoglycoside[d] • Ampicillin plus imipenem (if the ampicillin MIC is ≤32 μg/mL) • Q/D[e] (22.5 mg/kg per day in divided doses q8h) ± another active agent[f]
Nonendovascular bacteremia[g]	• High-dose daptomycin[b] ± another agent[c] ± an aminoglycoside[d] • Linezolid (600 mg IV q12h) • Q/D (22.5 mg/kg per day in divided doses q8h) ± another active agent[f]
Meningitis	• Linezolid (600 mg IV q12h) ± another CSF-penetrating active agent[h] • High-dose daptomycin[b] (plus intraventricular daptomycin) ± another CSF-penetrating active agent[h,i] • Q/D (22.5 mg/kg per day in divided doses q8h plus intraventricular Q/D)[i] ± another active agent[h]
Urinary tract infections	• Fosfomycin (3 g PO, one dose)[k] • Nitrofurantoin (100 mg PO q6h) • Ampicillin or amoxicillin (2 g IV/PO q4–6h)[l]

[a]Authors' preferences are underlined for each category; many of these regimens are off-label. [b]Daptomycin at doses of 10–12 mg/kg once daily is suggested (off-label). Close monitoring of creatine phosphokinase levels is recommended throughout therapy because of possible rhabdomyolysis. [c]Potentially active agents may include ampicillin or ceftaroline (even if the infecting strain is resistant in vitro) or tigecycline. In vitro synergism of daptomycin with ampicillin or ceftaroline has been observed against some isolates that subsequently become nonsusceptible to daptomycin during therapy. The synergism of daptomycin and β-lactams is associated with mutations in *liaFSR*. Consider combination therapy if the minimal inhibitory concentration (MIC) of daptomycin is ≥3 μg/mL. [d]Only if the organism does not exhibit high-level resistance to aminoglycosides (see Table 149-1, footnote *c*). [e]Quinupristin/dalfopristin (Q/D) lost U.S. Food and Drug Administration (FDA) approval for infections due to vancomycin-resistant *Enterococcus*. [f]Agents that may be useful in combination with Q/D (if the isolate is susceptible to each agent) include doxycycline with rifampin (one reported case) or fluoroquinolones (one reported case). [g]In selected cases of catheter-associated bacteremia, removal of the catheter and a short course of therapy (~5–7 days) may be sufficient. A single positive blood culture that is likely to be associated with a catheter in a patient who is otherwise doing well may not require therapy after removal of the catheter. [h]Fluoroquinolones (e.g., moxifloxacin) and rifampin (if the isolate is susceptible to each agent) reach therapeutic levels in the cerebrospinal fluid. [i]Intrathecal gentamicin (2–10 mg/d) if high-level resistance is not detected. Intraventricular daptomycin has been used in two cases of meningitis [j]Intrathecal Q/D (1–5 mg/d) has been used in combination with Q/D systemic therapy in meningitis. If Q/D is chosen, simultaneous use of both systemic and intrathecal therapy is suggested. [k]Approved by the FDA only for uncomplicated urinary tract infections caused by vancomycin-susceptible *E. faecalis*. [l]Concentrations of amoxicillin and ampicillin in urine far exceed those in serum and may be potentially effective even against isolates with high MICs. Doses up to 12 g/d are suggested for isolates with MICs of ≥64 μg/mL.

CHOICE OF ANTIMICROBIAL AGENTS

Among the β-lactams, the most active are the aminopenicillins (ampicillin, amoxicillin) and ureidopenicillins (i.e., piperacillin); next most active are penicillin G and imipenem. Cephalosporins, with the possible exception of ceftaroline, are not active as monotherapy. For *E. faecium*, a combination of high-dose ampicillin (up to 30 g/d) plus an aminoglycoside has been suggested—even for ampicillin-resistant strains if the MIC is ≤64 μg/mL—since a plasma ampicillin concentration higher than this value can be achieved at high doses. The only two aminoglycosides recommended for synergistic therapy in severe enterococcal infections are gentamicin and streptomycin. This is because the most common acquired enzyme conferring high-level resistance to gentamicin also is active against tobramycin and amikacin but not streptomycin, and the resistance mechanisms causing streptomycin high-level resistance do not

affect gentamicin. The use of amikacin is strongly discouraged because it is infrequently active tobramycin should never be used for the treatment of *E. faecium* infections due to the presence of a chromosomally encoded, species-specific, tobramycin-modifying enzyme and aminoglycoside monotherapy should not be employed. Vancomycin is an alternative to β-lactam drugs for the treatment of *E. faecalis* infections but is less useful against *E. faecium* because resistance is common.

As mentioned above, use of the aminoglycoside–ampicillin combination for *E. faecalis* infections has become increasingly problematic because of toxicity in critically ill patients and increased rates of high-level resistance to aminoglycosides. An observational, nonrandomized, comparative study encompassing a multicenter cohort was conducted in 17 Spanish hospitals and one Italian hospital; the results indicated that a 6-week course of ampicillin plus ceftriaxone is as effective as ampicillin plus gentamicin in the treatment of *E. faecalis* endocarditis, with less risk of toxicity. Therefore, this regimen should be considered in patients at risk for aminoglycoside toxicity or those with isolates displaying high-level resistance to aminoglycosides, and it is now recommended as first-line therapy for *E. faecalis* endocarditis. Use of dual β-lactam regimens for ampicillin-susceptible isolates of *E. faecium* has not been studied in the clinical setting. Limited in vitro data suggest that synergism between ampicillin and ceftriaxone is not reliably active against these isolates.

Linezolid is the only agent approved by the U.S. Food and Drug Administration (FDA) for the treatment of VRE infections (Table 149-2). (A prior approval for quinupristin/dalfopristin has been withdrawn.) Linezolid is not bactericidal, and its use in severe endovascular infections has produced mixed results; therefore, it is recommended only as an alternative to other agents for such infections. In addition, linezolid may cause significant toxicities (thrombocytopenia, peripheral neuropathy, optic neuritis, and lactic acidosis) when used in regimens given for >2 weeks. Nonetheless, linezolid may play a role in the treatment of enterococcal meningitis and other CNS infections, although clinical data are limited.

The lipopeptide daptomycin is a bactericidal antibiotic with potent in vitro activity against all enterococci. Although daptomycin is not approved by the FDA for the treatment of VRE or *E. faecium* infections, it has been used alone (at high dosage) or in combination with other agents (ampicillin, ceftaroline, and tigecycline) with apparent success against multidrug-resistant enterococcal infections (Tables 149-1 and 149-2). The main adverse reactions to daptomycin are elevated creatine phosphokinase levels and eosinophilic pneumonitis (rare). Daptomycin is not useful against pulmonary infections because the pulmonary surfactant inhibits its antibacterial activity.

Several meta-analyses have examined the question of which agent should be preferred for VRE bacteremia—linezolid or daptomycin. These studies concluded either no difference between the two drugs or favored linezolid due to lower all-cause and infection-related mortality, but were limited by small patient numbers and heterogenous outcomes. A subsequent large retrospective observational study from the Veterans Affairs database reported lower rates of all-cause mortality at 30 days and less microbiologic failure (i.e., positive cultures despite therapy) with daptomycin as compared to linezolid. One important observation from these investigations is that the efficacy of daptomycin is dependent on the dose, with improved outcomes seen with high-dose daptomycin therapy (≥10 mg/kg) as compared to standard-dose therapy (6 mg/kg). Genome sequencing of clinical isolates has revealed that mutations in genes associated with daptomycin resistance are not uncommon (see "Antimicrobial Resistance," below) and were associated with the emergence of resistance to daptomycin at lower simulated dosing regimens (6 mg/kg) in experimental models of infection. These data led the Clinical Laboratory and Standards Institute (CLSI) to change the daptomycin breakpoints in 2019. For *E. faecium*, all isolates with an MIC of ≤4 mg/L are placed in a "susceptible dose-dependent" category based on a dosing regimen of 8–12 mg/kg, while those with an MIC ≥8 mg/L are considered resistant. For all other enterococci, isolates are considered susceptible with an MIC of ≤2 mg/L, intermediate with an MIC of 4 mg/L, and resistant with an MIC ≥8 mg/L.

The glycylcycline drug tigecycline is active in vitro against all enterococci, regardless of the isolates' vancomycin susceptibility. However, its use as monotherapy for endovascular or severe enterococcal infections is not recommended because of low attainable blood levels. Newer generation tetracyclines, such as eravacycline and omadacycline, also display in vitro activity, but their role in the treatment of enterococcal infections remains to be evaluated.

Telavancin, a lipoglycopeptide approved by the FDA for the treatment of skin and soft tissue infections as well as hospital-associated pneumonia, is active against vancomycin-susceptible enterococci but not VRE. Likewise, dalbavancin, a lipoglycopeptide antibiotic with a long terminal half-life, has FDA approval for skin and soft tissue infections due to susceptible strains of *E. faecalis*, but no activity against VRE. Oritavancin, a novel glycopeptide with activity against VRE, has been approved for the treatment of acute bacterial skin and soft tissue infections caused by susceptible organisms, including vancomycin-susceptible *E. faecalis*. The MICs of oritavancin against VRE are low, and this compound may be a promising drug for VRE treatment in the future.

Lastly, tedizolid—a new oxazolidinone now available for clinical use—is approved only for the treatment of *E. faecalis* infections. Tedizolid is more potent than linezolid in vitro against VRE strains; however, its role in severe VRE infections remains to be determined.

ANTIMICROBIAL RESISTANCE

Resistance to β-lactam agents continues to be observed only infrequently in *E. faecalis* but is characteristic of *E. faecium*. The mechanism of ampicillin resistance in *E. faecium* is related to a penicillin-binding protein (PBP) designated PBP5, which is the critical target of β-lactam antibiotics. PBP5 exhibits low affinity for ampicillin and can synthesize cell wall in the presence of this antibiotic, even when other PBPs are inhibited. The version of this protein found in ampicillin-resistant hospital-associated strains has multiple amino-acid differences that even further decrease the affinity of PBP5 for ampicillin; these changes and/or increased production of PBP5 are the two most common mechanisms of high-level ampicillin resistance (e.g., MIC >32 μg/mL) in clinical strains.

Vancomycin is a glycopeptide antibiotic that inhibits cell-wall peptidoglycan synthesis in susceptible enterococci and has been widely used against enterococcal infections in clinical practice when the utility of β-lactams is limited by resistance, allergy, or adverse reactions. This effect is mediated by binding of the antibiotic to peptidoglycan precursors (UDP-MurNAc-pentapeptides) upon their exit from the bacterial cell cytoplasm. The interaction of vancomycin with the peptidoglycan is specific and involves the last two D-alanine residues of the precursor. The first isolates of VRE were documented in 1986, and vancomycin resistance (particularly in *E. faecium*) has since increased considerably around the world. The mechanism involves the replacement of the last D-alanine residue of peptidoglycan precursors with D-lactate (e.g., VanA and VanB) or D-serine (e.g., VanC), with consequent high- and low-level resistance, respectively. There is significant heterogeneity among isolates, but either substitution substantially decreases the affinity of vancomycin for the peptidoglycan; with the D-lactate substitution, the affinity for binding to the pentapeptide precursor is decreased by ~1000-fold. Vancomycin-resistant organisms also produce enzymes that destroy the D-alanine-D-alanine ending precursors, ensuring that additional binding sites for vancomycin are not available.

The genes encoding the machinery responsible for vancomycin resistance are located in the *van* operon and likely originated in soil bacteria. Several variants of the operon have been described, but VanA is the most common in clinical isolates in the United States, Latin America, and Europe, whereas VanB isolates are more frequent in Australia. Two enterococcal species, *E. gallinarum* and

E. casseliflavus, have intrinsic low-level resistance to vancomycin due to the presence of the VanC operon in the chromosome.

High-level resistance to aminoglycosides (of which gentamicin and streptomycin are the only two tested by clinical laboratories) abolishes the synergism observed between cell wall–active agents and the aminoglycoside. This important phenotype is routinely sought by the clinical laboratory in isolates from serious infections (Tables 149-1 and 149-2). Genes encoding aminoglycoside-modifying enzymes are usually the cause of high-level resistance to these compounds and are widely disseminated among enterococci, decreasing the options for the treatment of severe enterococcal infections. Additionally, ribosomal methyltransferases, enzymes that methylate rRNA and, as a consequence, disrupt the binding site for aminoglycosides, can also lead to high-level resistance.

Resistance to daptomycin has now been well documented in both *E. faecalis* and *E. faecium*. Daptomycin exerts its action by complexing with calcium and binding to phosphatidylglycerol in the bacterial membrane. After binding, daptomycin forms oligomers, with recent data suggesting that it displaces enzymes important for cell envelope synthesis (MurG and PlsX) and that it can form a complex with lipid II molecules critical for cell-wall synthesis, among other effects on the membrane. Resistance to this antibiotic in enterococci arises via two main pathways. The first involves mutations in genes that coordinate the cell-wall and cell-membrane stress response, most commonly a three-component system designated LiaFSR (for *l*ipid II *i*nterfering *a*ntibiotics). These mutations lead to activation of the system, with increased expression of an extracellular protein known as LiaX capable of binding daptomycin and enhancing the signaling response. In clinical isolates, mutations in LiaFSR may lead to tolerance (loss of bactericidal activity) usually in isolates with MICs near the daptomycin breakpoint (i.e., 3–4 mg/L). The second pathway involves changes in genes involved in phospholipid metabolism. It is thought that mutations priming the stress response system occur first, with the subsequent accrual of phospholipid changes leading to a fully resistant phenotype. Prior exposure to daptomycin has been identified as a risk factor for the emergence of daptomycin-resistant *E. faecium* in cancer patients. Resistance in the absence of exposure to the drug has also been well described, possibly due to the similarity of this antibiotic to antimicrobial peptides of the innate immune system. Thus, careful consideration of patient characteristics, bacterial phenotype, and daptomycin dose is warranted, and it is advisable to obtain infectious diseases consultation in complicated VRE infections.

The oxazolidonones (linezolid and tedizolid) act by binding to the ribosome and inhibiting the binding of aminoacyl-tRNAs, thus preventing protein synthesis. Resistance to this class of antibiotics is usually due to alterations of the binding site, either via mutations in the 23S rRNA genes or the presence of an rRNA methylase. Since enterococci carry multiple copies of the gene encoding the 23S rRNA, prolonged exposure to oxazolidonones can select for increasing levels of resistance by favoring propagation of the resistance allele via recombination. Changes in accessory ribosomal proteins have also been associated with linezolid resistance and may act to mitigate the fitness defects of mutations in the rRNA. More concerning is the emergence of plasmid-borne resistance genes, which can be readily transferred between enterococcal strains. Several of these genes were first recognized in bacterial isolates of animal origin, likely under the selective pressure of antibiotics such as florfenicol. The *cfr* (*c*hloramphenicol-*f*lorfenicol *r*esistance) gene encodes an rRNA methylase that modifies the 23S rRNA, leading to increases in the MIC of linezolid. Tedizolid tends to exhibit lower MICs in the presence of *cfr*; however, animal models suggest some variants of the enzyme may compromise the activity of this drug. Two other transmissible resistance genes, *optrA* and *poxtA*, encode a ribosomal protection factor that has been implicated in linezolid resistance in enterococcal strains of human and animal origin. While still relatively rare to encounter in clinical practice, these determinants have been identified across the globe and could be an emerging source of resistance.

Tigecycline retains activity in the presence of typical tetracycline resistance determinants, including drug efflux pumps and ribosomal protection factors. However, resistance has been documented and appears to be related to changes in the S10 ribosomal protein, which is situated near the binding site for the drug.

150 Diphtheria and Other Corynebacterial Infections

William R. Bishai, John R. Murphy

DIPHTHERIA

Diphtheria is a nasopharyngeal and skin infection caused by *Corynebacterium diphtheriae*. Toxigenic strains of *C. diphtheriae* produce a protein toxin that causes systemic toxicity, myocarditis, and polyneuropathy. The toxin is associated with the formation of pseudomembranes in the pharynx during respiratory diphtheria. While toxigenic strains most frequently cause pharyngeal diphtheria, nontoxigenic strains commonly cause cutaneous disease.

ETIOLOGY

C. diphtheriae is a gram-positive bacillus that is unencapsulated, nonmotile, and nonsporulating. The organism was first identified microscopically in 1883 by Klebs and a year later was isolated in pure culture by Löffler in Robert Koch's laboratory. The bacteria have a characteristic club-shaped bacillary appearance and typically form clusters of parallel rays, or *palisades*, that are referred to as "Chinese characters." The specific laboratory media recommended for the cultivation of *C. diphtheriae* rely upon tellurite, colistin, or nalidixic acid for the organism's selective isolation from other autochthonous pharyngeal microbes. *C. diphtheriae* may be isolated from individuals with both nontoxigenic (*tox*$^-$) and toxigenic (*tox*$^+$) phenotypes. Uchida and Pappenheimer demonstrated that corynebacteriophage beta carries the structural gene *tox*, which encodes diphtheria toxin, and that a family of closely related corynebacteriophages are responsible for toxigenic conversion of *tox*$^-$ *C. diphtheriae* to the *tox*$^+$ phenotype. Moreover, lysogenic conversion from a nontoxigenic to a toxigenic phenotype has been shown to occur in situ. Growth of toxigenic strains of *C. diphtheriae* under iron-limiting conditions leads to the optimal expression of diphtheria toxin and is believed to be a pathogenic mechanism during human infection. Less commonly, diphtheria-like disease may be caused by *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*, which express the same toxin and are considered members of the *C. diphtheriae* group (discussed below).

EPIDEMIOLOGY

While in many regions diphtheria has been controlled in recent years with effective vaccination, there have been sporadic outbreaks in the

United States and Europe. Diphtheria is still common in the Caribbean, Latin America, and the Indian subcontinent, where mass immunization programs are not enforced. Large-scale epidemics of diphtheria have occurred in the post–Soviet Union independent states. Additional outbreaks have recently been reported in Africa and Asia. In temperate regions, respiratory diphtheria occurs year-round but is most common during winter months.

C. diphtheriae is transmitted via the aerosol route, usually during close contact with an infected person. There are no significant reservoirs other than humans. The incubation period for respiratory diphtheria is 2–5 days, but disease onset has occurred as late as 10 days after exposure. Prior to the vaccination era, most individuals over the age of 10 were immune to *C. diphtheriae*; infants were protected by maternal IgG antibodies but became susceptible after ~6 months of age. Thus, the disease primarily affected children and nonimmune young adults.

The development of diphtheria antitoxin in 1898 by von Behring and of the diphtheria toxoid vaccine in 1924 by Ramon led to the near-elimination of diphtheria in Western countries. The annual incidence rate in the United States peaked in 1921, with 206,000 cases (191 cases per 100,000) and 15,520 deaths. In contrast, since 1980, the annual figure in the United States has been fewer than 5 cases per 100,000, with only 2 cases reported from 2004 through 2017. Nevertheless, pockets of colonization persist in North America, and groups or individuals who resist vaccination remain at risk. Immunity to diphtheria induced by childhood vaccination gradually decreases in adulthood. An estimated 30% of men 60–69 years old have antitoxin titers below the protective level. In addition to older age and lack of vaccination, risk factors for diphtheria outbreaks include alcoholism, low socioeconomic status, crowded living conditions, and Native American ethnic background. An outbreak of diphtheria in Seattle, Washington, between 1972 and 1982 comprised 1100 cases, most of which were cutaneous. During the 1990s in the states of the former Soviet Union, a much larger diphtheria epidemic included more than 140,000 cases and more than 4000 deaths; at its peak in 1995, more than 50,412 cases were reported. Clonally related toxigenic *C. diphtheriae* strains of the ET8 complex were associated with this outbreak. Beginning in 1998, this epidemic was controlled by mass vaccination programs, and between 2000 and 2009 the diphtheria incidence fell by >95%, with high-burden countries such as Latvia reporting fewer than 10 cases. During the epidemic, the incidence rate was high among individuals between 16 and 50 years of age. The epidemic was attributed to multiple factors, including socioeconomic instability, migration, deteriorating public health programs, unnecessary contraindications to vaccination, low-dose vaccine formulations, frequent vaccine and antitoxin shortages, delayed implementation of vaccination and treatment in response to cases, public mistrust, and lack of awareness.

Since 2010, significant outbreaks of diphtheria and diphtheria-related mortality have continued to be reported from many developing countries, including the Dominican Republic, Nigeria, India, Laos, Thailand, Indonesia, and Brazil. Statistics collected by the World Health Organization indicated that 7321 diphtheria cases were reported in 2014, but many more cases are likely to have gone unreported. Although 86% of the global population has been adequately vaccinated, only 28% of countries have successfully vaccinated >80% of individuals in all districts.

Cutaneous diphtheria is usually a secondary infection that follows a primary skin lesion due to trauma, allergy, or autoimmunity. Most often, these isolates lack the *tox* gene and thus do not express diphtheria toxin. In tropical latitudes, cutaneous diphtheria is more common than respiratory diphtheria. In contrast to respiratory disease, cutaneous diphtheria is not reportable in the United States. Nontoxigenic strains of *C. diphtheriae* have been associated with pharyngitis in Europe, causing outbreaks among men who have sex with men and persons who use illicit IV drugs.

PATHOGENESIS AND IMMUNOLOGY

Diphtheria toxin produced by *tox*$^+$ strains of *C. diphtheriae* is the primary virulence factor in clinical disease. The toxin is synthesized in precursor form; is released as a 535-amino-acid, single-chain protein; and, in sensitive species (e.g., guinea pigs and humans, but not mice or rats), has a 50% lethal dose of ~100 ng/kg of body weight. The toxin is produced in the pseudomembranous lesion and is taken up in the bloodstream, from which it is distributed to all organ systems in the body. Once bound to its cell surface receptor (a heparin-binding epidermal growth factor–like precursor), the toxin is internalized by receptor-mediated endocytosis and enters the cytosol from an acidified early endosomal compartment. In vitro, the toxin may be separated into two chains by digestion with serine proteases: the N-terminal A fragment and the C-terminal B fragment. Delivery of the A fragment into the eukaryotic cell cytosol results in irreversible inhibition of protein synthesis by NAD^+-dependent ADP-ribosylation of elongation factor 2. The eventual result is the death of the cell.

In 1926, Ramon at the Institut Pasteur found that formalinization of diphtheria toxin resulted in the production of a nontoxic but highly immunogenic diphtheria toxoid. Subsequent studies showed that immunization with diphtheria toxoid elicited antibodies that neutralized the toxin and prevented most disease manifestations. In the 1930s, mass immunization of children and susceptible adults with diphtheria toxoid commenced in the United States and Europe.

Individuals with a diphtheria antitoxin titer of >0.01 U/mL are at low risk of disease. In populations where a majority of individuals have protective antitoxin titers, the carrier rate for toxigenic strains of *C. diphtheriae* decreases and the overall risk of diphtheria among susceptible individuals is reduced. Nevertheless, individuals with nonprotective titers may contract diphtheria through either travel or exposure to individuals who have recently returned from regions where the disease is endemic.

Characteristic pathologic findings of diphtheria include mucosal ulcers with a pseudomembranous coating composed of an inner band of fibrin and a luminal band of neutrophils. Initially white and firmly adherent, in advanced diphtheria the pseudomembranes turn gray or even green or black as necrosis progresses. Mucosal ulcers result from toxin-induced necrosis of the epithelium accompanied by edema, hyperemia, and vascular congestion of the submucosal base. A significant fibrinosuppurative exudate from the ulcer develops into the pseudomembrane. Ulcers and pseudomembranes in severe respiratory diphtheria may extend from the pharynx into medium-sized bronchial airways. Expanding and sloughing membranes may result in fatal airway obstruction.

APPROACH TO THE PATIENT

Diphtheria

Diphtheria, although rare in the United States and other developed countries, should be considered when a patient has severe pharyngitis, particularly when there is difficulty swallowing, respiratory compromise, or signs of systemic disease (e.g., myocarditis or generalized weakness). The leading causes of pharyngitis are respiratory viruses (rhinoviruses, influenza viruses, parainfluenza viruses, coronaviruses, adenoviruses; ~25% of cases), group A streptococci (15–30%), group C streptococci (~5%), atypical bacteria such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* (15–20% in some series), and other viruses such as herpes simplex virus (~4%) and Epstein-Barr virus (<1% in infectious mononucleosis). Less common causes are acute HIV infection, gonorrhea, fusobacterial infection (e.g., Lemierre's syndrome), thrush due to *Candida albicans* or other *Candida* species, and diphtheria. The presence of a pharyngeal pseudomembrane or an extensive exudate should prompt consideration of diphtheria **(Fig. 150-1)**.

CLINICAL MANIFESTATIONS

Respiratory Diphtheria The clinical diagnosis of diphtheria is based on the constellation of sore throat; adherent tonsillar, pharyngeal, or nasal pseudomembranous lesions; and low-grade fever. In addition, diagnosis requires the isolation of *C. diphtheriae* or histopathologic isolation of compatible gram-positive organisms. The

FIGURE 150-1 Respiratory diphtheria due to toxigenic *C. diphtheriae* producing exudative pharyngitis in a child displaying a pseudomembrane extending from the uvula to the pharyngeal wall. The characteristic white pseudomembrane is caused by diphtheria toxin–mediated necrosis of the respiratory epithelial layer, producing a fibrinous coagulative exudate. Submucosal edema adds to airway narrowing. The pharyngitis is acute in onset, and respiratory obstruction from the pseudomembrane may occur in severe cases. Inoculation of pseudomembrane fragments or submembranous swabs onto Löffler's or tellurite selective medium reveals *C. diphtheriae. (Photograph courtesy of the Centers for Disease Control and Prevention and Immunization Action Coalition, used by permission.)*

FIGURE 150-2 Cutaneous diphtheria due to nontoxigenic *C. diphtheriae* on the lower extremity. *(From the Centers for Disease Control and Prevention, Public Health Image Library [PHIL]. #1941.)*

Centers for Disease Control and Prevention (CDC) recognizes *confirmed* respiratory diphtheria (laboratory proven or epidemiologically linked to a culture-confirmed case) and *probable* respiratory diphtheria (clinically compatible but not laboratory proven or epidemiologically linked). Carriers are defined as individuals who have positive cultures for *C. diphtheriae* and who either are asymptomatic or have symptoms but lack pseudomembranes. Most patients seek medical care for sore throat and fever several days into the illness. Occasionally, weakness, dysphagia, headache, and voice change are the initial manifestations. Neck edema and difficulty breathing are evident in more advanced cases and carry a poor prognosis.

The systemic manifestations of diphtheria stem from the effects of diphtheria toxin and include weakness as a result of neurotoxicity and cardiac arrhythmias or congestive heart failure due to myocarditis. Most commonly, the pseudomembranous lesion is located in the tonsillopharyngeal region. Less commonly, the lesions are located in the larynx, nares, and trachea or bronchial passages. Large pseudomembranes are associated with severe disease and a poor prognosis. A few patients develop massive swelling of the tonsils and present with "bull-neck" diphtheria, which results from edema of the submandibular and paratracheal region and is further characterized by foul breath, thick speech, and stridorous breathing. The diphtheritic pseudomembrane is gray or whitish and sharply demarcated. Unlike the exudative lesion associated with streptococcal pharyngitis, the pseudomembrane in diphtheria is tightly adherent to the underlying tissues. Attempts to dislodge the membrane may cause bleeding. Hoarseness suggests laryngeal diphtheria, in which laryngoscopy may be diagnostically helpful.

Cutaneous Diphtheria This dermatosis is characterized by punched-out ulcerative lesions with necrotic sloughing or pseudomembrane formation **(Fig. 150-2)**. The diagnosis requires cultivation of *C. diphtheriae* from lesions, which most commonly occur on the lower and upper extremities, head, and trunk.

Infections Due to Non-*diphtheriae Corynebacterium* Species and Nontoxigenic *C. diphtheriae* Non-*diphtheriae* species of *Corynebacterium* and related genera (discussed below) as well as nontoxigenic strains of *C. diphtheriae* itself have been found in bloodstream and respiratory infections, often in individuals with immunosuppression or chronic respiratory disease. These organisms can cause disease manifestations and should not necessarily be dismissed as colonizers.

Other Clinical Manifestations *C. diphtheriae* causes rare cases of endocarditis and septic arthritis, most often in patients with preexisting risk factors, such as abnormal cardiac valves, injection drug use, or cirrhosis.

COMPLICATIONS

Airway obstruction poses a significant early risk in patients presenting with advanced diphtheria. Pseudomembranes may slough and obstruct the airway or may advance to the larynx or into the tracheobronchial tree. Children are particularly prone to obstruction because of their small airways.

Polyneuropathy and myocarditis are late toxic manifestations of diphtheria. During a diphtheria outbreak in the Kyrgyz Republic in 1999, myocarditis was found in 22% and neuropathy in 5% of 676 hospitalized patients. The mortality rate was 7% among patients with myocarditis as opposed to 2% among those without myocardial manifestations. The median time to death in hospitalized patients was 4.5 days. Myocarditis is typically associated with arrhythmias and dilated cardiomyopathy.

Polyneuropathy is seen 3–5 weeks after the onset of diphtheria and has a slow indolent course. However, patients may develop severe and prolonged neurologic abnormalities. The disorders typically occur in the mouth and neck, with lingual or facial numbness as well as dysphonia, dysphagia, and cranial nerve paresthesias. More ominous signs include weakness of respiratory and abdominal muscles and paresis of the extremities. Sensory manifestations and sensory ataxia also are observed. Cranial nerve dysfunction typically precedes disturbances of the trunk and extremities because of proximity to the site of infection. Autonomic dysfunction also is associated with polyneuropathy and can lead to hypotension. Polyneuropathy is typically reversible in patients who survive the acute phase.

Other complications of diphtheria include pneumonia, renal failure, encephalitis, cerebral infarction, pulmonary embolism, and serum sickness from antitoxin therapy.

DIAGNOSIS

The diagnosis of diphtheria is based on clinical signs and symptoms plus laboratory confirmation. Respiratory diphtheria should be considered in patients with sore throat, pharyngeal exudates, and fever. Other symptoms may include hoarseness, stridor, or palatal paralysis. The presence of a pseudomembrane should prompt strong consideration of diphtheria. Once a clinical diagnosis of diphtheria is made, diphtheria antitoxin should be obtained and administered as rapidly as possible.

Laboratory diagnosis of diphtheria is based either on cultivation of *C. diphtheriae* or toxigenic *C. ulcerans* from the site of infection or on the demonstration of local lesions with characteristic histopathology. *Corynebacterium pseudodiphtheriticum*, a nontoxigenic organism, is a common component of the normal throat flora and does not pose a significant risk. Throat samples should be submitted to the laboratory for culture with the notation that diphtheria is being considered. This information should prompt cultivation on special selective medium and subsequent biochemical testing to differentiate *C. diphtheriae* from other nasopharyngeal commensal corynebacteria. All laboratory isolates of *C. diphtheriae,* including nontoxigenic strains, should be submitted to the CDC.

A diagnosis of cutaneous diphtheria requires laboratory confirmation since the lesions are not characteristic and are indistinguishable from other dermatoses. Diphtheritic ulcers occasionally—but not consistently—have a punched-out appearance (Fig. 150-2). Patients in whom cutaneous diphtheria is identified should have the nasopharynx cultured for *C. diphtheriae*. The laboratory medium for cutaneous diphtheria specimens is the same as that used for respiratory diphtheria: Löffler's or Tinsdale's selective medium in addition to nonselective medium such as blood agar. As has been mentioned, respiratory diphtheria remains a notifiable disease in the United States, whereas cutaneous diphtheria is not.

TREATMENT

Diphtheria

DIPHTHERIA ANTITOXIN

Prompt administration of diphtheria antitoxin is critical in the management of respiratory diphtheria. Diphtheria antitoxin, a horse antiserum, is effective in reducing the extent of local disease as well as the risk of complications of myocarditis and neuropathy. Rapid institution of antitoxin therapy is also associated with a significant reduction in mortality risk. Because diphtheria antitoxin cannot neutralize cell-bound toxin, prompt initiation is important. This product, which is no longer commercially available in the United States, can be obtained from the CDC Emergency Operations Center at 770-488-7100 (website: *www.cdc.gov/diphtheria/dat.html*) after first contacting the state health department. The current protocol for the use of diphtheria antitoxin involves a test dose to rule out immediate hypersensitivity. Patients who demonstrate hypersensitivity require desensitization before a full therapeutic dose of antitoxin is administered.

Given that the world supply of equine anti–diphtheria toxin is limited, a human monoclonal antibody with the potential to provide a safer alternative to equine antitoxin therapy is being developed.

ANTIMICROBIAL THERAPY

Antibiotics are used in the management of diphtheria primarily to prevent transmission to susceptible contacts. Antibiotics also prevent further toxin production and reduce the severity of local infection. Recommended treatment options for patients with respiratory diphtheria are as follows:

- Erythromycin, 500 mg IV q6h (for children: 40–50 mg/kg per day IV in two or four divided doses) until the patient can swallow comfortably; then 500 mg PO qid to complete a 14-day course
- Procaine penicillin G, 600,000 U IM q12h (for children: 12,500–25,000 U/kg IM q12h) until the patient can swallow comfortably; then oral penicillin V, 125–250 mg qid to complete a 14-day course

A clinical study in Vietnam found that penicillin was associated with a more rapid resolution of fever and a lower rate of bacterial resistance than erythromycin; however, relapses were more common in the penicillin group. Erythromycin therapy targets protein synthesis and thus offers the presumed benefit of stopping toxin synthesis more quickly than a cell wall–active β-lactam agent. Alternative therapeutic agents for patients who are allergic to penicillin or cannot take erythromycin include rifampin and clindamycin. Other reasonable antibiotics are clarithromycin, azithromycin, linezolid, and vancomycin, although they have not been studied in comparison to the agents above.

Eradication of *C. diphtheriae* should be documented after antimicrobial therapy is complete. A repeat throat culture 2 weeks later is recommended. For patients in whom the organism is not eradicated after a 14-day course of erythromycin or penicillin, an additional 10-day course followed by repeat culture is recommended. Drug-resistant strains of *C. diphtheriae* exist, and several reports have described multidrug-resistant strains, predominantly in Southeast Asia. Drug resistance should be considered when efforts at pathogen eradication fail.

Cutaneous diphtheria should be treated as described above for respiratory disease. Individuals infected with toxigenic strains should receive antitoxin. It is important to treat the underlying cause of the dermatoses in addition to the superinfection with *C. diphtheriae*.

Patients who recover from respiratory or cutaneous diphtheria should have antitoxin levels measured. If diphtheria antitoxin has been administered, this test should be performed 6 months later. Patients who recover from respiratory or cutaneous diphtheria should receive the appropriate vaccine to ensure the development of protective antibody titers.

MANAGEMENT STRATEGIES

Patients in whom diphtheria is suspected should be hospitalized in respiratory isolation rooms, with close monitoring of cardiac and respiratory function. A cardiac workup is recommended to assess the possibility of myocarditis. In patients with extensive pseudomembranes, an anesthesiology or an ear, nose, and throat consultation is recommended because of the possible need for tracheostomy or intubation. In some settings, pseudomembranes can be removed surgically. Treatment with glucocorticoids has not been shown to reduce the risk of myocarditis or polyneuropathy.

PROGNOSIS

The mortality rate for diphtheria is 5–10% but may approach 20% among children <5 years old and adults >40 years of age. Fatal pseudomembranous diphtheria typically occurs in patients with nonprotective antibody titers and in unimmunized patients. The pseudomembrane may actually increase in size from the time it is first noted. Risk factors for death include bullneck diphtheria; myocarditis with ventricular tachycardia; atrial fibrillation; complete heart block; an age of >60 years or <6 months; alcoholism; extensive pseudomembrane elongation; and laryngeal, tracheal, or bronchial involvement. Another important predictor of fatal outcome is the interval between the onset of local disease and the administration of antitoxin. Cutaneous diphtheria has a low mortality rate and is rarely associated with myocarditis or peripheral neuropathy.

PREVENTION

Vaccination Sustained campaigns for vaccination of children and adequate boosting vaccination of adults are responsible for the exceedingly low incidence of diphtheria in most developed nations. Currently, diphtheria toxoid vaccine is coadministered with tetanus vaccine (with or without acellular pertussis). DTaP (full-level diphtheria toxoid,

tetanus toxoid, and acellular pertussis vaccine) is currently recommended for children up to the age of 6; DTaP replaced the earlier whole-cell pertussis vaccine DTP in 1997. Tdap is a tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine formulated for adolescents and adults. Tdap was licensed for use in the United States in 2005 and is recommended for children ≥7 years old and for adults. It is recommended that all adults (i.e., persons >19 years old) receive a single dose of Tdap if they have not received it previously, regardless of the interval since the last dose of Td (tetanus and reduced-dose diphtheria toxoids, adsorbed). Tdap vaccination is a priority for health care workers, pregnant women, adults anticipating contact with infants, and adults not previously vaccinated for pertussis. Adults who have received acellular pertussis vaccine should continue to receive decennial Td booster vaccinations. **The vaccine schedule is detailed in Chap. 123.**

Prophylaxis Administration to Contacts Close contacts of diphtheria patients should undergo throat culture to determine whether they are carriers. After samples for throat culture are obtained, antimicrobial prophylaxis should be considered for all contacts, even those whose cultures are negative. The options are 7–10 days of oral erythromycin or one dose of IM benzathine penicillin G (1.2 million units for persons ≥6 years of age or 600,000 units for children <6 years of age).

Contacts of diphtheria patients whose immunization status is uncertain should receive the appropriate diphtheria toxoid–containing vaccine. The Tdap vaccine (rather than Td) is now the booster vaccine of choice for adults who have not recently received an acellular pertussis–containing vaccine. Carriers of *C. diphtheriae* in the community should be treated and vaccinated when identified.

OTHER CORYNEBACTERIAL AND *RHODOCOCCUS* INFECTIONS

Nondiphtherial corynebacteria, referred to as *diphtheroids* or *coryneforms*, are frequently considered colonizers or contaminants; however, they have been associated with invasive disease, particularly in immunocompromised patients. Importantly, even though they are termed nondiphtherial corynebacteria, *C. ulcerans* and *C. pseudotuberculosis* may produce diphtheria toxin and therefore cause severe human illness. These organisms have been isolated from the bloodstream, especially in association with catheter infection, endocarditis, prosthetic valve infection, meningitis, brain abscess, osteomyelitis, and peritonitis. Risk factors include indwelling intravenous or peritoneal catheters and neurosurgical shunts. Patients infected with these organisms are often immunosuppressed or have significant medical comorbidities. The nondiphtherial coryneforms are a collection of bacteria that are taxonomically grouped together in the genus *Corynebacterium* on the basis of their 16S rDNA signature nucleotides. Despite the shared rDNA signatures, these isolates are quite diverse. For example, their guanine-cytosine content ranges from 45 to 70%. Several nondiphtheroid corynebacteria, including *Corynebacterium jeikeium* and *Corynebacterium urealyticum*, are associated with resistance to multiple antibiotics. *Rhodococcus equi* is associated with necrotizing pneumonia and granulomatous infection, particularly in immunocompromised individuals.

MICROBIOLOGY AND LABORATORY DIAGNOSIS

These organisms are non-acid-fast, catalase-positive, aerobic or facultatively anaerobic rods. Their colonial morphologies on blood agar vary widely; some species are small and α-hemolytic (similar to lactobacilli), whereas others form large white colonies (similar to yeasts). Many nondiphtherial coryneforms require special media, such as Löffler's, Tinsdale's, or tellurite medium. These cultivation idiosyncrasies have led to a complex taxonomic categorization of the organisms.

EPIDEMIOLOGY

Humans are the natural reservoirs for several nondiphtherial coryneforms, including *C. xerosis, C. pseudodiphtheriticum*, *C. striatum*, *C. minutissimum*, *C. jeikeium*, *C. urealyticum*, and *Arcanobacterium haemolyticum*. Animal reservoirs including milk are responsible for carriage of *C. ulcerans* and *C. pseudotuberculosis*. Soil is the natural reservoir for *R. equi*.

CLINCAL MANIFESTATIONS

C. ulcerans This organism causes a diphtheria-like illness and produces both diphtheria toxin and a dermonecrotic toxin. The organism is a commensal in horses and cattle and has been isolated from cow's milk. In contrast to diphtheria, this infection is considered a zoonosis, and cases have been traced to contact with animal carriers, including dogs and pigs. *C. ulcerans* causes exudative pharyngitis, primarily during summer months, in rural areas, and among individuals exposed to animals. Treatment with antitoxin and antibiotics should be initiated when respiratory *C. ulcerans* is identified, and a contact investigation (including throat cultures to determine the need for antimicrobial prophylaxis and, in unimmunized contacts, administration of the appropriate diphtheria toxoid–containing vaccine) should be conducted. The organism grows on Löffler's, Tinsdale's, and tellurite agars as well as blood agar. In addition to exudative pharyngitis, cutaneous disease due to *C. ulcerans* has been reported. *C. ulcerans* is susceptible to a wide panel of antibiotics. Erythromycin and other macrolides appear to be the first-line agents.

C. pseudotuberculosis Infection caused by *C. pseudotuberculosis* is an important animal pathogen (most notably of sheep) that rarely causes human disease. *C. pseudotuberculosis* causes suppurative granulomatous lymphadenitis and an eosinophilic pneumonia syndrome among individuals who handle sheep; horses, cattle, goats, deer, and raw milk also have been implicated. Surgical excision of affected lymph nodes should be performed when feasible, and successful treatment with erythromycin or tetracycline has been reported. Some strains express diphtheria toxin and produce a diphtheria-like disease, which should be treated with antitoxin.

***C. jeikeium* (Group JK)** Originally described in American hospitals, *C. jeikeium* infection was subsequently reported in Europe. After a 1976 survey of diseases caused by nondiphtherial corynebacteria, CDC group JK emerged as an important opportunistic pathogen among neutropenic and HIV-infected patients. The organism has now been designated a separate species. *C. jeikeium* forms small, gray to white, glistening, nonhemolytic colonies on blood agar. It lacks urease and nitrate reductase and does not ferment most carbohydrates. The predominant syndrome associated with *C. jeikeium* is sepsis, sometimes with associated pneumonia, endocarditis, meningitis, osteomyelitis, or epidural abscess. Risk factors for *C. jeikeium* infection include hematologic malignancy, neutropenia from comorbid conditions, prolonged hospitalization, exposure to multiple antibiotics, and skin disruption. There is evidence that *C. jeikeium* is part of the inguinal, axillary, genital, and perirectal flora of hospitalized patients.

Broad-spectrum antimicrobial therapy appears to select for colonization. The organisms appear as gram-positive coccobacillary forms slightly resembling streptococci. *C. jeikeium* is resistant to the majority of antibiotic classes except oxazolidinones (e.g., linezolid) and glycopeptides (e.g., vancomycin). Effective therapy involves removal of the infectious source, whether a catheter, prosthetic joint, or prosthetic valve. Efforts have been made to prevent *C. jeikeium* infection with strict institution of infection control protocols for high-risk patients, particularly those in intensive care units.

***C. urealyticum* (Group D2)** Identified as a urease-positive nondiphtherial *Corynebacterium* in 1972, *C. urealyticum* is an opportunistic pathogen causing sepsis and urinary tract infection. *C. urealyticum* appears to be the etiologic agent of a severe urinary tract syndrome known as *alkaline-encrusted cystitis*, a chronic inflammatory bladder infection associated with deposition of ammonium magnesium phosphate on the surface and walls of ulcerating lesions in the bladder. In addition, *C. urealyticum* has been associated with pneumonia, peritonitis, endocarditis, osteomyelitis, and wound infection. It is similar to *C. jeikeium* in its resistance to most antibiotics except oxazolidinones and glycopeptides. Vancomycin therapy has been used successfully in severe infections.

***C. minutissimum* (Erythrasma)** Erythrasma is a cutaneous infection producing reddish-brown, macular, scaly, pruritic intertriginous patches. The dermatologic presentation under the Wood's lamp is of coral red fluorescence. *C. minutissimum* appears to be a common cause of erythrasma, although there is evidence for a polymicrobial etiology in certain settings. This microbe has also been associated with bacteremia in patients with hematologic malignancy. Erythrasma responds to topical erythromycin, clarithromycin, clindamycin, or fusidic acid, although more severe infections may require oral macrolide therapy.

Other Nondiphtherial Corynebacteria *C. xerosis* is a human commensal found in the conjunctiva, nasopharynx, and skin. This nontoxigenic organism is occasionally identified as a source of invasive infection in immunocompromised or postoperative patients and prosthetic joint recipients. *C. amycolatum* is a closely related species but tends to demonstrate more antibiotic resistance. *C. striatum* is found in the anterior nares, skin, face, and upper torso of healthy individuals. Also nontoxigenic, this organism has been associated with invasive opportunistic infections in severely ill or immunocompromised patients. *C. glucuronolyticum* is a nonlipophilic species that causes male genitourinary tract infections such as prostatitis and urethritis. These infections may be successfully treated with a wide variety of antibacterial agents, including β-lactams, rifampin, aminoglycosides, or vancomycin; however, the organism appears to be resistant to fluoroquinolones, macrolides, and tetracyclines. *C. imitans* has been identified in eastern Europe as a nontoxigenic cause of pharyngitis. *C. auris* has been identified in children with otitis media; it is susceptible to fluoroquinolones, rifampin, tetracycline, and vancomycin but resistant to penicillin G and variably susceptible to macrolides. *C. pseudodiphtheriticum* is a nontoxigenic species that is part of the normal human flora. Human infections—particularly endocarditis of either prosthetic or natural valves and invasive pneumonia—have been reported only rarely. Although *C. pseudodiphtheriticum* may be isolated from the nasopharynx of patients with suspected diphtheria, it is part of the normal flora and does not produce diphtheria toxin. *C. propinquum*, a close relative of *C. pseudodiphtheriticum*, is part of CDC group D-1 and has been isolated from the human respiratory tract and blood. *C. afermentans* and subspecies belongs to CDC group ANF-1; it is a rare human pathogen that has been isolated from human blood and abscesses.

Rhodococcus *Rhodococcus* species are phylogenetically related to the corynebacteria. These gram-positive coccobacilli have been associated with tuberculosis-like infections in humans with granulomatous pathology. While *R. equi* is best known, other near-relative species have been identified in human infections including *R. fascians*, *R. erythropolis*, *R. rhodochrous*, *Gordonia bronchialis*, *G. sputi*, *G. terrae*, and *Tsukamurella paurometabola*.

R. equi has been recognized as a cause of pneumonia in horses since the 1920s and as a cause of related infections in cattle, sheep, and swine. It is found in soil as an environmental microbe. The organisms vary in length; appear as spherical to long, curved, clubbed rods; and produce large irregular mucoid colonies. *R. equi* cannot ferment carbohydrates or liquefy gelatin and is often acid fast. An intracellular pathogen of macrophages, *R. equi* can cause granulomatous necrosis and caseation. This organism has most commonly been identified in pulmonary infection, but infections of brain, bone, and skin also have been reported. Most commonly, *R. equi* disease manifests as nodular and/or cavitary pneumonia of the upper lobe—a picture similar to that seen in tuberculosis or nocardiosis. Most patients are immunocompromised, often by HIV infection. Subcutaneous nodular lesions also have been identified. The involvement of *R. equi* should be considered when any patient presents with a tuberculosis-like syndrome.

Infection due to *R. equi* has been treated successfully with antibiotics that penetrate intracellularly, including macrolides, clindamycin, rifampin, and trimethoprim-sulfamethoxazole. β-Lactam antibiotics have not been useful. The organism is routinely susceptible to vancomycin, which is considered the drug of choice.

Arcanobacteria *Arcanobacterium haemolyticum* was identified as an agent of wound infections in U.S. soldiers in the South Pacific during World War II. It appears to be a human commensal of the nasopharynx and skin, but it is known to cause true pharyngitis as well as chronic skin ulcers. In contrast to the much more common pharyngitis caused by *Streptococcus pyogenes*, *A. haemolyticum* pharyngitis is associated with a scarlatiniform rash on the trunk and proximal extremities in about half of cases; this illness is occasionally confused with toxic shock syndrome. Because *A. haemolyticum* pharyngitis primarily affects teenagers, it has been postulated that the rash–pharyngitis syndrome may represent co-pathogenicity, synergy, or opportunistic secondary infection with Epstein-Barr virus. *A. haemolyticum* has also been reported as a cause of bacteremia, soft tissue infections, osteomyelitis, and cavitary pneumonia, predominantly in the setting of underlying diabetes mellitus. The organism is susceptible to most β-lactams, macrolides, fluoroquinolones, clindamycin, vancomycin, and doxycycline. However, resistance to trimethoprim-sulfamethoxazole as well as tetracycline is common.

151 *Listeria monocytogenes* Infections

Jennifer P. Collins, Patricia M. Griffin

Listeria monocytogenes is a ubiquitous environmental saprophyte and an intracellular pathogen in several animals. Humans develop *L. monocytogenes* infection—listeriosis—primarily through foodborne transmission. The clinical spectrum of listeriosis ranges from febrile gastroenteritis in healthy persons to invasive disease, including bacteremia and meningoencephalitis. Typical risk groups for invasive disease are pregnant women and their neonates, older adults, and immunocompromised persons.

MICROBIOLOGY

L. monocytogenes is a nonsporulating, facultatively anaerobic, short, gram-positive rod that grows well on blood agar, demonstrating small zones of β-hemolysis. Organisms sometimes appear gram-variable and resemble cocci, diplococci, or diphtheroids; this appearance can obscure the diagnosis. On light microscopy, *L. monocytogenes* demonstrates characteristic tumbling motility. It grows optimally at 30–37°C but can grow at refrigerator temperatures as low as 4°C. Serotypes are usually determined on the basis of somatic (O) and flagellar (H) antigens. Nearly all human illness is caused by serotypes 1/2a, 1/2b, and 4b.

PATHOGENESIS

L. monocytogenes lives in soil and decaying vegetable matter. Numerous bird and mammal species are reservoirs. In addition to its ability to grow at cold temperatures, *Listeria*'s tolerance to low-pH and high-salt environments facilitates its environmental survival. Human infection

typically occurs through ingestion of contaminated food. The infectious dose has not been well established but is likely to be very low for persons with severely impaired cellular immunity. Increased gastric pH, such as that due to proton pump inhibitors, probably promotes the organism's survival in the gastrointestinal tract. After transcytosis across the intestinal epithelium, the bacteria travel via mesenteric lymph nodes and the bloodstream to the liver and spleen, its target organs; dissemination to other organs can occur. *L. monocytogenes* can also migrate across the blood–brain barrier and the placenta.

Virulence factors, including a pore-forming cytolysin (listeriolysin O; LLO) and phospholipases, facilitate evasion of intracellular killing by mediating escape from the internalization vacuole; the organism can then enter the host cell cytosol. The surface protein ActA facilitates direct cell-to-cell movement within the cytosol, allowing *L. monocytogenes* to avoid encountering components of the host immune system, such as antibodies and complement, during dissemination. Iron promotes listerial growth of the organism in vitro, an effect that explains why listeriosis has been associated with iron-overload conditions, including hemochromatosis.

IMMUNE RESPONSE

Although *L. monocytogenes* is ubiquitous in the environment, infection is rare because of both innate and adaptive host immune responses. Studies of mice have contributed to a detailed understanding of the immune response to infection. Activation of innate immunity is important for host survival. Interferon γ and tumor necrosis factor α (TNF-α) are among the key cytokines involved in this response. T cells are the primary drivers of the adaptive immune response, furthering the clearance of infected cells. Cytotoxic (CD8+) T cells are the main contributors to long-term immunity.

These immune mechanisms explain the association between invasive listeriosis and immunocompromising conditions, particularly impaired cellular immunity. In light of numerous reports of invasive listeriosis in patients treated with TNF-α inhibitors, the U.S. Food and Drug Administration added listeriosis to the boxed warning for this drug class. Because *L. monocytogenes* induces a vigorous cell-mediated immune response, attenuated strains that express foreign antigens are undergoing clinical trials as a cancer immunotherapy.

EPIDEMIOLOGY

More than 50 years after *L. monocytogenes* was first identified as a human pathogen, a 1983 outbreak investigation implicated coleslaw, thus establishing foodborne transmission. It is now known that *L. monocytogenes* transmission is almost always foodborne. Listeriosis is a nationally notifiable disease in the United States. According to the Centers for Disease Control and Prevention's (CDC's) Foodborne Diseases Active Surveillance Network (FoodNet), the incidence of invasive listeriosis was 2.4–3.7 cases per million persons during 2008–2019 **(Fig. 151-1)**. Listeriosis is a substantial contributor to deaths from foodborne illness despite being a relatively uncommon cause of illness.

Only about 3% of cases of listeriosis are part of a recognized outbreak—i.e., have a source determined; however, outbreak investigations provide data on major food sources. Hot dogs and deli meats were the major sources of U.S. outbreaks until 2002, when an outbreak linked to turkey deli meat resulted in eight deaths and the recall of >30 million pounds of meat. After that outbreak, the U.S. Department of Agriculture's Food Safety and Inspection Service issued new regulations and intensified testing for *L. monocytogenes* in ready-to-eat meat and poultry plants, and producers added growth inhibitors. Since then, these products have rarely been implicated in outbreaks, yet the incidence of listeriosis has not declined significantly in about two decades (Fig. 151-1). Evidence that other sources are now more important is supported by the marked decline in isolations of *L. monocytogenes* from ready-to-eat meats (Fig. 151-1). Dairy products are an important source, especially soft cheese made with raw (unpasteurized) milk or produced from pasteurized milk in unsanitary facilities; ice cream and raw milk also have caused outbreaks. Raw produce is another important source; outbreaks have been traced to packaged salad, sprouts, cantaloupe and other fruit, caramel apples, and frozen vegetables. A single strain of *L. monocytogenes* can survive in a production facility for years. A small amount of contamination during production can lead to much higher levels when food is ingested because of the organism's ability to grow at refrigerator temperatures.

Most people with invasive listeriosis are older adults, whose risk increases with each decade over 59 years of age. Most other patients have impaired cellular immunity associated with hematologic malignancy, solid organ or bone marrow transplantation, HIV infection, or receipt of glucocorticoid or other immunosuppressive drugs. The group at highest risk is pregnant women, who almost always have only mild flulike symptoms but who transmit the infection to the fetus through the placenta. Some neonates may acquire infection in the hospital, as illustrated by an outbreak associated with contaminated mineral oil. Rarely, children and adults with no risk factors develop invasive listeriosis, probably through heavy contamination of food. The

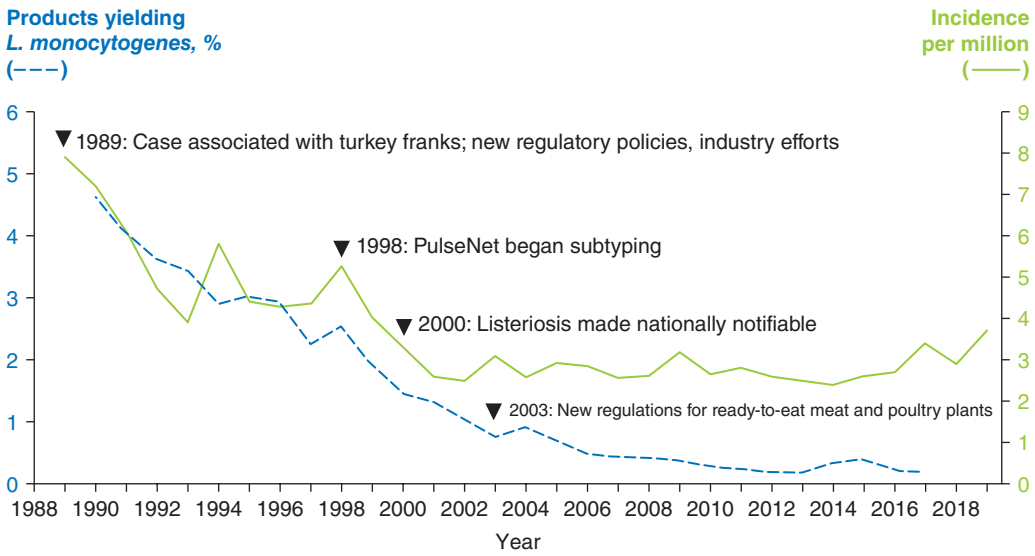

FIGURE 151-1 Incidence of listeriosis and percentage of ready-to-eat meat and poultry products with cultures that yielded *L. monocytogenes*, United States, 1989–2019. Incidence data are from the Center for Disease Control and Prevention's active sentinel site surveillance and include data from an early surveillance system (1986–1995) and from the Foodborne Diseases Active Surveillance Network (FoodNet) database (1996–2019). The incidence was 7.3 cases per million in 1986. Product data for 1990–2017 are publicly available through the U. S. Department of Agriculture Food Safety and Inspection Service Microbiological Testing Program for Ready-to-Eat Meat and Poultry Products.

diagnosis of listeriosis in a hospitalized patient with new symptoms should prompt investigation into the food provided during hospitalization as a source. In fact, outbreaks have been traced to food served to hospitalized patients, especially those with immunocompromising conditions; implicated foods include sandwiches, butter, precut celery, Camembert cheese, sausage, tuna salad, and ice cream. A large 2017–2018 outbreak of listeriosis in South Africa, linked to a ready-to-eat processed meat product, disproportionately affected people living with HIV and pregnant women. No outbreak-associated cases were detected in the 15 other countries that imported the product; this discrepancy suggests that listeriosis is underrecognized in low- to middle-income countries, particularly those with a high prevalence of HIV infection.

CLINICAL MANIFESTATIONS

L. monocytogenes infection can manifest in several ways. The incubation period differs according to host factors and dose consumed: on average, this interval is <24 h for gastroenteritis and ~11 days for invasive disease, although it can be much longer. Data from outbreak investigations suggest that the incubation period is longer in pregnant women than in nonpregnant adults.

Febrile Gastroenteritis *Listeria* organisms typically pass through healthy people without causing symptoms, but acute febrile gastroenteritis can occur. Outbreak investigations of *L. monocytogenes* febrile gastroenteritis have identified high organism density in implicated foods, suggesting that a large inoculum must be ingested to cause illness. Major manifestations are fever, diarrhea, headache, and constitutional symptoms. Illness is usually self-limited, with symptoms lasting an average of 1–3 days.

Bacteremia Bacteremia without a focus is the most common manifestation of invasive listeriosis. Major features are fever, chills, myalgias, and arthralgias, sometimes preceded by nausea or diarrhea—markers of the initial gut infection. Bacteremia can cause neurolisteriosis or localized infection at other sites, in which case the diagnosis may be suggested by neurologic or other focal findings. In a large French cohort study, the 3-month mortality rate for *L. monocytogenes* bacteremia was 46%; death was associated with older age, female sex, neoplasia, multiorgan failure, worsening of preexisting organ dysfunction, and monocytopenia (<200 cells/μL).

Neurolisteriosis *L. monocytogenes* has an affinity for the central nervous system. Neurolisteriosis is the second most common manifestation of invasive listeriosis. Signs of meningitis along with altered mental status, seizures, or focal neurologic findings suggest meningoencephalitis. A recent French cohort study found that 84% of patients with neurolisteriosis presented with meningoencephalitis. Isolate-based surveillance systems may not distinguish between meningitis and meningoencephalitis.

Onset of neurologic disease can be sudden or subacute, taking place over the course of several days. Patients typically have fever, headache, nausea, and vomiting—findings similar to those in other bacterial meningitides—but nuchal rigidity and meningeal signs occur less commonly than in the latter conditions. Most patients (~75%) have cerebrospinal fluid (CSF) white blood cell counts of <1000/μL (range, 100–5000/μL). CSF neutrophil predominance is typically less pronounced than in other bacterial meningitides. Approximately 30–40% of patients have low CSF glucose levels. Gram's staining of CSF sediment can show the expected gram-positive rods but commonly shows no organisms and sometimes shows gram-positive cocci, diplococci, or diphtheroids. In a U.S. study, *L. monocytogenes* caused <5% of cases of community-acquired bacterial meningitis in adults.

Uncommon neurolisteriosis manifestations include cerebritis, focal abscess, and rhombencephalitis (encephalitis of the cerebellum and brainstem). Patients with macroscopic abscesses often have positive blood cultures, but CSF findings may be normal in the absence of concurrent meningitis. Abscesses may be misdiagnosed as a primary or metastatic malignancy; they rarely occur in the cerebellum or spinal cord. Rhombencephalitis disproportionately affects otherwise healthy older adults. The classic presentation is biphasic, beginning with fever and headache and continuing after several days with signs of brainstem or cerebellar involvement, such as asymmetric cranial nerve palsies, ataxia, tremor, hemiparesis, or hemisensory deficits. Nearly half of patients with rhombencephalitis experience respiratory failure. The diagnosis may be delayed by the subacute course and by CSF findings, which are often only minimally abnormal. MRI is superior to CT for the diagnosis of neurolisteriosis, including rhombencephalitis.

Overall, the 3-month mortality rate for neurolisteriosis was 30% in a recent French cohort study; death was associated with the same risk factors as those documented for bacteremia. Neurolisteriosis-associated mortality was also higher among patients with a positive blood culture and among those treated with dexamethasone. Nearly half of survivors had long-term neurologic impairment.

Focal infections Hematogenous dissemination of *L. monocytogenes* infrequently causes endocarditis, pneumonia, localized abscesses in the liver or other internal organs, peritonitis, septic arthritis, osteomyelitis, urinary tract infection, or skin lesions. Direct inoculation has been reported as a rare cause of ocular infection, skin infection, and lymphadenitis.

Infection in Pregnant Women and Neonates Pregnancy-associated listeriosis is most common in the third trimester, presumably because of impaired maternal cell-mediated immunity. Typically, pregnant women either are asymptomatic or have a mild, flulike illness with fever, headache, myalgias, or arthralgias. Neurolisteriosis and death are rare in pregnant women without other risk factors. Although nearly all infected women fully recover, only a minority (~5%) have a normal delivery and postpartum course. In a study of 107 pregnancies in which *L. monocytogenes* was isolated from the mother, fetus, or neonate, 24% ended with fetal loss, 45% with premature birth, and 21% with abnormal delivery at term (i.e., fever, meconium release into amniotic fluid, abnormal fetal heart rate). Moreover, 88% of the 82 live-born neonates were ill, including 49% who required intensive care. Fetal loss is uncommon after 29 weeks of gestation. Granulomatosis infantiseptica is a severe in utero infection caused by *L. monocytogenes* and characterized by disseminated microabscesses and granulomas in the skin, liver, and spleen; most infants with this condition are stillborn or die soon after birth. Neonatal infection usually manifests in one of two ways: early-onset sepsis is hypothesized to result from in utero infection because it is typically diagnosed within 48 h after birth and is often associated with prematurity, whereas late-onset meningitis is thought to result from infection acquired at or soon after birth because it is typically diagnosed at ~2 weeks of age in full-term infants. A study of 128 pregnancy-associated listeriosis cases found that 47 (62%) of 76 ill neonates had early-onset disease. The case–fatality rate for neonatal listeriosis is 10–50%.

DIAGNOSIS

Because symptoms of listeriosis overlap with those of other infections, a high index of suspicion can facilitate timely diagnosis. Pregnant women with suspected listeriosis should have blood drawn for cultures, although blood cultures are positive only about half the time. Isolation of *L. monocytogenes* from a normally sterile site, such as blood, CSF, amniotic fluid, placental tissue, or fetal tissue, is diagnostic. *Listeria* must be distinguished from other gram-positive rods, especially diphtheroids. *L. monocytogenes* can be isolated from sterile specimens on routine medium; selective enrichment medium (such as PALCAM *Listeria* Selective Agar or Oxford Agar) enhances the capacity for isolation of the organism from nonsterile specimens, such as stool. Stool culture is not indicated in the evaluation of invasive listeriosis; culture on selective medium can be helpful for outbreak investigations of febrile gastroenteritis. Commercially available multiplex polymerase chain reaction panels for CSF specimens include *L. monocytogenes* as a target and may be a useful adjunct to culture. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry can rapidly identify an isolate as *L. monocytogenes*. Whole-genome sequencing has been a valuable tool for solving outbreaks of listeriosis, including a nosocomial outbreak associated with ice cream served in hospital milkshakes.

TREATMENT

Infections Caused by *Listeria monocytogenes*

L. monocytogenes treatment has not been evaluated in clinical trials. Recommendations are based on in vitro animal studies and observational clinical data. High-dose ampicillin (adult dose, 2 g IV every 4 h) or penicillin G (adult dose, 4 million units IV every 4 h) constitutes first-line therapy. Because penicillins are only weakly bactericidal against *L. monocytogenes*, many experts recommend adding gentamicin for synergy (1.0–1.7 mg/kg every 8 h if renal function is normal), particularly if the infection is severe. Small studies have had varying results with regard to the benefits of gentamicin. A large study provided evidence favoring amoxicillin–gentamicin as first-line therapy. Patients who are allergic to penicillin should undergo desensitization or be treated with trimethoprim-sulfamethoxazole (TMP-SMX; 5 mg/kg per dose of the trimethoprim component, given IV every 6–12 h). TMP-SMX should be avoided during the first trimester because it has been associated with neural tube and cardiovascular defects and in the perinatal period because it may increase the risk of kernicterus. Resistance to TMP-SMX has been reported; thus antibiotic susceptibility testing should be performed if this drug is considered. Treatment failures have been reported with meropenem despite in vitro susceptibility of the organism. *L. monocytogenes* is susceptible in vitro to several other drugs, including vancomycin, linezolid, tetracycline, macrolides, and fourth-generation fluoroquinolones (e.g., moxifloxacin), but relevant clinical reports are limited. Cephalosporins are not effective. A retrospective study of 31 patients found significantly reduced survival rates among patients treated with dexamethasone; the authors suggest avoiding this drug in neurolisteriosis. Prepartum antibiotic treatment of pregnant women with listeriosis enhances the chance of delivering a healthy infant.

The optimal duration of antibiotic therapy has not been established. Treatment duration usually depends on the clinical syndrome, disease severity, patient attributes, and response to treatment. The typical minimal treatment duration is 2 weeks for bacteremia, 2 weeks for early-onset neonatal disease, 3 weeks for meningitis, 4–6 weeks for endocarditis, and 6–8 weeks for brain abscess or encephalitis. Longer courses may be needed when patients are immunocompromised or are not improving as expected. Patients with neurolisteriosis do not routinely require a follow-up lumbar puncture if they are improving clinically during antibiotic therapy.

PREVENTION

Care of patients with listeriosis should be undertaken with standard precautions because person-to-person transmission is rare. Implementation of general precautions to prevent foodborne illness can help prevent listeriosis. These measures include fully cooking meats; washing fresh produce; cleaning hands, utensils, and kitchen surfaces after handling uncooked foods; and avoiding unpasteurized dairy products. Persons at increased risk for listeriosis should take additional precautions, including avoiding soft cheeses (particularly those made with unpasteurized milk) and either avoiding ready-to-eat and delicatessen foods (including meats, hot dogs, and smoked seafood) or heating these foods until the internal temperature is 165°F or until they are steaming hot. Additional CDC recommendations can be found at *www.cdc.gov/listeria/prevention.html*. Hospital dietary services should implement safe food-preparation procedures for immunocompromised patients and should not serve these patients higher-risk foods. Testing and treatment are not indicated for an asymptomatic person who has eaten a product recalled because of *L. monocytogenes* contamination, even if the person has risk factors for invasive listeriosis. TMP-SMX given as prophylaxis for *Pneumocystis jirovecii* infection (e.g., to persons infected with HIV or organ transplant recipients) helps prevent listeriosis.

152 Tetanus

C. Louise Thwaites, Lam Minh Yen

Tetanus is an acute disease manifested by skeletal muscle spasm and autonomic nervous system disturbance. It is caused by a powerful neurotoxin produced by the bacterium *Clostridium tetani* and is completely preventable by vaccination. *C. tetani* is found throughout the world, and tetanus commonly occurs where the vaccination coverage rate is low. In developed countries, the disease is seen occasionally in individuals who are incompletely vaccinated. In any setting, established tetanus is a severe disease with a high mortality rate.

DEFINITION

Tetanus is diagnosed on clinical grounds (sometimes with supportive laboratory confirmation of the presence of *C. tetani*; see "Diagnosis," below), and case definitions are often used to facilitate clinical and epidemiologic assessments. The Centers for Disease Control and Prevention (CDC) defines probable tetanus as "an acute illness with muscle spasms or hypertonia in the absence of a more likely diagnosis." *Neonatal* tetanus is defined by the World Health Organization (WHO) as "an illness occurring in a child who has the normal ability to suck and cry in the first 2 days of life but who loses this ability between days 3 and 28 of life and becomes rigid and has spasms." Given the unique presentation of neonatal tetanus, the history generally permits accurate classification of the illness with a high degree of probability. *Maternal* tetanus is defined by the WHO as tetanus occurring during pregnancy or within 6 weeks after the conclusion of pregnancy (whether with birth, miscarriage, or abortion).

ETIOLOGY

C. tetani is an anaerobic, gram-positive, spore-forming rod whose spores are highly resilient and can survive readily in the environment throughout the world. Spores resist boiling and many disinfectants. In addition, *C. tetani* spores and bacilli survive in the intestinal systems of many animals, and fecal carriage is common. The spores or bacteria enter the body through abrasions, wounds, or (in the case of neonates) the umbilical stump. Once in a suitable anaerobic environment, the organisms grow, multiply, and release tetanus toxin, an exotoxin that enters the nervous system and causes disease. Very low concentrations of this highly potent toxin can result in tetanus (minimal lethal human dose, 2.5 ng/kg).

In 20–30% of cases of tetanus, no puncture entry wound is found. Superficial abrasions to the limbs are the most common infection sites in adults. Deeper infections (e.g., attributable to open fracture,

abortion, or drug injection) are associated with more severe disease and worse outcomes. In neonates, infection of the umbilical stump can result from inadequate umbilical-cord care; in some cultures, for example, the cord is cut with grass or animal dung is applied to the stump. Circumcision or ear-piercing also can result in neonatal tetanus.

EPIDEMIOLOGY

Tetanus is a rare disease in the developed world. Two cases of neonatal tetanus have occurred in the United States since 2009. In 2018, 23 cases of tetanus were reported to the U.S. national surveillance system, almost all of which were in adults. Most cases occur in incompletely vaccinated or unvaccinated individuals. Vaccination status is known in 25% of cases reported in the United States between 2009 and 2015; among these cases, only 20% of patients had received three or more doses of tetanus toxoid–containing vaccine.

Persons >60 years of age are at greater risk of tetanus because antibody levels decrease over time. Approximately one-quarter of recent cases in the United States were in persons >65 years old. Diabetes is associated with increased tetanus risk, representing 13% of all cases and 25% of deaths in 2009–2015. People who inject drugs—particularly those injecting heroin subcutaneously ("skin-popping")—also are recognized as a high-risk group. Approximately 6% of all tetanus cases between 2009 and 2015 were in injection-drug users. The reasons for these outbreaks remain unclear but are thought to involve a combination of heroin contamination, skin-popping, and incomplete vaccination.

The global incidence of neonatal tetanus has reduced significantly following a concerted elimination program by WHO partnering with the United Nations Children's Fund (UNICEF) and the United Nations Population Fund (UNFPA). The incidence of tetanus among older children and adults is unknown, as few countries have good surveillance systems, although in 2015 there were estimated to be between 30,000 and 62,000 deaths from tetanus in this age group.

PATHOGENESIS

Genome sequencing of *C. tetani* has allowed identification of several exotoxins and virulence factors. Only those bacteria producing tetanus toxin (tetanospasmin) can cause tetanus. Although closely related to the botulinum toxins in structure and mode of action, tetanus toxin undergoes retrograde transport into the central nervous system (CNS) and thus produces clinical effects different from those caused by the botulinum toxins, which remain at the neuromuscular junction.

Tetanus toxin is intra-axonally transported to motor nuclei of the cranial nerves or ventral horns of the spinal cord. This toxin is produced as a single 150-kDa protein that is cleaved to produce heavy (100-kDa) and light (50-kDa) chains linked by a disulfide bond and noncovalent forces. The carboxy terminal of the heavy chain binds to specific membrane components in presynaptic α-motor nerve terminals; evidence suggests binding to both polysialogangliosides and membrane proteins. This binding results in toxin internalization and uptake into the nerves. Once inside the neuron, the toxin enters a retrograde transport pathway, whereby it is carried proximally to the motor neuron body. It is known that tetanus toxin exhibits several different pH-dependent conformations and therefore can interact with a variety of different receptors. During its passage from the periphery to the central nervous system, tetanus toxin can access neuronal trafficking systems and evade degradation.

Following retrograde transport in the motor neuron, the tetanus toxin undergoes translocation across the synapse to the GABA-ergic presynaptic inhibitory interneuron terminals. Here the light chain, which is a zinc-dependent endopeptidase, cleaves vesicle-associated membrane protein 2 (VAMP2, also known as *synaptobrevin*). This molecule is necessary for presynaptic binding and release of neurotransmitter; thus tetanus toxin prevents transmitter release and effectively blocks inhibitory interneuron discharge. The result is unregulated activity in the motor nervous system. Similar activity in the autonomic system accounts for the characteristic features of skeletal muscle spasm and autonomic system disturbance. The increased circulating catecholamine levels in severe tetanus are associated with cardiovascular complications.

Relatively little is known about the processes of recovery from tetanus. Recovery can take several weeks. Peripheral nerve sprouting is involved in recovery from botulism, and similar CNS sprouting may occur in tetanus. Other evidence suggests toxin degradation as a mechanism of recovery.

APPROACH TO THE PATIENT

Tetanus

The clinical manifestations of tetanus occur only after tetanus toxin has reached presynaptic inhibitory nerves. Once these effects become apparent, there may be little that can be done to affect disease progression. Treatment should not be delayed while the results of laboratory tests are awaited. Management strategies aim to neutralize remaining unbound toxin and support vital functions until the effects of the toxin have worn off. Recent interest has focused on intrathecal methods of antitoxin administration to neutralize toxin within the CNS and limit disease progression (see "Treatment," below).

CLINICAL MANIFESTATIONS

Tetanus produces a wide spectrum of clinical features that are broadly divided into generalized (including neonatal) and local. In the usually mild form of local tetanus, only isolated areas of the body are affected and only small areas of local muscle spasm may be apparent. If the cranial nerves are involved in localized cephalic tetanus, the pharyngeal or laryngeal muscles may spasm, with consequent aspiration or airway obstruction, and the prognosis may be poor. In the typical progression of generalized tetanus **(Fig. 152-1)**, muscles of the face and jaw often are affected first, presumably because of the shorter distances toxin must travel up motor nerves to reach presynaptic terminals. Neonates typically present with an inability to suck.

In assessing prognosis, the speed at which tetanus develops is important. The incubation period (time from wound to first symptom) and the period of onset (time from first symptom to first generalized spasm) are of particular significance; shorter times are associated with worse outcome. In neonatal tetanus, the younger the infant is when symptoms occur, the worse the prognosis.

The most common initial symptoms are trismus (lockjaw), muscle pain and stiffness, back pain, and difficulty swallowing. In neonates, difficulty in feeding is the usual presentation. As the disease progresses, muscle spasm develops. Generalized muscle spasm can be very painful. Commonly, the laryngeal muscles are involved early or even in isolation. This is a life-threatening event as complete airway obstruction may ensue. Spasm of the respiratory muscles results in respiratory failure. Without ventilatory support, respiratory failure is the most common cause of death in tetanus. Spasms strong enough to produce tendon avulsions and crush fractures have been reported, but this outcome is extremely rare.

Autonomic disturbance is maximal during the second week of severe tetanus, and death due to cardiovascular events becomes the major risk. Blood pressure is usually labile, with rapid fluctuations from high to low accompanied by tachycardia. Episodes of bradycardia and heart block also can occur. Autonomic involvement is evidenced by gastrointestinal stasis, sweating, increased tracheal secretions, and acute (often high-output) renal failure.

DIAGNOSIS

The diagnosis of tetanus is based on clinical findings. As stated above, treatment should not be delayed while laboratory tests are conducted. Culture of *C. tetani* from a wound provides supportive evidence. Serum anti-tetanus immunoglobulin G also may be measured in a sample taken before the administration of antitoxin or immunoglobulin; levels >0.1 IU/mL (measured by standard enzyme-linked immunosorbent assay) are deemed protective and do not support the diagnosis of tetanus. If levels are below this threshold, a bioassay for serum tetanus toxin may be helpful, but a negative result does not exclude the diagnosis, and these levels are not generally performed. Polymerase chain

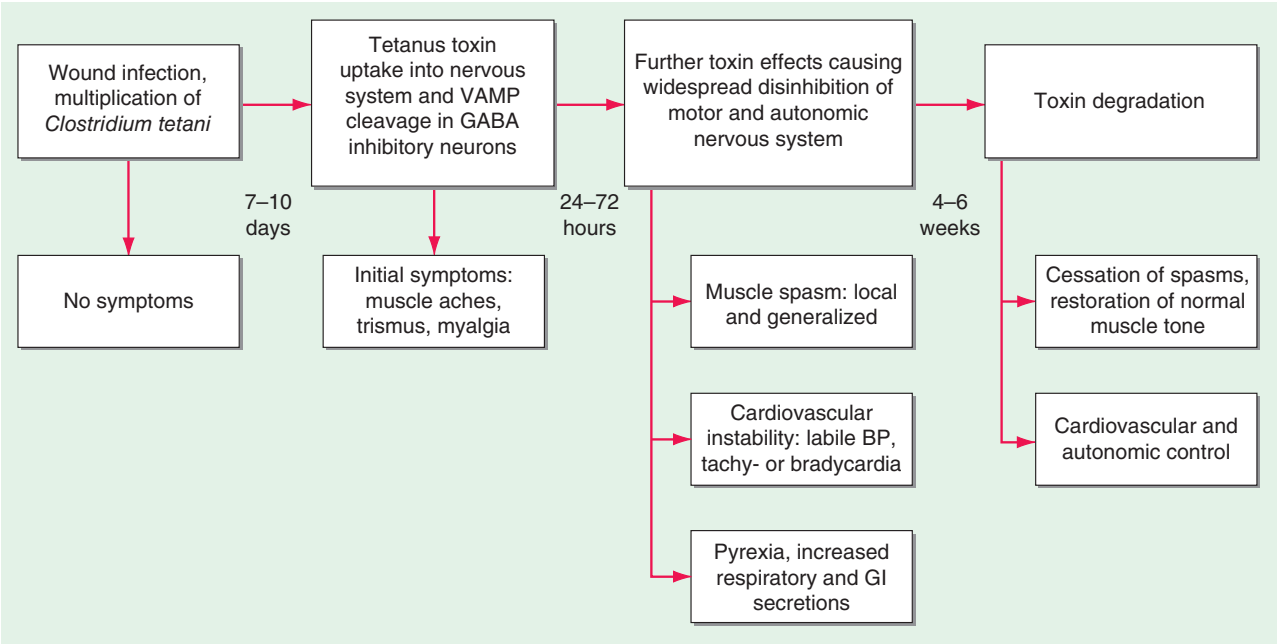

FIGURE 152-1 Clinical and pathologic progression of tetanus. BP, blood pressure; GABA, γ-aminobutyric acid; GI, gastrointestinal; VAMP, vesicle-associated membrane protein (synaptobrevin).

reaction also has been used for detection of tetanus toxin, but its sensitivity is unknown, and, similarly, a negative result does not exclude the diagnosis.

The few conditions that mimic generalized tetanus include strychnine poisoning and dystonic reactions to antidopaminergic drugs. Abdominal muscle rigidity is characteristically continuous in tetanus but is episodic in the latter two conditions. Cephalic tetanus can be confused with trismus of other etiologies, such as oropharyngeal infection. Hypocalcemia and meningoencephalitis are included in the differential diagnosis of neonatal tetanus.

TREATMENT

Tetanus

If possible, the entry wound should be identified, cleaned, and debrided of necrotic material in order to remove anaerobic foci of infection and prevent further toxin production. Metronidazole (400 mg rectally or 500 mg IV every 6 h for 7 days) is preferred for antibiotic therapy. An alternative is penicillin (100,000–200,000 IU/kg per day), although this drug theoretically may exacerbate spasms and in one study was associated with increased mortality. Failure to remove pockets of ongoing infection may result in recurrent or prolonged tetanus.

Antitoxin should be given early in an attempt to deactivate any circulating tetanus toxin and prevent its uptake into the nervous system. Two preparations are available: human tetanus immune globulin (TIG) and equine antitoxin. TIG is the preparation of choice, as it is less likely to be associated with anaphylactoid reactions. A single IM dose (500–5000 IU) is given, with a portion injected around the wound. Equine-derived antitoxin is available widely and is used in low-income countries; after hypersensitivity testing, 10,000–20,000 U is administered IM as a single dose or as divided doses. Some evidence indicates that intrathecal administration of TIG inhibits disease progression and leads to a better outcome. The results of relevant studies have been supported by a meta-analysis of trials involving both adults and neonates, with TIG doses of 50–1500 IU administered intrathecally. However, most preparations are not licensed for intrathecal use.

Spasms are controlled by heavy sedation with benzodiazepines. Chlorpromazine and phenobarbital are commonly used worldwide, and IV magnesium sulfate has been used as a muscle relaxant. A significant problem with all these treatments is that the doses necessary to control spasms also cause respiratory depression; thus, in resource-limited settings without mechanical ventilators, controlling spasms while maintaining adequate ventilation is problematic, and respiratory failure is a common cause of death. In locations with ventilation equipment, severe spasms are best controlled with a combination of sedatives or magnesium and relatively short-acting, cardiovascularly inert, nondepolarizing neuromuscular blocking agents that allow titration against spasm intensity. Infusions of propofol also have been used successfully to control spasms and provide sedation.

It is important to establish a secure airway early in severe tetanus. Ideally, patients should be nursed in calm, quiet environments because light and noise can trigger spasms. Tracheal secretions are increased in tetanus, and dysphagia due to pharyngeal involvement combined with hyperactivity of laryngeal muscles makes endotracheal intubation difficult. Patients may need ventilator support for several weeks. Thus tracheostomy is the usual method of securing the airway in severe tetanus.

Cardiovascular instability in severe tetanus is notoriously difficult to treat. Rapid fluctuations in blood pressure and heart rate can occur. Cardiovascular stability is improved by increasing sedation with IV magnesium sulfate (plasma concentration, 2–4 mmol/L or titrated against disappearance of the patella reflex), morphine, fentanyl, or other sedatives. In addition, drugs acting specifically on the cardiovascular system (e.g., esmolol, calcium antagonists, and inotropes) may be required. Short-acting drugs that allow rapid titration are preferred; particular care should be taken when longer-acting β antagonists are administered, as their use has been associated with hypotensive cardiac arrest.

Complications arising from treatment are common and include thrombophlebitis associated with diazepam injection, ventilator-associated pneumonia, central-line infections, and septicemia. In some centers, prophylaxis against deep-vein thrombosis and thromboembolism is routine.

Recovery from tetanus may take 4–6 weeks. Patients must be given a full primary course of immunization as tetanus toxin is poorly immunogenic and the immune response following natural infection is inadequate.

TABLE 152-1 Factors Associated with a Poor Prognosis in Tetanus

ADULT TETANUS	NEONATAL TETANUS
Age >70 years	Younger age, premature birth
Incubation period <7 days	Incubation period <6 days
Short time from first symptom to admission	Delay in hospital admission
Puerperal, IV, postsurgery, burn entry site	Grass used to cut cord
Period of onset[a] <48 h	Low birth weight
Heart rate >140 beats/min[b]	Fever on admission
Systolic blood pressure >140 mmHg[b]	
Severe disease or spasms[b]	
Temperature >38.5°C[b]	

[a]Time from first symptom to first generalized spasm. [b]At hospital admission.

PROGNOSIS

Rapid development of tetanus is associated with more severe disease and poorer outcome; it is important to note time of onset and length of incubation period. More sophisticated modeling has revealed other important predictors of prognosis **(Table 152-1)**. In many adults, particularly in the elderly, surviving tetanus is associated with reduced long-term functional outcome measures. Studies of children and neonates have suggested a higher incidence of neurologic sequelae. Neonates may be at increased risk of learning disabilities, behavioral problems, cerebral palsy, and deafness.

PREVENTION

Tetanus is prevented by good wound care and immunization **(Chap. 123)**. In neonates, use of safe, clean delivery and cord-care practices as well as maternal vaccination are essential. The WHO guidelines for tetanus vaccination consist of a primary course of three doses in infancy, boosters at 4–7 and 12–15 years of age, and one booster in adulthood. In the United States, the CDC suggests an additional dose at 15–18 months with booster at 11–12 years of age and every 10 years thereafter. For those with incomplete primary vaccination series in infancy, specific "catch-up" schedules are published. For those age 7 years or older, the recommendation is a three-dose primary course with 4 weeks between the first two doses, followed by a booster 6–12 months later. Catch-up schedules for those under 7 years involve a primary series of four doses of tetanus toxoid–containing vaccine if the child is under 12 months when the first dose is given, or three doses for those over 12 months at first dose.

Standard WHO recommendations for prevention of maternal and neonatal tetanus call for administration of two doses of tetanus toxoid at least 4 weeks apart to previously unimmunized pregnant women. A third dose should be given at least 6 months later, followed by one dose in subsequent pregnancies (or intervals of at least 1 year), to a total of five doses to provide long-term immunity. However, in high-risk areas, a more intensive approach has been successful, with all women of childbearing age receiving a primary course along with education on safe delivery and postnatal practices.

Individuals sustaining tetanus-prone wounds should be immunized if their vaccination status is incomplete or unknown or if their last booster was given >10 years earlier. Patients with an inadequate vaccine status who sustain wounds not classified as clean or minor should also undergo passive immunization with TIG. It is recommended that tetanus toxoid be given in conjunction with diphtheria toxoid in a preparation with or without acellular pertussis: DTaP for children <7 years old, Td for 7- to 9-year-olds, and Tdap for children >9 years old and adults.

In the early 1980s, tetanus caused more than 1 million deaths a year, accounting for an estimated 5% of maternal deaths and 14% of all neonatal deaths. In 1989, the World Health Assembly adopted a resolution to eliminate neonatal tetanus by the year 2000; elimination was defined as <1 case/1000 live births in every district in every country. By 1999, elimination was still to be achieved in 57 countries and the deadline was extended until 2005, with the additional target of eliminating maternal tetanus (tetanus occurring during pregnancy or within 6 weeks of its end). Ratification of the Millennium Development Goals, in particular goal 4 (achieving a two-thirds reduction in the mortality rate among children under 5), has further focused attention on reducing deaths from vaccine-preventable disease, particularly in the first 4 weeks of life. The target was to achieve maternal and neonatal tetanus elimination by 2020, but as of December 2020, 12 countries have yet to achieve this goal.

Because vaccination reduces the incidence of neonatal tetanus by an estimated 94%, immunization of pregnant women with two doses of tetanus toxoid at least 4 weeks apart has been the primary method of maternal and neonatal tetanus elimination. In some areas, all women of childbearing age have been targeted as a means of increasing vaccination coverage. In addition, educational programs have focused on improving hygiene during the birth process, an intervention that in itself is estimated to reduce neonatal tetanus deaths by up to 40%.

The latest available data show that significant progress has been made: in recent years, 47 countries have achieved maternal and neonatal tetanus elimination, including China, India, and Indonesia. Worldwide, deaths from neonatal tetanus fell by 96% between 1990 and 2015; in the latter year, with 72% of mothers receiving at least 2 doses of tetanus toxoid–containing vaccine and an estimated 34,000 neonatal tetanus deaths, mainly in Africa and Southeast Asia. Despite this relative success, immunization programs need to be ongoing as there is no herd immunity effect for tetanus and *C. tetani* contamination of soil and feces is widespread.

The rate of primary vaccination coverage in infancy (three doses of DTP) is 86%, but rates for the subsequent boosters necessary for long-term protection are unknown. Dedicated public health initiatives are lacking, and the continuing reports of sizable case series in the medical literature suggest that tetanus continues to pose a significant global health burden.

153 Botulism

Carolina Lúquez, Jeremy Sobel

Botulism is a rare, life-threatening disease characterized by cranial nerve palsies and symmetric descending flaccid paralysis. Four forms of naturally occurring botulism have been described: foodborne botulism, infant botulism, wound botulism, and adult intestinal colonization. Other forms of botulism include iatrogenic botulism and inhalational botulism. Effective treatment depends on early clinical diagnosis.

ETIOLOGY AND PATHOGENESIS

Botulism is caused by botulinum neurotoxins (BoNTs), which are produced by *Clostridium botulinum*. Rare strains of *Clostridium butyricum* and *Clostridium baratii* can also produce BoNTs. Seven distinct serotypes of BoNT (A through G) are well characterized; serotypes A, B, E, and F reportedly cause disease in humans. Novel serotypes—BoNT/FA (or H or HA), BoNT/En, and BoNT/X—have been proposed, but the scientific community has not yet reached a consensus as to whether each represents a new serotype or a combination of known serotypes, as in the case of BoNT/FA (or H or HA), or whether they represent true toxins or botulinum-like proteins, as in the case of BoNT/En and BoNT/X. BoNTs are encoded by the *bont* gene, which is also diverse in its DNA sequence. At least 40 unique subtypes of BoNT have been identified within serotypes A, B, E, and F. By definition, a variant of BoNT represents a new subtype when its amino acid sequence differs by at least 2.6% from those of all known subtypes within that particular serotype. Although 2.6% is an arbitrary threshold, this figure has provided the basis for genetic subtype designations for the past decade, aiding in the classification of BoNTs as new DNA or amino acid sequences become publicly available. In addition, *bont* genes typically reside within two types of gene clusters. One type includes *ha* genes encoding hemagglutinin proteins, which facilitate the absorption of toxins across the epithelial barrier. The other type of cluster includes *orfX* genes that encode proteins with unknown functions. Both cluster types include an *ntnh* gene, which encodes for a nontoxic nonhemagglutinin protein. It has been proposed that these accessory proteins form a complex with BoNTs and protect them from external proteolytic activity.

Despite their structural variability, BoNTs all have a similar mechanism of action: they target neurons and block neurotransmission by cleaving SNARE-family proteins in the host, with consequent inhibition of acetylcholine release. BoNTs are metalloproteases composed of a light chain and a heavy chain. The light chain has catalytic activity, and the heavy chain contains a translocation domain and a receptor-binding domain. The receptor-binding domain of the heavy chain mediates the neurospecific binding of BoNTs, which leads to its internalization within endocytic compartments. Interaction of the translocation domain of the heavy chain with the membrane of endocytic vesicles leads to the translocation of the light chain into the cytosol. Once in the cytosol, the light chain cleaves specific SNARE-family proteins. Serotypes A and E cleave SNAP-25; serotypes B, D, F, and G cleave VAMP; and serotype C cleaves SNAP-25 and syntaxin. Cleavage of any of these proteins disrupts the assembly of synaptic fusion complexes, and this disruption inhibits the fusion of the membrane of the synaptic vesicle containing acetylcholine with the neuronal cell membrane. Clinically, the result is flaccid paralysis of voluntary muscles. The irreversible binding of BoNTs to their targets has a clinical consequence: once toxin binding has occurred, the resulting paralysis persists for weeks or months, until nerve endings have been regenerated.

BoNTs are produced by *C. botulinum* and some strains of *C. butyricum* and *C. baratii*, which are gram-positive, rod-shaped, spore-forming, anaerobic bacteria. Under most environmental conditions, *C. botulinum* exists as spores that are heat-resistant and ubiquitous in soil. In general, *C. botulinum* spores require temperatures above boiling to ensure destruction; their thermal resistance increases with higher pH and lower salt content. Spores present in foods can survive most preservation methods and, if the conditions allow it, can germinate and produce BoNTs in significant amounts to cause disease.

BoNTs are among the most toxic substances known. Extremely small amounts of BoNT can cause severe disease and death. Severity of disease varies with dose, serotype, and route of exposure. The lethal dose of BoNT in humans is not known but can be estimated by extrapolation of toxicity data from animal studies. The estimated human lethal dose of BoNT acquired via the IV or IM route is 0.1–1 ng/kg of body weight. The human lethal dose of BoNT acquired by inhalation of aerosolized toxin is estimated at 1–75 ng/kg. The degree of toxicity of BoNT acquired by the oral route is estimated to be much lower: 0.1–1 μg/kg.

As stated above, four naturally occurring and two non–naturally occurring forms of botulism are known. Foodborne botulism is caused by the ingestion of foods contaminated with BoNT. Wound botulism occurs when spores of BoNT-producing species of *Clostridium* contaminate a wound and then germinate, multiply, and produce toxin. Infant botulism is caused by BoNT-producing species of *Clostridium* colonizing the intestinal tract of infants ≤1 year of age. Adult intestinal colonization is similar to infant botulism but affects persons >1 year of age. Iatrogenic botulism occurs when a patient given injections of BoNT experiences signs of systemic botulism. BoNTs can also be aerosolized and used as a bioweapon, entering the human body by inhalation.

Foodborne Botulism Foodborne botulism is the most common form reported in many countries. Every case of foodborne botulism represents a public health emergency because of the potential for causing outbreaks. Foodborne botulism is an intoxication in which food containing preformed toxin is ingested. Spores of BoNT-producing species of *Clostridium* are ubiquitous in soil and can be found on vegetables and other foodstuffs. *C. botulinum* type E is commonly found in aquatic environments and in aquatic animals. Because the spores are found in many foods, improper preparation or storage may produce the confluence of conditions that allow germination and growth of BoNT-producing species of *Clostridium*, which in turn result in production of BoNT. Both historically and at the present time, canned foods are of concern because they create anaerobic environments. To render these foods safe, proper processing procedures in conditions of enough heat and pressure to inactivate *Clostridium* spores, along with sufficient acidity, salinity, or other preservative methods to limit the organism's growth and its production of BoNT, are required. Low-acidity foods, such as corn, peppers, potatoes, and beets, represent a higher risk. A series of botulism outbreaks from commercially canned foods in the early twentieth century resulted in standardization of retort canning methods and promulgation and enforcement of production safety codes. Consumption of fish or other foods of marine origin can cause botulism if prepared or conserved improperly. Most foodborne botulism cases in the United States are caused by home-canned vegetables such as green beans; however, commercially prepared foods, including chicken broth, carrot juice, hot dog chili sauce, and nacho cheese, have also been implicated in recent outbreaks. Marine mammal and fish products traditionally prepared by Alaskan Natives and First Peoples are the main source of botulism in Alaska and Canada.

Wound Botulism Wound botulism is caused by germination and growth of *C. botulinum* spores in a wound or necrotic tissue where they produce BoNT, which then enters circulation and produces systemic disease. Few cases of wound botulism were described in the United States until 1981, when the first case associated with injection drug use was reported. Since then, botulism cases due to injection drug use, especially in association with subcutaneous or tissue injection (skin popping) of black tar heroin, have substantially increased in the United States. Black tar heroin was introduced into the United States in the 1970s and, since the late 1980s, has become the predominant form of heroin west of the Mississippi River. Black tar heroin is contaminated with by-products of the manufacturing process, adulterants, and diluents and therefore is considered the most probable source of *C. botulinum* spores. In recent decades, the few cases of wound botulism not associated with injection drug use have been associated with vehicle crashes, gunshot wounds, open-fracture wounds, and penetrating wounds caused by contaminated objects.

Infant Botulism Infant botulism is the most common form of botulism in the United States. It affects infants ≤1 year old, with a mean age at onset of 14 weeks. It has been suggested that the intestinal microbiota in infants may induce susceptibility to botulism; animal models seem to support this claim. Spores of BoNT-producing species of *Clostridium* can enter the body by ingestion. The highly resistant spores survive passage through the stomach and colonize the intestine, where they germinate, grow, and produce BoNT in situ. Infants can continue excreting *C. botulinum* for weeks after clinical recovery. Spores of BoNT-producing species of *Clostridium* have been found in honey. Consumption of honey has been epidemiologically implicated

in infant botulism; therefore, honey should not be fed to babies ≤1 year of age. Honey exposure, however, explains only a small proportion of cases. As spores are found in dust and soil, most infant botulism patients probably acquire BoNT-producing species of *Clostridium* by swallowing dust particles. Why only a few dozen infants are affected each year when presumably most infants regularly ingest clostridial spores remains unknown.

Adult Intestinal Botulism Similar to infant botulism, adult intestinal colonization is caused by spores of BoNT-producing species of *Clostridium* colonizing the large intestine, growing, and producing BoNT in situ. Although spores are routinely ingested and excreted by humans, the adult intestinal tract does not support spore germination and toxin production under normal circumstances. Adult intestinal colonization is usually associated with inborn anatomic abnormalities, gastrointestinal surgery, or prolonged use of antibiotics, which may alter the normal intestinal microbiota and facilitate colonization by BoNT-producing species of *Clostridium*. Although these associated conditions are relatively common, fewer than 30 cases of adult intestinal colonization have been reported worldwide.

Iatrogenic Botulism Iatrogenic botulism occurs in patients injected with large doses of BoNT for treatment of muscle complications related to such conditions as cerebral palsy and spastic dystonia. The small doses of botulinum toxin used for wrinkle elimination in dermatologic practice are usually insufficient to cause systemic disease. In 2004, an outbreak of four cases caused by the injection of an unlicensed, highly concentrated BoNT product for cosmetic purposes occurred in the United States. Similarly, in 2017, an outbreak of nine cases occurred in Egypt in association with an unlicensed, highly concentrated BoNT preparation.

Weaponized Inhalational Botulism BoNTs were weaponized by the biological weapons programs of several countries in the twentieth century. Aerosolized BoNTs can be used as a bioweapon, exerting their effect by entering the body through inhalation. In the United States, BoNTs are designated as Tier 1 select agents—i.e., agents that present the greatest risk of deliberate misuse with significant potential for mass casualties or devastating effects on the economy, critical infrastructure, or public confidence. Tier 1 agents pose a severe threat to public health and safety. Terrorists have attempted to use BoNT as a bioweapon: Aum Shinrikyo, a Japanese cult, tried unsuccessfully to aerosolize BoNT in terrorism attacks at multiple sites in Japan between 1990 and 1995.

EPIDEMIOLOGY

Foodborne Botulism In the United States, foodborne botulism is the third most common form of botulism. From 2001 to 2017, 326 foodborne botulism cases were reported, with a mean of 19 cases per year. Most cases (65%) were caused by serotype A BoNT, which was followed in frequency by serotype E (25%). Serotypes B and F caused 7% and 1% of foodborne botulism cases, respectively. Outbreaks caused by serotype E usually had a shorter incubation period, those caused by type A had higher numbers of patients who required mechanical ventilation, and those caused by type B had lower numbers of deaths.

Foodborne botulism cases are usually sporadic (i.e., cases occur singly), but small and large outbreaks can also occur. From 2001 to 2017, five foodborne botulism outbreaks affecting 10 or more people were reported in the United States (Table 153-1). Every case of foodborne botulism is considered a public health emergency because it may be the first in an outbreak involving additional patients.

Most foodborne botulism cases in the United States are due to a wide variety of home-canned vegetables and pickled vegetables (e.g., beets, green beans, carrots, mushrooms, asparagus, peppers, beans, mustard greens, corn, tomato sauce, olives, and pumpkin butter), vegetables baked in aluminum foil (e.g., potatoes and beets), home-canned meat-based foods (e.g., tuna, pickled pigs' feet, stew, and pasta in meat sauce), oil-based foods (e.g., pasta and jarred pesto or homemade garlic-infused oil), herbal deer antler tea, home-prepared fermented tofu, commercial clam chowder, or commercial grain and vegetable products. In Alaska, traditional Alaskan Native foods linked to foodborne botulism cases have included seal oil, seal blubber, dried herring in seal oil, fermented seal flipper, stinkheads and other fermented fish heads, stinkfish, salmon eggs, beaver tail, whitefish, fish eggs, fermented beluga, and whale blubber.

TABLE 153-1 Total Foodborne Botulism Outbreaks of 10 or More Cases Reported in the United States Between 2001 and 2017

YEAR	STATE	FOOD SOURCE	NO. OF CONFIRMED CASES
2001	Texas	Chili	16
2007	Multistate	Commercially canned hot dog chili sauce	10
2015	Ohio	Home-canned potatoes used to prepare a potato salad, served at a church potluck	27
2016	Mississippi	Pruno, illegal alcoholic beverage consumed by inmates at a federal facility	19
2017	California	Commercially produced nacho cheese, sold at a convenience store	10

Commercial food manufacturing processes include retort canning, in which high temperature and pressure destroy the highly resistant clostridial spores, and manipulations that inhibit bacterial growth, such as acidification or addition of growth inhibitors that prevent germination and growth of BoNT-producing species of *Clostridium* and the production of BoNT. However, commercial foods occasionally still cause botulism if safe manufacturing processes are not followed or fail or if foods are stored or used inappropriately by the retailer or consumer. For instance, an outbreak of 10 cases associated with commercially canned hot dog chili sauce occurred in 2007 as a result of deficiencies in the canning process. Other commercial food–associated outbreaks that occurred in the United States between 2001 and 2017 include a 2001 outbreak of 16 cases linked to chili that was stored at inappropriate temperatures and later served at a church event in Texas and a 2006 outbreak linked to commercial carrot juice, which included four cases in the United States and two cases in Canada. The investigation of the latter outbreak led to an international product recall. The juice, which had no added sugar, salt, or preservatives, was stored at inappropriate temperatures.

Pruno, an illicit prison-brewed alcoholic beverage, first caused a botulism outbreak in a California prison in 2004, affecting four prisoners. In 2011, a second outbreak due to pruno was reported and involved eight patients at a prison in Utah. In 2012, two outbreaks associated with pruno occurred in a single prison in Arizona, with four and eight cases, respectively. The largest outbreak from pruno occurred in 2016 in a Mississippi prison; 31 cases were identified, including 19 confirmed and 12 suspected.

Wound Botulism Wound botulism was once rare in the United States, but its frequency has been increasing for decades, and it is now the second most common form of botulism. Between 2001 and 2017, 372 cases of wound botulism were reported, with an average of 22 cases per year. Most cases (92%) were caused by BoNT serotype A and 5% by serotype B (5%). Most cases (95%) were among persons who injected drugs (mainly black tar heroin), and the remaining 5% of cases were due to traumatic injuries.

Infant Botulism Infant botulism is the most common form of botulism in the United States. Between 2001 and 2017, 1858 infant botulism cases were reported. BoNT serotypes A and B caused most cases (40% and 58%, respectively). Only two cases were due to serotype E. One of these two cases was due to *C. botulinum* type E and the other to *C. butyricum* type E; both cases represented the first report anywhere in this country of infant botulism due to those respective organisms. A small fraction (<1%) of cases were caused by serotype F. Of note, 13 infant botulism cases were due to strains of *C. botulinum* that can produce two BoNT serotypes (A and B or B and F).

Botulism of Other Etiologies Between 2001 and 2017, 49 cases were reported as being of "unknown or other etiology." This category includes laboratory-confirmed botulism cases that do not meet the definition of foodborne, infant, or wound botulism. Most of these cases were caused by serotype A (65%) and serotype F (25%). Many were thought to be cases of adult intestinal colonization, although confirmation of this form of botulism is not always possible.

CLINICAL MANIFESTATIONS

Botulism produces a syndrome characterized by bilateral cranial nerve palsies that may be followed by symmetric, descending flaccid paralysis that may cause respiratory arrest. There are no sensory deficits; patients are fully conscious, with normal intellectual function, although cranial nerve palsies may give a mistaken impression of altered consciousness. The incubation period (based on data for foodborne botulism cases, where exposure can be identified) is 1 or 2 days, but a range of 6 h to >7 days has been reported. Several recent systematic reviews substantiate long-known observations that the syndrome is essentially identical for all types of botulism in patients of all ages, although elicitation of the typical signs and symptoms may be challenging in infants and young children. A recent systematic review of 16 cases of botulism in pregnant women reported the same clinical syndrome as in nonpregnant individuals. In all botulism syndromes, the first neurologic manifestation usually is ptosis, which can be striking. Ocular findings of fuzzy vision or frank diplopia are caused by extraocular muscle paralysis due to palsies of cranial nerves III, IV, and VI. Flat, youthfully unlined, expressionless facies are produced by cranial nerve VII (facial nerve) palsy. Dysarthria is also a prominent manifestation. Oral and nasal regurgitation of foods or beverages is caused by cranial nerve IX (glossopharyngeal nerve) palsy. The autonomic system may be affected, producing anhidrosis manifesting as severe pharyngeal pain and erythema that has been mistaken for pharyngitis; paradoxically, other patients experience an inability to manage copious oral secretions. Autonomic dysfunction may produce hemodynamic instability requiring monitoring. Cranial nerve palsy may produce pharyngeal muscle flaccidity, causing airway collapse and respiratory arrest early in the course of illness, while reduction in diaphragmatic and accessory muscle function may cause respiratory compromise hours or days later. Cranial nerve palsies may be followed by descending symmetric flaccid paralysis of the muscles of the neck, shoulders, upper limbs, and lower limbs; proximal muscle groups of each limb are affected before distal muscle groups.

A recent analysis of 332 U.S. botulism cases found the following frequencies for patient-reported symptoms: difficulty swallowing, 86%; fatigue, 85%; blurred vision, 80%; slurred speech, 78%; double vision, 76%; shortness of breath, 65%; and dry mouth, 62%. The analysis also reported the following frequencies of observed signs: afebrile body temperature, 99%; descending paralysis, 93%; alert and oriented status, 93%; ptosis, 81%; limb weakness, 78%; decreased palatal reflex, 54%; facial palsy, 47%; and dilated pupils. Sixty-six percent of patients were intubated and received mechanical ventilation. These findings are similar to those reported in many smaller series. Rarely, asymmetry of cranial nerve palsies or distal muscle paralysis is reported and, at least in some cases (especially those described in reports based on chart abstractions), may reflect an incomplete or incompletely recorded neurologic examination. Despite intact sensorium, symptoms such as ptosis, dysarthria, and gait instability may be mistaken for diminished consciousness and lack of coordination and may be erroneously attributed to intoxication from alcohol or other substances. Paresthesias have been reported in some patients; these sensations are not explained by the known activity of botulinum toxin. Paralysis of the diaphragm and accessory muscles of respiration may occur, producing respiratory compromise. Distal tendon reflexes diminish symmetrically. Constipation due to intestinal paralysis develops in almost all patients. Nausea and vomiting may occur in foodborne botulism, preceding neurologic symptoms. Whether these manifestations are due to BoNT, other products of BoNT-producing species of *Clostridium*, or other contaminants of spoiled food is unknown. These gastrointestinal symptoms have not been reported in wound botulism.

Death in untreated patients during the first hours to days of illness is caused by airway obstruction resulting from pharyngeal muscle paralysis and inadequate tidal volume resulting from paralysis of diaphragmatic and accessory respiratory muscles. The combination of expressionless facies from cranial nerve paralysis and immobility from voluntary muscle paralysis may give patients with botulism a placid appearance that masks the agitation expected with respiratory distress. Respiratory compromise occurs early in the course of disease in a substantial proportion of patients: the largest systematic literature review to date of foodborne and wound botulism cases (402 patients) reported that the average time from symptom onset to hospitalization was 2 days and that, at hospital admission, 42% of patients had respiratory symptoms; of these patients, 42% presented with no extremity weakness. In the same review, 87% of patients who required mechanical ventilation were intubated during the first 2 days of hospitalization. The severity of disease varies greatly between patients and is probably governed by the dose of toxin to which they have been exposed. Without treatment, some patients do not progress beyond ptosis and mild palsy in one or two cranial nerves; others experience fulminant cranial nerve palsies and rapidly progressive descending flaccid paralysis eventually affecting most or all voluntary muscles as well as respiratory failure requiring intubation and mechanical ventilation within hours.

The different BoNT serotypes are associated with variations in the botulism syndrome. BoNT type A is associated with more rapid disease progression, more frequent respiratory compromise and mechanical ventilation, and longer duration of paralysis. Type B is associated with a milder syndrome, with less severe and shorter-duration paralysis. Intoxication with the rarely occurring type F produces a syndrome of rapidly progressing paralysis that often leads to respiratory failure, with more rapid recovery than occurs with other toxin types. However, all toxin types causing human illness can cause severe disease; the clinical approach is the same for all.

The paralysis of botulism can last for weeks or months—the time required for regeneration of affected nerve endings and recovery of voluntary muscle function. For severely affected patients with extensive paralysis, management consists of protracted intensive care, with detection and treatment of attendant risks not specific to botulism, such as ventilator-associated pneumonia, decubitus ulcers, and psychological trauma. More than 95% of noninfant botulism patients in the United States recover; hospital discharge is often followed by protracted rehabilitative care. The survival rate for infant botulism is near 100%.

CLINICAL DIAGNOSIS AND LABORATORY CONFIRMATION

Rapid clinical diagnosis is essential. A diagnostic aid for botulism, "Clinical Criteria to Trigger Suspicion of Botulism," has been published by botulism consultants at the Centers for Disease Control and Prevention (CDC; accessible at *https://academic.oup.com/cid/article/66/suppl_1/S38/4780423*). The paralysis of botulism lasts for weeks or months, and administration of equine-source botulinum antitoxin (BAT)—the specific therapy to arrest the progression of paralysis—depends on the correct diagnosis. At this time, laboratory confirmation of botulism, which may require ≥24 h, must take place at a specialized public health laboratory. Therefore, effective, timely treatment relies on rapid clinical diagnosis of botulism in a patient with clinically compatible findings. A clinician suspecting noninfant botulism in a patient should immediately contact the state health department's emergency 24-h line. The state will connect the clinician with a botulism clinical consultant at the CDC (or, in Alaska and California, at the state health department), who will review the case with the clinician, assist in the shipping of appropriate specimens to a public health laboratory for definitive diagnosis, and, when indicated, arrange for immediate shipping of BAT from the federal stockpile at no charge. A clinician suspecting infant botulism in a patient should immediately contact the Infant Botulism Treatment and Prevention Program's on-call physician at (510) 231-7600, who will provide consultation, assist with specimen collection, and, when indicated, assist with the provision of human-derived botulinum antitoxin (BabyBIG), a specific treatment licensed for treatment of infant botulism.

The neurologic examination is the key to clinical diagnosis of botulism, as it readily uncovers the cranial nerve deficits that are invariably present in botulism and focuses the differential diagnosis. In principle, the distinct syndrome of bilateral cranial palsies and descending flaccid paralysis in a fully conscious patient should render the diagnosis and prompt treatment of botulism straightforward. The presentation of two or more patients with this syndrome is almost pathognomonic, since other illnesses considered during the differential diagnosis of botulism do not produce outbreaks. In practice, however, sporadic (lone) cases of botulism are misdiagnosed, and sometimes the diagnosis is missed even in the setting of an outbreak. In part, these failures may be due to the rarity of botulism and the clinician's unfamiliarity with its presentation. A possible cause of misdiagnosis is failure to perform a complete neurologic examination; indeed, review of some botulism patients' charts reveals documentation of the first neurologic examination, which suggested the correct diagnosis, days after hospital admission. As stated earlier, the combination of ptosis, dysarthria, and perceived gate instability from muscle paralysis in some cases may be misinterpreted as intoxication from alcohol or other substances. In other cases, rapidly progressing botulism may result in pharyngeal collapse and respiratory distress relatively early in the course, leading the clinical team to focus on airway management and primary respiratory diagnoses and thus delaying the neurologic evaluation.

Standard clinical studies, including bloodwork and radiology, are not useful in diagnosing botulism. In contrast to the findings in Guillain-Barré syndrome (GBS; see below), lumbar-puncture cerebrospinal fluid (CSF) values—and specifically the protein level—are usually normal in botulism. The CSF protein level may be very slightly elevated in a minority of botulism cases. The fact that botulism produces no abnormal findings on brain imaging may help rule out rare basilar strokes that produce nonlateralizing symptoms. The Tensilon test helps rule out myasthenia gravis. Electromyography, when performed by an experienced practitioner, can provide support for the diagnosis. Botulism is indicated by findings consistent with neuromuscular junction blockage, normal axonal conduction, and potentiation with rapid repetitive stimulation in affected muscles.

Once a neurologic examination reveals the cranial nerve palsies of botulism and any additional bilateral flaccid paralysis, the differential diagnosis may include GBS, myasthenia gravis, Lambert-Eaton syndrome, and tick paralysis. Less likely conditions include tetrodotoxin or shellfish poisoning, antimicrobial-associated paralysis, and rarer poisonings. A careful history and physical examination can further narrow the range of diagnoses. GBS is a rare (~1 case per 100,000 population per year in the United States) autoimmune demyelinating polyneuropathy that follows acute infection by *Campylobacter jejuni*, certain viruses, and other bacteria. In 95% of cases, GBS presents as an ascending paralysis. Recent reports from Peru indicate massive outbreaks of GBS of unknown cause, challenging the previously held notion that conditions causing flaccid paralysis other than botulism occur only as sporadic cases. The 5% of GBS cases presenting as the Miller Fisher variant are characterized by the triad of ophthalmoplegia, ataxia, and areflexia, which may resemble early descending paralysis. The CSF protein level is elevated in GBS, but the increase may take place days after symptom onset; thus, normal CSF levels should be taken into account along with the duration of symptoms, and lumbar puncture may need to be repeated. Electromyography performed by an experienced operator may yield findings indicative of GBS and not botulism. A strongly positive Tensilon test, with or without the presence of autoantibodies, confirms myasthenia gravis; borderline positive Tensilon tests have been reported in botulism patients. In most stroke patients, the physical examination should reveal asymmetric paralysis and upper motor neuron signs; brain imaging can help reveal rare basilar strokes that can produce symmetric bulbar palsies. The history and physical examination should rule out Lambert-Eaton syndrome, which is characterized by proximal limb weakness in patients with advanced cancer.

Laboratory testing confirms clinically diagnosed botulism cases and determines the BoNT serotype causing the disease. In addition, laboratory testing can confirm epidemiologic data by demonstrating presence of BoNT in the suspected food. Botulism cases are confirmed by the laboratory when BoNT is identified in serum or stool specimens or when a BoNT-producing species of *Clostridium* is isolated from stool specimens or wound cultures. Identification of preformed BoNT in food consumed by patients also confirms foodborne botulism.

The gold standard for identification and serotyping of BoNT in clinical or food specimens is the mouse bioassay. The drawback is that this highly sensitive and specific method requires the use of animals. Specimens are injected IP into the mice with and without antitoxin; the mice are then observed for up to 96 h for signs of botulism. If the specimen contains BoNT at levels sufficient to affect the mice quickly, results may be available within 24 h of injection. Low levels of toxin may produce signs later, so that mice should be monitored for 4 days after injection. Many in vitro methods have been developed for detection of BoNT and BoNT-producing species of *Clostridium* in clinical and food specimens. For instance, public health laboratories in the United States can use a real-time polymerase chain reaction test that detects *bont* genes encoding serotypes A through G. This test is a useful screening method to determine whether BoNT-producing species of *Clostridium* are present in cultures of clinical specimens, but positive results must be confirmed. Another in vitro method, the Endopep mass spectrometry (Endopep-MS) assay, is highly sensitive and specific and can detect BoNT in clinical specimens and foods. The advantage of Endopep-MS is that it detects active BoNT and therefore represents an ideal alternative to the mouse bioassay. Immune-based assays can provide rapid and sensitive results; their main limitation is that they detect antigens, which may not necessarily represent active BoNT. Cell-based in vitro assays are also a possible alternative to the mouse bioassay as they detect biological activity of BoNT.

TREATMENT

Botulism

Treatment for botulism consists of two components: meticulous monitoring and supportive care, including admittance to the intensive care unit when indicated, and administration of botulinum antitoxin, the only specific therapy for botulism, as quickly as possible. Paralysis from botulism can be rapidly progressive. Vital capacity, and often hemodynamic parameters, should be frequently monitored and mechanical ventilation instituted immediately if needed. Paralysis induced by BoNT lasts weeks or months, and patients with extensive paralysis require painstaking care to avoid complications associated with protracted immobilization, including respirator-dependent pneumonia, decubitus ulcers, and psychological trauma. Patients who have recovered from severe botulism report that their appearance and immobility often led caregivers to assume they were unconscious; as a consequence, patients were sometimes subjected to painful procedures without warning and to insensitive comments. Signage should remind all caregivers that botulism patients are conscious but "locked in." Psychological support should be instituted for intubated botulism patients from the outset. With proper supportive care, >95% of botulism patients in the United States recover, even without antitoxin therapy; however, antitoxin, if promptly administered, can substantially reduce the extent and duration of illness (see below).

Botulinum antitoxin is the only specific treatment for botulism. The antitoxin prevents the progression of paralysis but does not reverse existing paralysis. If given early enough in the course of disease, it may avert respiratory compromise, obviate mechanical intubation, and forestall protracted paralysis and hospitalization along with associated complications. Accordingly, it is essential to administer antitoxin as soon as possible. A recent systematic literature review and meta-analysis covering nearly a century of the published literature in noninfant botulism patients confirmed long-known findings from smaller studies by showing significantly reduced mortality rates among patients treated with equine antitoxin, especially when treatment was administered within 48 h of symptom onset. Another large systematic literature review of

pediatric noninfant botulism recently showed significantly reduced mortality risk among children treated with equine antitoxin. Published studies have demonstrated a substantial reduction in the duration and severity of illness among patients with infant botulism who are treated with human-derived botulinum antitoxin.

The equine botulinum antitoxin used to treat noninfant botulism consists of antibodies produced in horses immunized with botulinum toxoids (inactivated toxins) and toxins. The antibodies are type-specific (anti-A neutralizes BoNT type A and so forth). The currently licensed antitoxin product in the United States, heptavalent botulinum antitoxin (BAT), contains antibodies to BoNT types A, B, C, D, E, F, and G. These equine antibodies have undergone despeciation to reduce antigenicity and the risk of anaphylaxis to foreign protein. A recent systematic literature review, along with studies of BAT use, indicated that <2% of recipients experience serious adverse reactions. Administration of one vial of BAT elicits circulating antitoxin concentrations sufficient to neutralize toxin levels one to two orders of magnitude higher than those found in the serum of most botulism patients. As noted earlier, clinicians suspecting botulism in a patient should immediately call their state health department's emergency contact to be put in touch with a botulism clinical consultant who will review the case and assist in its management, including shipment of BAT from the federal stockpile at no charge. The botulinum antitoxin used to treat infants, BabyBIG, consists of human antibodies obtained from hyperimmunized volunteers. The product is licensed for treatment of infant botulism due to BoNT types A and B and, as noted earlier, can be obtained through the Infant Botulism Treatment and Prevention Program.

There is no prophylactic treatment for botulism. Persons who may have been exposed to botulinum toxin should be evaluated by a physician and carefully observed for the development of symptoms of botulism. If symptoms appear, the patient should be treated immediately with botulinum antitoxin.

PREVENTION

No vaccine is licensed for the prevention of botulism. In the United States, a botulinum toxoid vaccine was available through the CDC until 2011, but it was discontinued because of a decline in immunogenicity of some serotypes and an increase in occurrence of moderate local reactions. Several vaccine candidates are currently in clinical trials.

Because most foodborne botulism cases are caused by home-canned or home-preserved foods, the prevention of foodborne botulism depends mainly on proper preparation and preservation that ensures the destruction of spores of BoNT-producing species of *Clostridium* that may be present in the food or on the creation of an environment that will not allow the germination and growth of these spores, such as low pH or low water activity. Water activity is a measure of how much water is free, unbound, and thus available to microorganisms to use for growth. If foods have low water activity, it means they do not have much free water, and growth of *C. botulinum* will be limited or inhibited. Using pressure canners and properly cleaning items employed in the canning process can reduce the risk of foodborne botulism. Among other resources, the *USDA Complete Guide to Home Canning* provides a detailed description of safe home-canning practices. Other ways of preventing foodborne botulism include refrigerating homemade oils infused with garlic or herbs and discarding any of these oils that have not been used after 4 days; maintaining baked potatoes or similar foods wrapped in aluminum foil at temperatures above 140°F until served and then refrigerating leftovers; refrigerating canned or pickled foods after opening; and boiling home-canned foods before eating, especially those foods that are low in acid.

Wound botulism largely affects people who inject drugs, especially black tar heroin. Using safe injection practices may help prevent wound botulism and many other infections, such as HIV and hepatitis C virus infections. Thus, educating injection drug users on the prevention of wound botulism and other infections is vital in protecting their health. As wound botulism can also follow traumatic injuries, keeping wounds clean is key.

The risk factors for infant botulism are not fully understood, but possible sources of spores of BoNT-producing species of *Clostridium* include foods and dust. In most cases of infant botulism, no source of spores is identified. Honey is the only food that has been identified as an epidemiologically associated reservoir of spores of BoNT-producing species of *Clostridium*. Honey should not be fed to infants ≤1 year of age.

GLOBAL CONSIDERATIONS

Botulism has been reported from all parts of the world. The European Centre for Disease Prevention and Control has reported an average of 110 botulism cases each year from 2007 to 2018. During that period, 1315 botulism cases were reported from 25 countries, with the most cases in Italy (311 cases), Romania (239 cases), and Poland (202 cases). Foodborne botulism is the most common form of botulism in Europe. Most laboratory-confirmed cases reported from Italy, Romania, and Poland were due to BoNT serotype B. The country of Georgia has a high incidence of botulism (0.9 case per 100,000 persons) relative to rates in the European Union (<0.1/100,000) and the United States (0.01/100,000). From 1980 to 2002, a total of 879 cases of botulism were reported in Georgia; all of them were foodborne, most were associated with home-preserved vegetables, and the majority were due to serotype B. From 1958 to 1983, 986 foodborne botulism outbreaks affecting 4377 individuals were reported from China. Most cases were due to serotype A and were associated with bean products. Botulism in Thailand has been associated with fermented bamboo shoots and fermented soybeans. In 2006, a large foodborne botulism outbreak associated with bamboo shoots occurred in Thailand and affected 209 people who attended a local festival. In South America, Brazil and Argentina have reported several outbreaks of foodborne botulism. For instance, between 2001 and 2008, Brazil reported 18 outbreaks, most of which were associated with meat-based foods such as home-canned meat, homemade pork liver pâté, and commercially canned liver pâté. From 1994 to 2007, Argentina reported 36 outbreaks, most frequently involving home-canned vegetables. Although reports of foodborne botulism in Africa are rare, five outbreaks were reported in South Africa between 1959 and 2002, with the majority due to serotype B and associated with noncommercial foods. In addition, one outbreak of 91 cases was reported in Egypt in 1991 and was due to serotype E associated with a traditional salted fish.

Wound botulism cases have been reported most frequently from the United States, next most frequently from the United Kingdom, and occasionally from Italy, France, and Australia. Clusters of wound botulism are rare, but, according to a report from the European Centre for Disease Prevention and Control, 23 cases of wound botulism among people who had injected heroin were reported in Norway and Scotland between December 2014 and February 2015. Other countries that have reported wound botulism cases include Argentina, China, and Ecuador.

Although rarely reported, infant botulism cases have been noted on all continents except Africa. Outside the United States (where there were 2419 cases), Argentina reported the largest number of cases (366) and Australia the next largest number (32) between 1976 and 2006. Canada, Italy, and Japan also reported a relatively large number of cases (27, 26, and 22, respectively).

154 Gas Gangrene and Other Clostridial Infections

Amy E. Bryant, Dennis L. Stevens

The genus *Clostridium* encompasses >60 species that may be commensals of the gut microflora or may cause a variety of infections in humans and animals through the production of a plethora of proteinaceous exotoxins. *C. tetani* and *C. botulinum*, for example, cause specific clinical disease by elaborating single but highly potent toxins. In contrast, *C. perfringens* and *C. septicum* cause aggressive necrotizing infections that are attributable to multiple toxins, including bacterial proteases, phospholipases, and cytotoxins.

ETIOLOGIC AGENT

Vegetative cells of *Clostridium* species are pleomorphic, rod-shaped, and arranged singly or in short chains **(Fig. 154-1)**; the cells have rounded or sometimes pointed ends. Although clostridia stain gram-positive in the early stages of growth, they may appear to be gram-negative or gram-variable later in the growth cycle or in infected tissue specimens. Most strains are motile by means of peritrichous flagella; *C. septicum* swarms on solid media. Nonmotile species include *C. perfringens*, *C. ramosum*, and *C. innocuum*. Most species are obligately anaerobic, although clostridial tolerance to oxygen varies widely; some species (e.g., *C. septicum*, *C. tertium*) will grow but will not sporulate in air.

Clostridia produce more protein toxins than any other bacterial genus, and >25 clostridial toxins lethal to mice have been identified. These proteins include neurotoxins, enterotoxins, cytotoxins, collagenases, permeases, necrotizing toxins, lipases, lecithinases, hemolysins, proteinases, hyaluronidases, DNases, ADP-ribosyltransferases, and neuraminidases. Botulinum and tetanus neurotoxins are the most potent toxins known, with lethal doses of 0.2–10 ng/kg for humans. Epsilon toxin, a 33-kDa protein produced by *C. perfringens* types B and D, causes edema and hemorrhage in the brain, heart, spinal cord, and kidneys of animals. It is among the most lethal of the clostridial toxins and is considered a potential agent of bioterrorism. The genomic sequences of some pathogenic clostridia are now available and are likely to facilitate a comprehensive approach to understanding the virulence factors involved in clostridial pathogenesis.

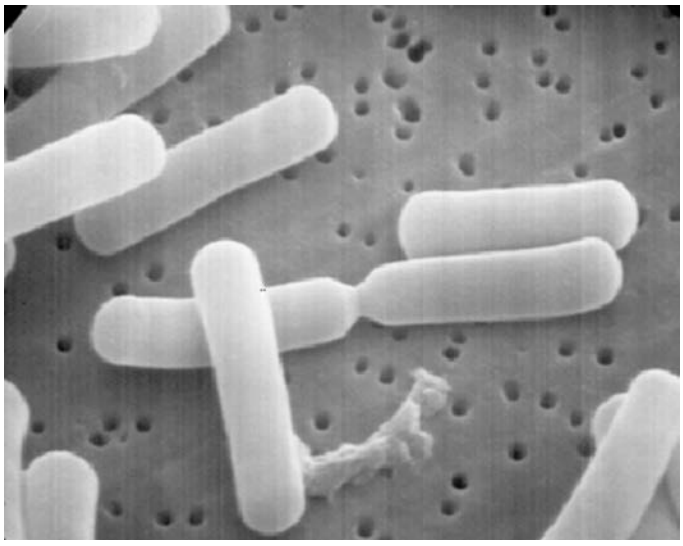

FIGURE 154-1 Scanning electron micrograph of *C. perfringens*.

EPIDEMIOLOGY AND TRANSMISSION

Clostridium species are widespread in nature, forming endospores that are commonly found in soil, feces, sewage, and marine sediments. The ecology of *C. perfringens* in soil is greatly influenced by the degree and duration of animal husbandry in a given location and is relevant to the incidence of gas gangrene caused by contamination of war wounds with soil. For example, the incidence of clostridial gas gangrene is higher in agricultural regions of Europe than in the Sahara Desert of Africa. Similarly, the incidences of tetanus and food-borne botulism are clearly related to the presence of clostridial spores in soil, water, and many foods. Clostridia are present in large numbers in the indigenous microbiota of the intestinal tract of humans and animals, in the female genital tract, and on the oral mucosa. It should be noted that not all commensal clostridia are toxigenic.

Clostridial infections remain a serious public-health concern worldwide. In developing nations, food poisoning, necrotizing enterocolitis, and gas gangrene are common because large portions of the population are poor and have little or no immediate access to health care. These infections remain prevalent in developed countries as well. Gas gangrene commonly follows knife or gunshot wounds or vehicular accidents or develops as a complication of surgery or gastrointestinal carcinoma. Severe clostridial infections have emerged as a health threat to injection drug users and to women undergoing childbirth or abortion. Historically, clostridial gas gangrene has been the scourge of the battlefield. The global political situation portends another possible scenario involving mass casualties of war or terrorism, with extensive injuries conducive to gas gangrene. Thus, there is an ongoing need to develop novel strategies to prevent or attenuate the course of clostridial infections in both civilians and military personnel. Vaccination against exotoxins important in pathogenesis would be of great benefit in developing nations and could also be used safely in at-risk populations such as the elderly, patients with diabetes who may require lower-limb surgery due to trauma or poor circulation, and those undergoing intestinal surgery. Moreover, a hyperimmune globulin would be a valuable tool for prophylaxis in victims of acute traumatic injury or for attenuation of the spread of infection in patients with established gas gangrene.

CLINICAL SYNDROMES

Life-threatening clostridial infections range from intoxications (e.g., food poisoning, tetanus) to necrotizing enteritis/colitis, bacteremia, myonecrosis, and toxic shock syndrome (TSS). **Tetanus and botulism are discussed in Chaps. 152 and 153, respectively. Colitis due to *C. difficile* is discussed in Chap. 134.**

CLOSTRIDIAL WOUND CONTAMINATION

Of open traumatic wounds, 30–80% reportedly are contaminated with clostridial species. In the absence of devitalized tissue, the presence of clostridia does not necessarily lead to infection. In traumatic injuries, clostridia are isolated with equal frequency from both suppurative and well-healing wounds. Thus, diagnosis and treatment of clostridial infection should be based on clinical signs and symptoms and not solely on bacteriologic findings.

POLYMICROBIAL INFECTIONS INVOLVING CLOSTRIDIA

Clostridial species may be found in polymicrobial infections also involving microbial components of the indigenous flora. In these infections, clostridia often appear in association with non-spore-forming anaerobes and facultative or aerobic organisms. Head and neck infections, conjunctivitis, brain abscess, sinusitis, otitis, aspiration pneumonia, lung abscess, pleural empyema, cholecystitis, septic arthritis, and bone infections all may involve clostridia. These conditions are often associated with severe local inflammation but may lack the characteristic systemic signs of toxicity and rapid progression seen in other clostridial infections. In addition, clostridia are isolated from ~66% of intraabdominal infections in which the mucosal integrity of the bowel or respiratory system has been compromised. In this setting, *C. ramosum*, *C. perfringens*, and *C. bifermentans* are the most commonly isolated species. Their presence does not invariably lead to a poor outcome. Clostridia have been isolated from suppurative infections of the female genital tract (e.g., ovarian or pelvic abscess) and from diseased gallbladders. Although the most frequently isolated species is *C. perfringens*, gangrene is not typically observed; however, gas formation in the biliary system can lead to emphysematous cholecystitis, especially in diabetic patients. *C. perfringens* in association with mixed aerobic and anaerobic microbes can cause aggressive life-threatening type I necrotizing fasciitis or Fournier's gangrene.

The treatment of mixed aerobic/anaerobic infection of the abdomen, perineum, or gynecologic organs should be based on Gram's staining, culture, and antibiotic sensitivity information. Reasonable empirical treatment consists of ampicillin or ampicillin/sulbactam combined with either clindamycin or metronidazole **(Table 154-1)**. Broader gram-negative coverage may be necessary if the patient has recently been hospitalized or treated with antibiotics. Such coverage can be obtained by substituting ticarcillin/clavulanic acid, piperacillin/sulbactam, or a penem antibiotic for ampicillin or by adding a fluoroquinolone or an aminoglycoside to the regimen. Empirical treatment should be given for 10–14 days or until the patient's clinical condition improves.

ENTERIC CLOSTRIDIAL INFECTIONS

C. perfringens type A is one of the most common bacterial causes of food-borne illness in the United States and Canada. The foods typically implicated include improperly cooked meat and meat products (e.g., gravy) in which residual spores germinate and proliferate during slow cooling or insufficient reheating. Illness results from the ingestion of food containing at least ~10^8 viable vegetative cells, which sporulate in the alkaline environment of the small intestine, producing *C. perfringens* enterotoxin in the process. The diarrhea that develops within 7–30 h of ingestion of contaminated food is generally mild and self-limiting; however, in the very young, the elderly, and the immunocompromised, symptoms are more severe and occasionally fatal. Enterotoxin-producing *C. perfringens* has been implicated as an etiologic agent of persistent diarrhea in elderly patients in nursing homes and tertiary-care institutions and has been considered to play a role in antibiotic-associated diarrhea without pseudomembranous colitis.

C. perfringens strains associated with food poisoning possess the gene (*cpe*) coding for enterotoxin, which acts by forming pores in host cell membranes. *C. perfringens* strains isolated from non-food-borne diseases, such as antibiotic-associated and sporadic diarrhea, carry *cpe* on a plasmid that may be transmitted to other strains. Several methods have been described for the detection of *C. perfringens* enterotoxin in feces, including cell culture assay (Vero cells), enzyme-linked immunosorbent assay, reversed-phase latex agglutination, and polymerase chain reaction (PCR) amplification of *cpe*. Each method has its advantages and limitations.

Enteritis necroticans (gas gangrene of the bowel) is a fulminating clinical illness characterized by extensive necrosis of the intestinal mucosa and wall. Cases can occur sporadically in adults or as epidemics in people of all ages. Enteritis necroticans is caused by α toxin– and β toxin–producing strains of *C. perfringens* type C; β toxin is located on a plasmid and is mainly responsible for pathogenesis. This life-threatening infection causes ischemic necrosis of the jejunum. In Papua New Guinea during the 1960s, enteritis necroticans (known in that locale as *pigbel*) was found to be the most common cause of death in childhood; it was associated with pig feasts and occurred both sporadically and in outbreaks. Intramuscular immunization against the β toxin resulted in a decreased incidence of the disease in Papua New Guinea, although the condition remains common. Enteritis necroticans has also been recognized in the United States, the United Kingdom, Germany (where it is known as *darmbrand*), and other developed nations; especially affected are adults who are malnourished or who have diabetes, alcoholic liver disease, or neutropenia.

Necrotizing enterocolitis, a disease resembling enteritis necroticans but associated with *C. perfringens* type A, has been found in North

TABLE 154-1 Treatment of Clostridial Infections

CONDITION	ANTIBIOTIC TREATMENT	PENICILLIN ALLERGY	ADJUNCTIVE TREATMENT/NOTE
Wound contamination	None	—	Treatment should be based on clinical signs and symptoms as listed below and not solely on bacteriologic findings.
Polymicrobial anaerobic infections involving clostridia (e.g., abdominal wall, gynecologic)	Ampicillin (2 g IV q4h) ***plus*** Clindamycin (600–900 mg IV q6–8h) ***plus*** Ciprofloxacin (400 mg IV q6–8 h)	Vancomycin (1 g IV q12h) ***plus*** Metronidazole (500 mg IV q6h) ***plus*** Ciprofloxacin (400 mg IV q6–8h)	Empirical therapy should be initiated. Therapy should be based on Gram's stain and culture results and on sensitivity data when available. Add gram-negative coverage if indicated (see text).
Clostridial sepsis	Penicillin (3–4 mU IV q4–6h) ***plus*** Clindamycin (600–900 mg IV q6–8h)	Clindamycin alone ***or*** Metronidazole (as above) ***or*** Vancomycin (as above)	Transient bacteremia without signs of systemic toxicity may be clinically insignificant.
Gas gangrene[a]	Penicillin G (4 mU IV q4–6 h) ***plus*** Clindamycin (600–900 mg IV q6–8h)	Cefoxitin (2 g IV q6h) ***plus*** Clindamycin (600–900 mg IV q6–8h)	Emergent surgical exploration and thorough debridement are extremely important. Hyperbaric oxygen therapy may be considered after surgery and antibiotic initiation.

[a] *C. tertium* is resistant to penicillin, cephalosporins, and clindamycin. Appropriate antibiotic therapy for *C. tertium* infection is vancomycin (1 g q12h IV) or metronidazole (500 mg q8h IV).

America in previously healthy adults. It is also a serious gastrointestinal disease of low-birth-weight (premature) infants hospitalized in neonatal intensive care units. The etiology and pathogenesis of this disease have remained enigmatic for more than four decades. Pathologic similarities between necrotizing enterocolitis and enteritis necroticans include the pattern of small-bowel necrosis involving the submucosa, mucosa, and muscularis; the presence of gas dissecting the tissue planes; and the degree of inflammation. In contrast to enteritis necroticans, which most commonly involves the jejunum, necrotizing enterocolitis affects the ileum and frequently the ileocecal valve. Both diseases may manifest as intestinal gas cysts, although this feature is more common in necrotizing enterocolitis. The sources of the gas, which contains hydrogen, methane, and carbon dioxide, are probably the fermentative activities of intestinal bacteria, including clostridia. Epidemiologic data support an important role for *C. perfringens* or other gas-producing microorganisms (e.g., *C. neonatale*, certain other clostridia, or *Klebsiella* species) in the pathogenesis of necrotizing enterocolitis.

Patients with suspected clostridial enteric infection should undergo nasogastric suction and receive IV fluids. Pyrantel is given by mouth, and the bowel is rested by fasting. Benzylpenicillin (1 mU) is given IV every 4 h, and the patient is observed for complications requiring surgery. Patients with mild cases recover without surgical intervention. However, if surgical indications are present (gas in the peritoneal cavity, absent bowel sounds, rebound tenderness, abdominal rigidity), the mortality rate ranges from 35 to 100%; a fatal outcome is due in part to perforation of the intestine.

As pigbel continues to be a common disease in Papua New Guinea, consideration should be given to the use of a *C. perfringens* type C β toxoid vaccine in local areas. Two doses given 3–4 months apart are preventive.

CLOSTRIDIAL BACTEREMIA

Clostridium species are important causes of bloodstream infections. Molecular epidemiologic studies of anaerobic bacteremia have identified *C. perfringens* and *C. tertium* as the two most frequently isolated species; these organisms cause up to 79 and 5%, respectively, of clostridial bacteremias. Occasionally, *C. perfringens* bacteremia occurs in the absence of an identifiable infection at another site. When associated with myonecrosis, bacteremia has a grave prognosis.

C. septicum is also commonly associated with bacteremia. This species is isolated only rarely from the feces of healthy individuals but may be found in the normal appendix. More than 50% of patients whose blood cultures are positive for this organism have some gastrointestinal anomaly (e.g., diverticular disease) or underlying malignancy (e.g., carcinoma of the colon). In addition, a clinically important association of *C. septicum* bacteremia with neutropenia of any origin—and, more specifically, with neutropenic enterocolitis involving the terminal ileum or cecum—has been observed. Patients with diabetes mellitus, severe atherosclerotic cardiovascular disease, or anaerobic myonecrosis (gas gangrene) also may develop *C. septicum* bacteremia. *C. septicum* has been recovered from the bloodstream of cirrhotic patients, as have *C. perfringens*, *C. bifermentans*, and other clostridia. Infections of the bloodstream by *C. sordellii* and *C. perfringens* have been associated with TSS.

Bloodstream infection by *C. tertium*, either alone or in combination with *C. septicum* or *C. perfringens*, can be found in patients with serious underlying disease such as malignancy or acute pancreatitis, with or without neutropenic enterocolitis; the frequency has not been systematically studied. *C. tertium* may present special problems in terms of both identification and treatment. This organism may stain gram-negative; is aerotolerant; and is resistant to metronidazole, clindamycin, and cephalosporins.

Other clostridia from the *C. clostridioforme* group (including *C. clostridioforme*, *C. hathewayi*, and *C. bolteae*) can cause bacteremia.

The clinical importance of recognizing clostridial bacteremia—especially that due to *C. septicum*—and starting appropriate treatment immediately (Table 154-1) cannot be overemphasized. Patients with this condition usually are gravely ill, and infection may metastasize to distant anatomic sites, resulting in spontaneous myonecrosis (see next section). Alternative methods to identify bacteremia-causing clostridial species, such as PCR or other rapid diagnostic tests, are not currently available. Anaerobic blood cultures and Gram's stain interpretation remain the best diagnostic tests at this point.

CLOSTRIDIAL SKIN AND SOFT TISSUE INFECTIONS

Histotoxic clostridial species such as *C. perfringens*, *C. histolyticum*, *C. septicum*, *C. novyi*, and *C. sordellii* cause aggressive necrotizing infections of the skin and soft tissues. These infections are attributable in part to the elaboration of bacterial proteases, phospholipases, and cytotoxins. Necrotizing clostridial soft tissue infections are rapidly progressive and are characterized by marked tissue destruction, gas in the tissues, and shock; they frequently end in death. Severe pain, crepitus, brawny induration with rapid progression to skin sloughing, violaceous bullae, and marked tachycardia are characteristics found in the majority of patients.

Clostridial Myonecrosis (Gas Gangrene)

• **TRAUMATIC GAS GANGRENE** *C. perfringens* myonecrosis (gas gangrene) is one of the most fulminant gram-positive bacterial infections of humans. Even with appropriate antibiotic therapy and management in an intensive care unit, tissue destruction can progress rapidly. Gas gangrene is accompanied by bacteremia, hypotension, and multiorgan failure and is invariably fatal if untreated. Gas gangrene is a true emergency and requires immediate surgical debridement.

The development of gas gangrene requires an anaerobic environment and contamination of a wound with spores or vegetative organisms. Devitalized tissue, foreign bodies, and ischemia reduce locally available oxygen levels and favor outgrowth of vegetative cells and spores. Thus, conditions predisposing to traumatic gas gangrene include crush-type injury, laceration of large or medium-sized arteries, and open fractures of long bones that are contaminated with soil or bits of clothing containing the bacterial spores. Gas gangrene of the abdominal wall and flanks follows penetrating injuries such as knife or gunshot wounds that are sufficient to compromise intestinal integrity, with resultant leakage of the bowel contents into the soft tissues. Proximity to fecal sources of bacteria is a risk factor for cases following hip surgery, adrenaline injections into the buttocks, or amputation of the leg for ischemic vascular disease. In the last decade, cutaneous gas gangrene caused by *C. perfringens*, *C. novyi*, and *C. sordellii* has been described in the United States and northern Europe among persons injecting black-tar heroin subcutaneously.

The incubation period for traumatic gas gangrene can be as short as 6 h and is usually <4 days. The infection is characterized by the sudden onset of excruciating pain at the affected site and the rapid development of a foul-smelling wound containing a thin serosanguineous discharge and gas bubbles. Brawny edema and induration develop and give way to cutaneous blisters containing bluish to maroon-colored fluid. Such tissue later may become liquefied and slough. The margin between healthy and necrotic tissue often advances several inches per hour despite appropriate antibiotic therapy, and radical amputation remains the single best life-saving intervention. Shock and organ failure frequently accompany gas gangrene; when patients become bacteremic, the mortality rate exceeds 50%.

Diagnosis of traumatic gas gangrene is not difficult because the infection always begins at the site of significant trauma, is associated with gas in the tissue, and is rapidly progressive. Gram's staining of drainage or tissue biopsy is usually definitive, demonstrating large gram-positive (or gram-variable) rods, an absence of inflammatory cells, and widespread soft tissue necrosis.

SPONTANEOUS (NONTRAUMATIC) GAS GANGRENE Spontaneous gas gangrene generally occurs via hematogenous seeding of normal muscle with histotoxic clostridia—principally *C. perfringens*, *C. septicum*, and *C. novyi* and occasionally *C. tertium*—from a gastrointestinal tract portal of entry (as in colonic malignancy, inflammatory bowel disease, diverticulitis, necrotizing enterocolitis, cecitis, or distal ileitis or after gastrointestinal surgery, including colonoscopic polypectomy). These

gastrointestinal pathologies permit bacterial access to the bloodstream; consequently, aerotolerant *C. septicum* can proliferate in normal tissues. Patients surviving bacteremia or spontaneous gangrene due to *C. septicum* should undergo aggressive diagnostic studies to rule out gastrointestinal pathology.

Additional predisposing host factors include leukemia, lymphoproliferative disorders, cancer chemotherapy, radiation therapy, and AIDS. Cyclic, congenital, or acquired neutropenia also is strongly associated with an increased incidence of spontaneous gas gangrene due to *C. septicum*; in such cases, necrotizing enterocolitis, cecitis, or distal ileitis is common, particularly among children.

The first symptom of spontaneous gas gangrene may be confusion followed by the abrupt onset of excruciating pain in the absence of trauma. These findings, along with fever, should heighten suspicion of spontaneous gas gangrene. However, because of the lack of an obvious portal of entry, the correct diagnosis is frequently delayed or missed. The infection is characterized by rapid progression of tissue destruction with demonstrable gas in the tissue **(Fig. 154-2)**. Swelling increases, and bullae filled with clear, cloudy, hemorrhagic, or purplish fluid appear. The surrounding skin has a purple hue, which may reflect vascular compromise resulting from the diffusion of bacterial toxins into surrounding tissues. Invasion of healthy tissue rapidly ensues, with quick progression to shock and multiple-organ failure. Mortality rates in this setting range from 67 to 100% among adults; among children, the mortality rate is 59%, with the majority of deaths occurring within 24 h of onset.

PATHOGENESIS OF GAS GANGRENE In traumatic gas gangrene, organisms are introduced into devitalized tissue. It is important to recognize that, for *C. perfringens* and *C. novyi*, trauma must be sufficient to interrupt the blood supply and thereby to establish an optimal anaerobic environment for growth of these species. These conditions are not strictly required for the more aerotolerant species such as *C. septicum* and *C. tertium*, which can seed normal tissues from gastrointestinal lesions. Once introduced into an appropriate niche, the organisms proliferate locally and elaborate exotoxins.

The major *C. perfringens* extracellular toxins implicated in gas gangrene are α toxin and θ toxin. A lethal hemolysin that has both phospholipase C and sphingomyelinase activities, α toxin has been implicated as the major virulence factor of *C. perfringens*: immunization of mice with the C-terminal domain of α toxin provides protection against lethal challenge with *C. perfringens*, and isogenic α toxin–deficient mutant strains of *C. perfringens* are not lethal in a murine model of gas gangrene. Recently, a human single-chain recombinant antibody to α toxin that has significant preventive and therapeutic efficacy in mice has been developed.

FIGURE 154-2 Radiograph of patient with spontaneous gas gangrene due to *C. septicum*, demonstrating gas in the affected arm and shoulder.

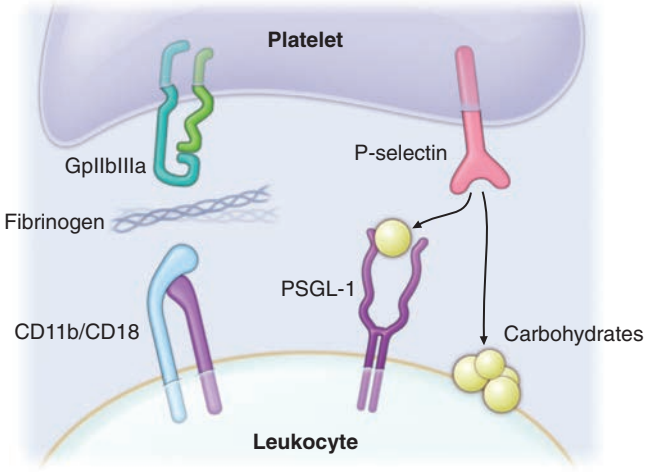

FIGURE 154-3 Schematic illustration of the molecular mechanisms of *C. perfringens* toxin–induced platelet/neutrophil aggregates. Homotypic aggregates of platelets (not shown) and heterotypic aggregates of platelets and leukocytes are due to α toxin–induced activation of the platelet fibrinogen receptor gpIIb/IIIa and upregulation of leukocyte CD11b/CD18. Binding of fibrinogen (*red*) bridges the connection between these adhesion molecules on adjacent cells. An auxiliary role for α toxin–induced upregulation of platelet P-selectin and its binding to leukocyte P-selectin glycoprotein ligand 1 (PSGL-1) or other leukocyte surface carbohydrates also has been demonstrated.

It has been shown in experimental models that the severe pain, rapid progression, marked tissue destruction, and absence of neutrophils in *C. perfringens* gas gangrene are attributable in large part to α toxin–induced occlusion of blood vessels by heterotypic aggregates of platelets and neutrophils. The formation of these aggregates, which occurs within minutes, is largely mediated by α toxin's ability to activate the platelet adhesion molecule gpIIb/IIIa **(Fig. 154-3)**; the implication is that platelet glycoprotein inhibitors (e.g., eptifibatide, abciximab) may be therapeutic for maintaining tissue blood flow.

C. perfringens θ toxin (*perfringolysin O* [PFO]) is a member of the thiol-activated cytolysin family known as cholesterol-dependent cytolysins, which includes streptolysin O from group A *Streptococcus*, pneumolysin from *Streptococcus pneumoniae*, and several other toxins. Cholesterol-dependent cytolysins bind as oligomers to cholesterol in host cell membranes. At high concentrations, these toxins form ring-like pores resulting in cell lysis. At sublytic concentrations, θ toxin hyperactivates phagocytes and vascular endothelial cells. θ toxin–mediated activation of the macrophage inflammasome, with production of interleukin 1β, has also been reported.

Cardiovascular collapse and end-organ failure occur late in the course of *C. perfringens* gas gangrene and are largely attributable to both direct and indirect effects of α and θ toxins. In experimental models, θ toxin causes markedly reduced systemic vascular resistance but increased cardiac output (i.e., "warm shock"), probably via induction of endogenous mediators (e.g., prostacyclin, platelet-activating factor) that cause vasodilation. This effect is similar to that observed in gram-negative sepsis. In sharp contrast, α toxin directly suppresses myocardial contractility; the consequence is profound hypotension due to a sudden reduction in cardiac output. The roles of other endogenous mediators, such as cytokines (e.g., tumor necrosis factor, interleukin 1, interleukin 6) and vasodilators (e.g., bradykinin) have not been fully elucidated.

C. septicum produces three main toxins—α toxin (lethal, hemolytic, necrotizing activity), β toxin (DNase), and γ toxin (hyaluronidase)—as

well as a protease and a neuraminidase. Unlike the α toxin of *C. perfringens*, that of *C. septicum* does not possess phospholipase activity. The mechanisms remain to be fully elucidated, but it is likely that each of these toxins contributes uniquely to *C. septicum* gas gangrene.

TREATMENT

Gas Gangrene

Patients with suspected gas gangrene (either traumatic or spontaneous) should undergo prompt surgical inspection of the infected site. Direct examination of a Gram-stained smear of the involved tissues is of major importance. Characteristic histologic findings in clostridial gas gangrene include widespread tissue destruction, a paucity of leukocytes in infected tissues in conjunction with an accumulation of leukocytes in adjacent vessels **(Fig. 154-4)**, and the presence of gram-positive rods (with or without spores). CT and MRI are invaluable for determining whether the infection is localized or is spreading along fascial planes, and needle aspiration or punch biopsy may provide an etiologic diagnosis in at least 20% of cases. However, these techniques should not replace surgical exploration, Gram's staining, and histopathologic examination. When spontaneous gas gangrene is suspected, blood should be cultured since bacteremia usually precedes cutaneous manifestations by several hours.

For patients with evidence of clostridial gas gangrene, thorough emergent surgical debridement is of extreme importance. All devitalized tissue should be widely resected back to healthy viable muscle and skin so as to remove conditions that allow anaerobic organisms to continue proliferating. Closure of traumatic wounds or compound fractures should be delayed for 5–6 days until it is certain that these sites are free of infection.

Except for infection caused by *C. tertium* (see below), antibiotic treatment of traumatic or spontaneous gas gangrene (Table 154-1) consists of the administration of penicillin and clindamycin for 10–14 days. Penicillin is recommended on the basis of in vitro sensitivity data; clindamycin is recommended because of its superior efficacy over penicillin in animal models of *C. perfringens* gas gangrene and in some clinical reports. Controlled clinical trials comparing the efficacy of these agents in humans have not been performed. In the penicillin-allergic patient, clindamycin may be used alone. The superior efficacy of clindamycin is probably due to its ability to inhibit bacterial protein toxin production, its insensitivity to the size of the bacterial load or the stage of bacterial growth, and its ability to modulate the host's immune response.

Although *C. perfringens* remains largely susceptible to first-line antibiotics, antibiotic resistance has been reported. Case reports from the United Kingdom and from Spain found clindamycin-resistant *C. perfringens* in cellulitis and in a spontaneous abscess, respectively. Larger studies from Canada and Taiwan also showed increasing resistance to clindamycin among bloodstream isolates. In 2014, Marchand-Austin et al published a 2-year prospective Canadian study that examined antimicrobial susceptibility of anaerobic bacteria isolated from blood, body fluids, and abscesses. Of 1412 isolates submitted for susceptibility testing, 68 were *C. perfringens*. Of these, all were universally susceptible to penicillin but 3.8% were clindamycin-resistant. Notably, for *Clostridium* species other than *C. perfringens* (n = 289), 14.2% were penicillin-resistant and 21.6% clindamycin-resistant. A more recent study from Iran found that 21.2% of *C. perfringens* isolates were resistant to penicillin. Lastly, a 2019 study from Hungary found resistance to penicillin (2.6%) and clindamycin (3.8%) among *C. perfringens* isolates (n = 313) from tissues with gas gangrene. Among the non-perfringens gas gangrene isolates (n = 59), higher resistance to penicillin and clindamycin was observed (6.8% and 8.5%, respectively). These findings, though not universal, highlight the importance of good anaerobic microbiology susceptibility testing to provide up-to-date information to guide optimal clinical management decisions for clostridial infections.

C. tertium is resistant to penicillin, cephalosporins, and clindamycin. Appropriate antibiotic therapy for *C. tertium* infection is vancomycin (1 g every 12 h IV) or metronidazole (500 mg every 8 h IV).

The value of adjunctive treatment with hyperbaric oxygen (HBO) for gas gangrene remains controversial. Basic-science studies suggest that HBO can inhibit the growth of *C. perfringens* but not that of the more aerotolerant *C. septicum*. In vitro, blood and macerated muscle inhibit the bactericidal potential of HBO. Numerous studies in animals demonstrate little efficacy of HBO alone, whereas antibiotics alone—especially those that inhibit bacterial protein synthesis—confer marked benefits. Addition of HBO to the therapeutic regimen provides some additional benefit, but only if surgery and antibiotic administration precede HBO treatment.

In conclusion, gas gangrene is a rapidly progressive infection whose outcome depends on prompt recognition, emergent surgery, and timely administration of antibiotics that inhibit toxin production. Gas gangrene associated with bacteremia probably represents a later stage of illness and is associated with the worst outcomes. Emergent surgical debridement is crucial to ensure survival, and ancillary procedures (e.g., CT or MRI) or transport to HBO units should not delay this intervention. Some trauma centers associated with HBO units may have special expertise in managing these aggressive infections, but proximity and speed of transfer must be carefully weighed against the need for haste.

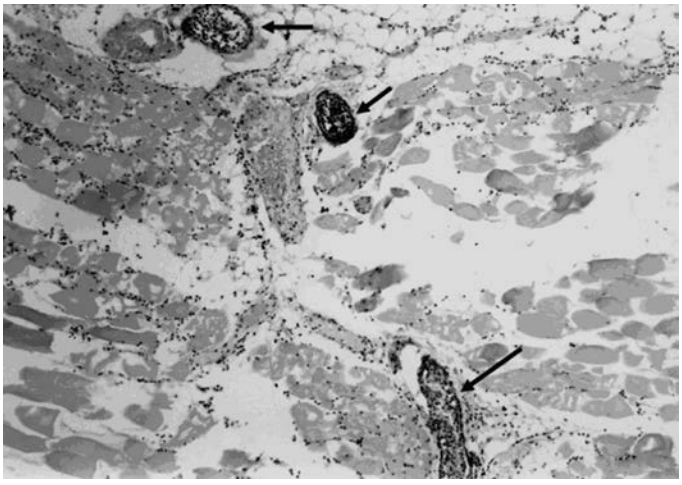

FIGURE 154-4 Histopathology of experimental gas gangrene due to *C. perfringens*, demonstrating widespread muscle necrosis, a paucity of leukocytes in infected tissues, and accumulation of leukocytes in adjacent vessels (*arrows*). These features are due to the effects of α and θ toxins on muscle cells, platelets, leukocytes, and endothelial cells.

PROGNOSIS OF GAS GANGRENE The prognosis for patients with gas gangrene is more favorable when the infection involves an extremity rather than the trunk or visceral organs, since debridement of the latter sites is more difficult. Gas gangrene is most likely to progress to shock and death in patients with associated bacteremia and intravascular hemolysis. Mortality rates are highest for patients in shock at the time of diagnosis. Mortality rates are relatively high among patients with spontaneous gas gangrene, especially that due to *C. septicum*. Survivors of gas gangrene may undergo multiple debridements and face long periods of hospitalization and rehabilitation.

PREVENTION OF GAS GANGRENE Initial aggressive debridement of devitalized tissue can reduce the risk of gas gangrene in contaminated deep wounds. Interventions to be avoided include prolonged application of tourniquets and surgical closure of traumatic wounds; patients with compound fractures are at significant risk for gas gangrene if the wound is closed surgically. Vaccination against α toxin is protective in experimental animal models of *C. perfringens* gas gangrene but has not been investigated in humans. In addition, as mentioned above, a hyperimmune globulin would represent a significant advance for prophylaxis in victims of acute traumatic injury or for attenuation of the spread of infection in patients with established gas gangrene.

Toxic Shock Syndrome Clostridial infection of the endometrium, particularly that due to *C. sordellii*, can develop after gynecologic procedures, childbirth, or abortion (spontaneous or elective, surgical or medical) and, once established, proceeds rapidly to TSS and death. Systemic manifestations, including edema, effusions, profound leukocytosis, and hemoconcentration, are followed by the rapid onset of hypotension and multiple-organ failure. Elevation of the hematocrit to 75–80% and leukocytosis of 50,000–200,000 cells/μL, with a left shift, are characteristic of *C. sordellii* infection. Pain may not be a prominent feature, and fever is typically absent. In one series, 18% of 45 cases of *C. sordellii* infection were associated with normal childbirth, 11% with medically induced abortion, and 0.4% with spontaneous abortion; the case–fatality rate was 100% in these groups. Of the infections in this series that were not related to gynecologic procedures or childbirth, 22% occurred in injection drug users, and 50% of these patients died. Other infections followed trauma or surgery (42%), mostly in healthy persons, and 53% of these patients died. Overall, the mortality rate was 69% (31 of 45 cases). Of patients who succumbed, 85% died within 2–6 days after infection onset or following procedures. Rapidly fatal, spontaneous *C. bifermentans* necrotizing endometritis with toxic shock, leukemoid reaction, and capillary leak has also been described.

Early diagnosis of *C. sordellii* infections often proves difficult for several reasons. First, the prevalence of these infections is low. Second, the initial symptoms are nonspecific and frankly misleading. Early in the course, the illness resembles any number of infectious diseases, including viral syndromes. Given these vague symptoms and an absence of fever, physicians usually do not aggressively pursue additional diagnostic tests. The absence of local evidence of infection and the lack of fever make early diagnosis of *C. sordellii* infection particularly problematic in patients who develop deep-seated infection following childbirth, therapeutic abortion, gastrointestinal surgery, or trauma. Such patients are frequently evaluated for pulmonary embolization, gastrointestinal bleeding, pyelonephritis, or cholecystitis. Unfortunately, such delays in diagnosis increase the risk of death, and, as in most necrotizing soft tissue infections, patients are hypotensive with evidence of organ dysfunction by the time local signs and symptoms become apparent. In contrast, infection is more readily suspected in injection drug users presenting with local swelling, pain, and redness at injection sites; early recognition probably contributes to the lower mortality rates in this group.

Physicians should suspect *C. sordellii* infection in patients who present within 2–7 days after injury, surgery, drug injection, childbirth, or abortion and who report pain, nausea, vomiting, and diarrhea but are afebrile. There is little information regarding appropriate treatment for *C. sordellii* infections. In fact, the interval between onset of symptoms and death is often so short that there is little time to initiate empirical antimicrobial therapy. Indeed, anaerobic cultures of blood and wound aspirates are time-consuming, and many hospital laboratories do not routinely perform antimicrobial sensitivity testing on anaerobes. Antibiotic susceptibility data from older studies suggest that *C. sordellii*, like most clostridia, is susceptible to β-lactam antibiotics, clindamycin, tetracycline, and chloramphenicol but is resistant to aminoglycosides and sulfonamides. Antibiotics that suppress toxin synthesis (e.g., clindamycin) may possibly prove useful as therapeutic adjuncts since they are effective in necrotizing infections due to other toxin-producing gram-positive organisms.

Other Clostridial Skin and Soft Tissue Infections *Crepitant cellulitis* (also called *anaerobic cellulitis*) occurs principally in diabetic patients and characteristically involves subcutaneous tissues or retroperitoneal tissues, whereas the muscle and fascia are not involved. This infection can progress to fulminant systemic disease.

Cases of *C. histolyticum* infection with cellulitis, abscess formation, or endocarditis have also been documented in injection drug users. Endophthalmitis due to *C. sordellii* or *C. perfringens* has been described. *C. ramosum* is also isolated frequently from clinical specimens, including blood and both intraabdominal and soft tissues. This species may be resistant to clindamycin and multiple cephalosporins.

Section 6 Diseases Caused by Gram-Negative Bacteria

155 Meningococcal Infections

Manish Sadarangani, Andrew J. Pollard

DEFINITION

Infection with *Neisseria meningitidis* most commonly manifests as asymptomatic colonization in the nasopharynx of healthy adolescents and adults. Invasive disease occurs rarely, usually presenting as either bacterial meningitis or meningococcal septicemia. Patients may also present with occult bacteremia, pneumonia, septic arthritis, conjunctivitis, and chronic meningococcemia.

ETIOLOGY AND MICROBIOLOGY

N. meningitidis is a gram-negative aerobic diplococcus that colonizes humans only and that causes disease after transmission to a susceptible individual. Several related neisserial organisms have been recognized, including the pathogen *N. gonorrhoeae* and the commensals *N. lactamica*, *N. flavescens*, *N. mucosa*, *N. sicca*, and *N. subflava*. *N. meningitidis* is a catalase- and oxidase-positive organism that utilizes glucose and maltose to produce acid.

TABLE 155-1 Structure of the Polysaccharide Capsule of Common Disease-Causing Meningococci

MENINGOCOCCAL CAPSULAR GROUP	CHEMICAL STRUCTURE OF OLIGOSACCHARIDE	CURRENT DISEASE EPIDEMIOLOGY
A	2-Acetamido-2-deoxy-D-mannopyranosyl phosphate	Epidemic disease mainly in sub-Saharan Africa; sporadic cases worldwide
B	α-2,8-*N*-acetylneuraminic acid	Sporadic cases worldwide; propensity to cause hyperendemic disease
C	α-2,9-*O*-acetylneuraminic acid	Small outbreaks and sporadic disease
Y	4-*O*-α-D-glucopyranosyl-*N*-acetylneuraminic acid	Sporadic disease and occasional small institutional outbreaks
W	4-*O*-α-D-galactopyranosyl-*N*-acetylneuraminic acid	Sporadic disease; outbreaks of disease associated with mass gatherings; epidemics in sub-Saharan Africa
X	(α1→4) *N*-acetyl-D-glucosamine-1-phosphate	Sporadic disease and large outbreaks in the meningitis belt of Africa

Meningococci associated with invasive disease are usually encapsulated with polysaccharide, and the antigenic nature of the capsule determines an organism's capsular group (serogroup) **(Table 155-1)**. In total, 12 capsular groups have been identified (A–C, X–Z, E, W, H–J, and L), but just six of these—A, B, C, X, Y, and W (formerly W135)—account for the majority of cases of invasive disease. Group D is often listed as the thirteenth capsular group but has recently been identified as an unencapsulated variant of group C. Meningococci are commonly isolated from the nasopharynx in studies of carriage; the lack of capsule often is a result of phase variation of capsule expression, but as many as 16% of isolates lack the genes for capsule synthesis and assembly. These "capsule-null" meningococci and those that express capsules other than A, B, C, X, Y, and W are only rarely associated with invasive disease and are most commonly identified in the nasopharynx of asymptomatic carriers.

Beneath the capsule, meningococci are surrounded by an outer phospholipid membrane containing lipopolysaccharide (LPS, endotoxin) and multiple outer-membrane proteins **(Figs. 155-1 and 155-2)**. Antigenic variability in porins expressed in the outer membrane defines the serotype (PorB) and serosubtype (PorA) of the organism, and structural differences in LPS determine the immunotype. Serologic methods for typing of meningococci are restricted by the limited availability of serologic reagents that can distinguish among the organisms' highly variable surface proteins. Where available, high-throughput antigen gene sequencing has superseded serology for meningococcal typing. A large database of antigen gene sequences for the outer-membrane proteins PorA, PorB, FetA, Opa, NadA, Neisserial heparin binding antigen (NHBA), and factor H–binding protein (fHbp) is available online (*pubmlst.org/organisms/neisseria-spp*). The number of specialized iron-regulated proteins found in the meningococcal outer membrane (e.g., FetA and transferrin-binding proteins) highlights the organisms' dependence on iron from human sources. A thin peptidoglycan cell wall separates the outer membrane from the cytoplasmic membrane.

The structure of meningococcal populations involved in local and global spread has been studied with multilocus enzyme electrophoresis (MLEE), which characterizes isolates according to differences in the electrophoretic mobility of cytoplasmic enzymes. However, this technique was replaced by multilocus sequence typing (MLST), in which meningococci are characterized by sequence types assigned on the basis of sequences of internal fragments of 7 housekeeping genes. The online MLST database currently includes more than 15,000 unique *Neisseria* sequence types. A limited number of hyperinvasive lineages of *N. meningitidis* have been recognized and are responsible for the majority of cases of invasive meningococcal disease worldwide. Hyperinvasive lineages may be associated with more than one capsular group. The apparent genetic stability of these meningococcal clones over decades and during wide geographic spread indicates that they are well adapted to the nasopharyngeal environment of the host and to efficient transmission. While MLST has become established as the main method for meningococcal genotyping in many reference laboratories over the past 15 years, whole-genome sequencing is gradually replacing this approach, with more than 4500 genomes already available in the United Kingdom's national library.

The group B meningococcal genome is >2 megabases in length and contains 2158 coding regions. Many genes undergo phase variation that makes it possible to control their expression; this capacity is likely to be important in meningococcal adaptation to the host environment and evasion of the immune response. Meningococci can obtain DNA from their environment and can acquire new genes—including the capsular operon—such that *capsule switching* from one capsular group to another can occur.

EPIDEMIOLOGY

Patterns of Disease Up to 500,000 cases of meningococcal disease are thought to occur worldwide each year, although the numbers have been declining recently as a result of both immunization programs and secular trends. About 10% of affected individuals die. There are several patterns of disease: epidemic, outbreak (small clusters of cases), hyperendemic, and sporadic or endemic.

Epidemics have continued since the original descriptions of meningococcal disease, especially affecting the sub-Saharan meningitis belt of Africa, where tens to hundreds of thousands of cases (caused mainly by capsular group A but also by capsular groups C, W, and X) may be reported over a season and rates may be as high as 1000 cases per 100,000 population. Capsular group A epidemics took place in Europe and North America after the First and Second World Wars, and capsular group A outbreaks have been documented over the past 30 years in New Zealand, China, Nepal, Mongolia, India, Pakistan, Poland, and Russia. However, 65% of outbreaks reported in the meningitis belt between 2010 and 2017 were caused by capsular group C and 35% by capsular group W meningococci, following an immunization campaign to control capsular group A outbreaks.

Clusters of cases occur where there is an opportunity for increased transmission—i.e., in closed or semi-closed communities such as schools, colleges, universities, military training centers, and refugee camps. Recently, such clusters have been especially strongly linked with a particular clone (sequence type 11) that is mainly associated with capsular group C or W but was first described in association with capsular group B. Clusters of capsular group W disease associated with

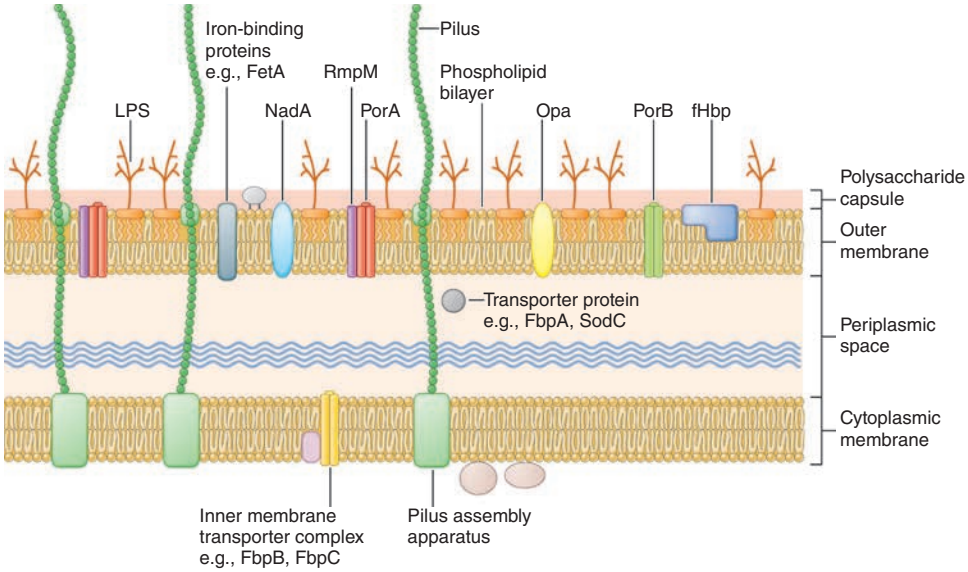

FIGURE 155-2 Cross-section through surface structures of *Neisseria meningitidis*. LPS, lipopolysaccharide. *(Reproduced with permission from M Sadarangani, AJ Pollard: Serogroup B meningococcal vaccines–an unfinished story. Lancet Infect Dis 10:112, 2010.)*

the Hajj pilgrimage in 2000/2001 led to a requirement for vaccination against meningococcal disease for travel to Saudi Arabia. Wider and more prolonged community outbreaks (hyperendemic disease) due to single clones of capsular group B meningococci account for ≥10 cases per 100,000. Regions affected in the past decade include the U.S. Pacific Northwest, New Zealand (both islands), and the province of Normandy in France.

Most countries now experience predominantly sporadic cases (0.3–5 cases per 100,000 population), with many different disease-causing clones involved and usually no clear epidemiologic link between one case and another. The disease rate and the distribution of meningococcal strains vary in different regions of the world and also in any one location over time. For example, in the United States, the rate of meningococcal disease fell from 1.2 cases per 100,000 population in 1997 to 0.10 cases per 100,000 in 2018 **(Fig. 155-3)**. Meningococcal disease in the United States was previously dominated by capsular groups B and C; however, capsular group Y emerged during the 1990s and in 2018 group B was predominant in children age <5 years, whereas adults 45 years and older were infected with groups B, C, and Y **(Fig. 155-4)**. In contrast, rates of disease in England and Wales rose to >5 cases per 100,000 during the 1990s because of an increase in cases caused by the ST11 capsular group C clone. As a result of a mass immunization program against capsular group C in 1999, capsular group B then became predominant. Introduction of a MenB vaccine since 2015 has led to a significant reduction in group B cases, with an increase in recent years of capsular group W infections (Fig. 155-4). Over the last decade, most industrialized nations have seen a general decrease in meningococcal disease; this decrease is linked to immunization against capsular group C meningococci in Europe, Canada, and Australia and to adolescent immunization programs for capsular groups A, C, Y, and W in the United States. However, other factors, including changes in population immunity and prevalent clones of meningococci (factors that, in combination, probably explain the cyclic nature of meningococcal disease rates) as well as a reduction in smoking and passive exposure to tobacco smoke (driven by bans on smoking in buildings and public spaces) across wealthy countries, are likely to have contributed to the fall in cases. Over the past decade, a hyperinvasive ST11 clone bearing a W capsule has emerged in South America and spread to the United Kingdom and has also emerged in other countries in Europe and in Australia, leading to a considerable increase in capsular group W cases. Increases in capsular group Y disease have also been noted in various countries in Europe, Canada, and South Africa.

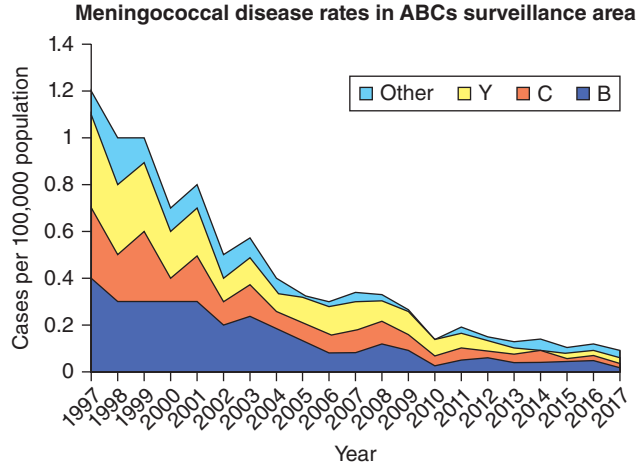

FIGURE 155-3 Meningococcal disease in the United States, 1997–2017. ABCs, active bacterial cores. *(Adapted from ABC Surveillance data, Centers for Disease Control and Prevention; www.cdc.gov.)*

Factors Associated with Disease Risk and Susceptibility The principal determinant of disease susceptibility is age, with the peak incidence in the first year of life **(Fig. 155-5)**. The susceptibility of the very young presumably results from an absence of specific adaptive immunity in combination with very close contact with colonized individuals, including parents. Compared with other age groups, infants appear to be particularly susceptible to capsular group B disease: >30% of capsular group B cases in the United States occur during the first year of life. In the early 1990s in North America, the median ages for patients with disease due to capsular groups B, C, Y, and W were 6, 17, 24, and 33 years, respectively.

After early childhood, a second peak of disease occurs among adolescents and young adults (15–25 years of age) in Europe and North America. It is thought that this peak relates to social behaviors and environmental exposures in this age group, as discussed below. Most cases of infection with *N. meningitidis* in developed countries today are sporadic, and the rarity of the disease suggests that individual susceptibility may be important. A number of factors probably contribute to individual susceptibility, including the host's genetic constitution, environment, and contact with a carrier or a case.

The best-documented genetic association with meningococcal disease is complement deficiency, chiefly of the terminal complement components (C5–9), properdin, or factor D; such a deficiency increases the risk of disease by up to 600-fold and may result in recurrent attacks. Complement components are believed to be important for the bactericidal activity of serum, which is considered the principal mechanism of immunity against invasive meningococcal disease. However, when investigated, complement deficiency is found in only a very small proportion of individuals with meningococcal disease (0.3%). Conversely, 7–20% of persons whose disease is caused by the less common capsular groups (W, X, Y, Z, E) have a complement deficiency. Complement deficiency appears to be associated with capsular group B disease only rarely. Individuals with recurrences of meningococcal disease, particularly those caused by non-B capsular groups, should be assessed for complement deficiency by measurement of total hemolytic complement activity. There is also limited evidence that hyposplenism (through reduction in phagocytic capacity) and hypogammaglobulinemia (through absence of specific antibody) increase the risk of meningococcal disease. Genetic studies have revealed various

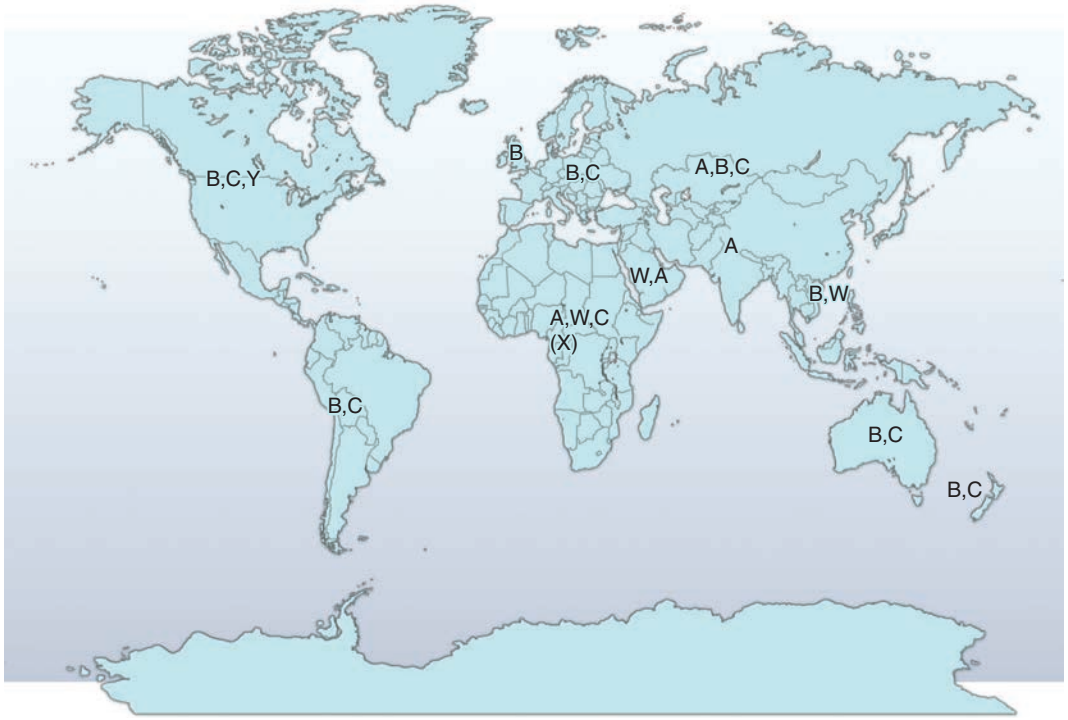

FIGURE 155-4 Global distribution of meningococcal capsular groups, 1999–2009.

associations with disease susceptibility, including complement and mannose-binding lectin deficiency, single-nucleotide polymorphisms in Toll-like receptor (TLR) 4 and complement factor H, and variants of Fc gamma receptors.

Factors that increase the chance of a susceptible individual's acquiring *N. meningitidis* via the respiratory route also increase the risk of meningococcal disease. Acquisition occurs through close contact with carriers as a result of overcrowding (e.g., in poor socioeconomic settings, in refugee camps, during the Hajj pilgrimage to Mecca, during freshman-year residence in college dormitories) and certain social behaviors (e.g., attendance at bars and nightclubs, kissing). Secondary cases may occur in close contacts of an index case (e.g., household members, persons kissing the infected individual); the risk to these contacts may be as high as 1000 times the background rate in the population. Factors that damage the nasopharyngeal epithelium also increase the risk of both colonization with *N. meningitidis* and invasive disease. The most important of these factors are tobacco smoking (odds ratio, 4.1) and passive exposure to tobacco smoke. In addition, recent viral respiratory tract infection, infection with *Mycoplasma* species, and winter or the dry season have been associated with meningococcal disease; all of these factors presumably either increase the expression of adhesion molecules in the nasopharynx, thus enhancing meningococcal adhesion, or facilitate meningococcal invasion of the bloodstream.

PATHOGENESIS

N. meningitidis has evolved as an effective colonizer of the human nasopharynx, with asymptomatic infection rates of >25% described in some series of adolescents and young adults and among residents of crowded communities. Point-prevalence studies reveal widely divergent rates of carriage for different types of meningococci. This variation suggests that some types may be adapted to a short duration of carriage with frequent transmission to maintain the population, while others may be less efficiently transmitted but may overcome this disadvantage by colonizing for a long period. Despite the high rates of carriage among adolescents and young adults, only ~10% of adults carry meningococci, and colonization is very rare in early childhood. Many of the same factors that increase the risk of meningococcal disease also increase the risk of carriage. Colonization of the nasopharynx involves a series of interactions of meningococcal adhesins (e.g., Opa proteins and pili) with their ligands on the epithelial mucosa. *N. meningitidis* produces an IgA1 protease that is likely to reduce interruption of colonization by mucosal IgA.

Colonization should be considered the normal state of meningococcal infection, with an increased risk of invasion being the unfortunate consequence (for both host and organism) of adaptations of hyperinvasive meningococcal lineages. The meningococcal capsule is an important virulence factor: acapsular strains only very rarely cause invasive disease. The capsule provides resistance to phagocytosis and may be important in preventing desiccation during transmission between hosts. Antigenic diversity in surface structures and an ability to vary levels of their expression probably have evolved as important factors in maintaining meningococcal populations within and between individual hosts.

Invasion through the mucosa into the bloodstream occurs rarely, usually within a few days of acquisition of an invasive strain by a susceptible individual. Only occasional cases of prolonged colonization prior to invasion have been documented. Once the organism

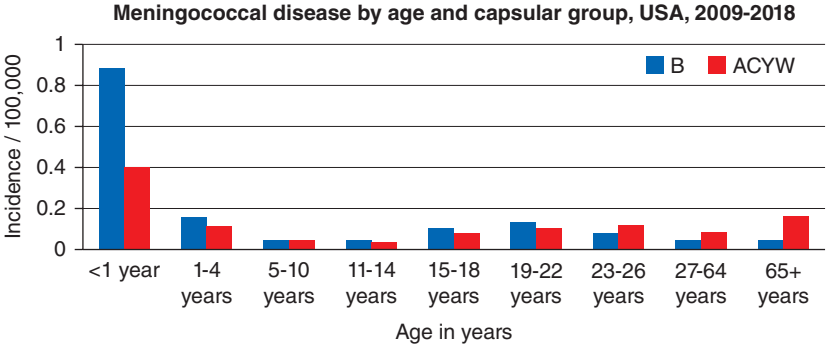

FIGURE 155-5 Age distribution of capsular groups B and ACWY meningococcal disease USA, 2009-2018. *(Adapted from www.cdc.gov/meningococcal/surveillance/surveillance-data.html#figure01.)*

is in the bloodstream, its growth may be limited if the individual is partially immune, although bacteremia may allow seeding of another site, such as the meninges or the joints. Alternatively, unchecked proliferation may continue, resulting in high bacterial counts in the circulation. During growth, meningococci release blebs of outer membrane (Fig. 155-1) containing outer-membrane proteins and LPS. Endotoxin binds cell-bound CD14 in association with TLR4 to initiate an inflammatory cascade with the release of high levels of various mediators, including tumor necrosis factor (TNF) α, soluble TNF receptor, interleukin (IL) 1, IL-1 receptor antagonist, IL-1β, IL-6, IL-8, IL-10, plasminogen-activator inhibitor 1 (PAI-1), and leukemia inhibitory factor. Soluble CD14-bound endotoxin acts as a mediator of endothelial activation. The severity of meningococcal disease is related both to the levels of endotoxin in the blood and to the magnitude of the inflammatory response. The latter is determined to some extent by polymorphisms in the inflammatory response genes (and their inhibitors), and the release of the inflammatory cascade heralds the development of meningococcal septicemia (meningococcemia). Endothelial injury is central to many clinical features of meningococcemia, including increased vascular permeability, pathologic changes in vascular tone, loss of thromboresistance, intravascular coagulation, and myocardial dysfunction. Endothelial injury leads to increased vascular permeability (attributed to loss of glycosaminoglycans and endothelial proteins), with subsequent gross proteinuria. Leakage of fluid and electrolytes into the tissues from capillaries ("capillary leak syndrome") leads to hypovolemia, tissue edema, and pulmonary edema. Initial compensation results in vasoconstriction and tachycardia, although cardiac output eventually falls. While resuscitation fluids may restore circulating volume, tissue edema will continue to increase, and, in the lung, the consequence may be respiratory failure.

Intravascular thrombosis (caused by activation of procoagulant pathways in association with upregulation of tissue factor on the endothelium) occurs in some patients with meningococcal disease and results in purpura fulminans and infarction of areas of skin or even of whole limbs. At the same time, multiple anticoagulant pathways are downregulated through loss of endothelial thrombomodulin and protein C receptors and decreases in levels of antithrombin III, protein C, protein S, and tissue factor pathway inhibitor. Thrombolysis is also profoundly impaired in meningococcal sepsis through the release of high levels of PAI-1.

Shock in meningococcal septicemia appears to be attributable to a combination of factors, including hypovolemia, which results from the capillary leak syndrome secondary to endothelial injury, and myocardial depression, which is driven by hypovolemia, hypoxia, metabolic derangements (e.g., hypocalcemia), and cytokines (e.g., IL-6). Decreased perfusion of tissues as a result of intravascular thrombosis, vasoconstriction, tissue edema, and reduced cardiac output in meningococcal septicemia can cause widespread organ dysfunction, including renal impairment and—later in the disease—a decreased level of consciousness due to central nervous system involvement.

Bacteria that reach the meninges cause a local inflammatory response—with release of a spectrum of cytokines similar to that seen in septicemia—that presents clinically as meningitis and is thought to determine the severity of neuronal injury. Local endothelial injury may result in cerebral edema and rapid onset of raised intracranial pressure in some cases.

CLINICAL MANIFESTATIONS

As discussed above, the most common form of infection with *N. meningitidis* is asymptomatic carriage of the organism in the nasopharynx. Despite the location of infection in the upper airway, meningococcal pharyngitis is rarely reported; however, upper respiratory tract symptoms are common prior to presentation with invasive disease. It is not clear whether these symptoms relate to preceding viral infection (which may promote meningococcal acquisition and/or invasion) or to meningococcal acquisition itself. After acquiring the organism, susceptible individuals develop disease manifestations in 1–10 days (usually <4 days, although colonization for 11 weeks has been documented).

Along the spectrum of presentations of meningococcal disease, the most common clinical syndromes are meningitis and meningococcal septicemia. In fulminant cases, death may occur within hours of the first symptoms. Occult bacteremia is also recognized and, if untreated, progresses in two-thirds of cases to focal infection, including meningitis or septicemia. Meningococcal disease may also present as pneumonia, pyogenic arthritis or osteomyelitis, purulent pericarditis, endophthalmitis, conjunctivitis, primary peritonitis, or (rarely) urethritis. Perhaps because it is difficult to diagnose, meningococcal pneumonia is not commonly reported but is associated with capsular groups Y, W, and Z and appears most often to affect individuals >10 years of age.

Rash A nonblanching rash (petechial or purpuric) develops in >80% of cases of meningococcal disease; however, the rash is often absent early in the illness. Usually initially blanching in nature (macules, maculopapules, or urticaria) and indistinguishable from more common viral rashes, the rash of meningococcal infection becomes petechial or frankly purpuric over the hours after onset. In the most severe cases, large purpuric lesions develop (purpura fulminans; **Fig. A1-41**). Some patients (including those with overwhelming sepsis) may have no rash. While petechial rash and fever are important signs of meningococcal disease, fewer than 10% of children (and, in some clinical settings, fewer than 1% of patients) with this presentation are found to have meningococcal disease. Most patients presenting with a petechial or purpuric rash have a viral infection **(Table 155-2)**. The skin lesions exhibit widespread endothelial necrosis and occlusion of small vessels in the dermis and subcutaneous tissues, with a neutrophilic infiltrate.

Meningitis Meningococcal meningitis commonly presents as nonspecific manifestations, including fever, vomiting, and (especially in infants and young children) irritability, and is indistinguishable from other forms of bacterial meningitis unless there is an associated petechial or purpuric rash, which occurs in two-thirds of cases. Headache is rarely reported in early childhood but is more common in later childhood and adulthood. When headache is present, the following features, in association with fever or a history of fever, are suggestive of bacterial meningitis: neck stiffness, photophobia, decreased level of consciousness, seizures or status epilepticus, and focal neurologic signs. Classic signs of meningitis, such as neck stiffness and photophobia, are often absent in infants and young children with bacterial meningitis, who more usually present with fever and irritability and may have a bulging fontanelle.

While 30–50% of patients present with a meningitis syndrome alone, up to 40% of meningitis patients also present with some features of septicemia. Most deaths from meningococcal meningitis alone (i.e., without septicemia) are associated with raised intracranial pressure presenting as a reduced level of consciousness, relative bradycardia and hypertension, focal neurologic signs, abnormal posturing, and signs of brainstem involvement—e.g., unequal, dilated, or poorly reactive pupils; abnormal eye movement; and impaired corneal responses **(Chap. 28)**.

Cytomegalovirus
Parvovirus
Deficiency of protein C or S (including postvaricella protein S deficiency)
Platelet disorders (e.g., idiopathic thrombocytopenic purpura, drug effects, bone marrow infiltration)
Henoch-Schönlein purpura, connective tissue disorders, trauma (including nonaccidental injuries in children)
Pneumococcal, streptococcal, staphylococcal, or gram-negative bacterial sepsis

Septicemia Meningococcal septicemia alone accounts for up to 20% of cases of meningococcal disease. The condition may progress from early nonspecific symptoms to death within hours. Mortality rates among children with this syndrome have been high (25–40%), but early aggressive management (as discussed below) may reduce the figure to <10%. Early symptoms are nonspecific and suggest an influenza-like illness with fever, headache, and myalgia accompanied by vomiting and abdominal pain. As discussed above, the rash, if present, may appear to be viral early in the course until petechiae or purpuric lesions develop. Purpura fulminans occurs in severe cases (Fig. A1-41), with multiple large purpuric lesions and signs of peripheral ischemia. Surveys of patients have indicated that limb pain, pallor (including a mottled appearance and cyanosis), and cold hands and feet may be prominent. Shock is manifested by tachycardia, poor peripheral perfusion, tachypnea, and oliguria. Decreased cerebral perfusion leads to confusion, agitation, or decreased level of consciousness. With progressive shock, multiorgan failure ensues; hypotension is a late sign in children, who more commonly present with compensated shock (tachycardia, poor peripheral perfusion, and normal blood pressure). Poor outcome is associated with an absence of meningism, hypotension, young age, coma, relatively low temperature (<38°C), leukopenia, and thrombocytopenia. Spontaneous hemorrhage (pulmonary, gastric, or cerebral) may result from consumption of coagulation factors and thrombocytopenia.

Chronic Meningococcemia Chronic meningococcemia, which is rarely recognized, presents as repeated episodes of petechial rash **(Fig. A1-42)** associated with fever, joint pain, features of arthritis, and splenomegaly that may progress to acute meningococcal septicemia if untreated. During the relapsing course, bacteremia characteristically clears without treatment and then recurs. The differential diagnosis includes bacterial endocarditis, acute rheumatic fever, Henoch-Schönlein purpura, infectious mononucleosis, disseminated gonococcal infection, and immune-mediated vasculitis. This condition has been associated with complement deficiencies in some cases and with inadequate sulfonamide therapy in others.

A study from the Netherlands found that half of isolates from patients with chronic meningococcemia had an underacylated lipid A (part of the surface LPS molecule) due to an *lpxL1* gene mutation, which markedly reduces the inflammatory response to endotoxin.

Postmeningococcal Reactive Disease In a small proportion of patients, an immune complex disease develops ~4–10 days after the onset of meningococcal disease, with manifestations that include a maculopapular or vasculitic rash (2% of cases), arthritis (up to 8% of cases), iritis (1%), pericarditis, and/or polyserositis associated with fever. The immune complexes involve meningococcal polysaccharide antigen and result in immunoglobulin and complement deposition with an inflammatory infiltrate. These features resolve spontaneously without sequelae. It is important to recognize this condition since a new onset of fever and rash, and/or arthritis, can lead to concerns about relapse of meningococcal disease and unnecessarily prolonged antibiotic treatment.

DIAGNOSIS

Like other invasive bacterial infections, meningococcal disease may produce elevations of the white blood cell (WBC) count and of values for inflammatory markers (e.g., C-reactive protein and procalcitonin levels or the erythrocyte sedimentation rate). Values may be normal or low in rapidly progressive disease, and a lack of rise in these laboratory test values does not exclude the diagnosis. However, in the presence of fever and a petechial rash, these elevations are suggestive of meningococcal disease. In patients with severe meningococcal septicemia, common laboratory findings include hypoglycemia, acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, anemia, and coagulopathy.

Although meningococcal disease is often diagnosed on clinical grounds, in suspected meningococcal meningitis or meningococcemia, blood should routinely be sent for culture to confirm the diagnosis and to facilitate public health investigations; blood cultures are positive in up to 75% of cases. Culture media containing sodium polyanethol sulfonate, which may inhibit meningococcal growth, should be avoided. Meningococcal viability is reduced if there is a delay in transport of the specimen to the microbiology laboratory for culture or in plating of cerebrospinal fluid (CSF) samples. In countries where treatment with antibiotics before hospitalization is recommended for meningococcal disease, the majority of clinically suspected cases are culture negative. Real-time polymerase chain reaction (PCR) analysis of whole-blood samples increases the diagnostic yield by >40%, and results obtained with this method may remain positive for several days after administration of antibiotics. Indeed, in the United Kingdom, more than half of clinically suspected cases are currently identified by PCR.

Unless contraindications exist (raised intracranial pressure, uncorrected shock, disordered coagulation, thrombocytopenia, respiratory insufficiency, local infection, ongoing convulsions), lumbar puncture should be undertaken to identify and confirm the etiology of suspected meningococcal meningitis, whose presentation cannot be distinguished from that of meningitis of other bacterial causes. Some authorities have recommended a CT brain scan prior to lumbar puncture because of the risk of cerebral herniation in patients with raised intracranial pressure. However, a normal CT scan is not uncommon in the presence of raised intracranial pressure in meningococcal meningitis, and the decision to perform a lumbar puncture should be made on clinical grounds. CSF features of meningococcal meningitis (elevated protein level and WBC count, decreased glucose level) are indistinguishable from those of other types of bacterial meningitis unless a gram-negative diplococcus is identified. (Gram's staining is up to 80% sensitive for meningococcal meningitis.) CSF should be submitted for culture (sensitivity, 90%) and (where available) PCR analysis. CSF antigen testing with latex agglutination is insensitive and should be replaced by molecular diagnosis when possible.

Lumbar puncture should generally be avoided in meningococcal septicemia, as positioning for the procedure may critically compromise the patient's circulation in the context of hypovolemic shock. Delayed lumbar puncture may still be useful when the diagnosis is uncertain, particularly if molecular diagnostic technology is available.

In other types of focal infection, culture and PCR analysis of normally sterile body fluids (e.g., synovial fluid) may aid in the diagnosis. Although some authorities have recommended cultures of scrapings or aspirates from skin lesions, this procedure adds little to the diagnostic yield when compared with a combination of blood culture and PCR analysis. Urinary antigen testing also is insensitive, and serologic testing for meningococcal infection has not been adequately studied. Because *N. meningitidis* is a component of the normal human nasopharyngeal flora, identification of the organism on throat swabs has limited diagnostic value, but strains identified in the nasopharynx in the context of a probable case are likely to be those responsible for disease.

TREATMENT

Meningococcal Infections

Death from meningococcal disease is associated most commonly with hypovolemic shock (meningococcemia) and occasionally with raised intracranial pressure (meningococcal meningitis). Therefore, management should focus on the treatment of these urgent clinical issues in addition to the administration of specific antibiotic therapy. Delayed recognition of meningococcal disease or its associated physiologic derangements, together with inadequate emergency management, is associated with poor outcome. Since the disease is rare, protocols for emergency management have been developed (see *www.meningitis.org*).

Airway patency may be compromised if the level of consciousness is depressed as a result of shock (impaired cerebral perfusion) or raised intracranial pressure; this situation may require intervention. In meningococcemia, pulmonary edema and pulmonary oligemia (presenting as hypoxia) require oxygen therapy or elective endotracheal intubation. In cases with shock, aggressive fluid

resuscitation (with replacement of the circulating volume several times in severe cases) and inotropic support may be necessary to maintain cardiac output. If shock persists after volume resuscitation at 40 mL/kg, the risk of pulmonary edema is high, and elective intubation is recommended to improve oxygenation and decrease the work of breathing. Metabolic derangements, including hypoglycemia, acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, anemia, and coagulopathy, should be anticipated and corrected. However, aggressive fluid resuscitation with unbuffered electrolyte solutions was found to increase mortality in febrile African children. Studies of the effects of lower volumes of buffered solutions and similar studies in resource-rich settings are required. In the presence of raised intracranial pressure, management includes correction of coexistent shock and neurointensive care to maintain cerebral perfusion.

Empirical antibiotic therapy for suspected meningococcal disease consists of a third-generation cephalosporin such as ceftriaxone (75–100 mg/kg per day [maximum, 4 g/d] in one or two divided IV doses) or cefotaxime (200 mg/kg per day [maximum, 8 g/d] in four divided IV doses) to cover the various other (potentially penicillin-resistant) bacteria that may produce an indistinguishable clinical syndrome. Although unusual in most isolates, reduced meningococcal sensitivity to penicillin (a minimal inhibitory concentration of 0.12–1.0 μg/mL) has been reported.

Both meningococcal meningitis and meningococcal septicemia are conventionally treated for 7 days, although courses of 3–5 days may be equally effective. Furthermore, a single dose of ceftriaxone or an oily suspension of chloramphenicol has been used successfully in resource-poor settings. No data are available to guide the duration of treatment for meningococcal infection at other foci (e.g., pneumonia, arthritis); antimicrobial therapy is usually continued until clinical and laboratory evidence of infection has resolved. Cultures usually become sterile within 24 h of initiation of appropriate antibiotic chemotherapy.

The use of glucocorticoids for adjunctive treatment of meningococcal meningitis remains controversial since no relevant studies have had sufficient power to determine true efficacy. One large study in adults did indicate a trend toward benefit, and in clinical practice a decision to use glucocorticoids usually must precede a definite microbiologic diagnosis. Therapeutic doses of glucocorticoids are not recommended in meningococcal septicemia, but many intensivists recommend replacement glucocorticoid doses for patients who have refractory shock in association with impaired adrenal gland responsiveness, management that is supported by limited evidence.

Various other adjunctive therapies for meningococcal disease have been considered, but few have been subjected to clinical trials and none can currently be recommended. An antibody to LPS (HA1A) failed to confer a demonstrable benefit. Recombinant bactericidal/permeability-increasing protein (which is not currently available) was tested in a study that had inadequate power to show an effect on mortality rates; however, there were trends toward lower mortality rates among patients who received a complete infusion, and this group also had fewer amputations, fewer blood-product transfusions, and a significantly improved functional outcome. Given that protein C concentrations are reduced in meningococcal disease, the use of activated protein C has been considered. A survival benefit was demonstrated in adult sepsis trials; however, trials in pediatric sepsis (of particular relevance for meningococcal disease) found no benefit and indicated a potential risk of bleeding complications with use of activated protein C.

The postmeningococcal immune-complex inflammatory syndrome has been treated with nonsteroidal anti-inflammatory agents until spontaneous resolution occurs.

COMPLICATIONS

About 10% of patients with meningococcal disease die despite the availability of antimicrobial therapy and other intensive medical interventions. The most common complication of meningococcal disease (10% of cases) is scarring after necrosis of purpuric skin lesions, for which skin grafting may be necessary. The lower limbs are most often affected; next in frequency are the upper limbs, the trunk, and the face. On average, 13% of the skin surface area is involved. Amputations are necessary in 1–2% of survivors of meningococcal disease because of a loss of tissue viability after peripheral ischemia or compartment syndromes. Unless there is local infection, amputation should usually be delayed to allow the demarcation between viable and nonviable tissue to become apparent. Approximately 5% of patients with meningococcal disease suffer hearing loss, and 7% have neurologic complications. In one study, pain was reported by 21% of survivors, and in a recent analysis of capsular group B meningococcal disease (the MOSAIC study) as many as one-quarter of survivors had psychological disorders. In some investigations, the rate of complications is higher for capsular group C disease (mostly associated with the ST11 clone) than for capsular group B disease. In patients with severe hypovolemic shock, renal perfusion may be impaired and prerenal failure is common, but permanent renal replacement therapy is rarely needed.

Several studies suggest adverse psychosocial outcomes after meningococcal disease, with reduced quality of life, lowered self-esteem, and poorer neurologic development, including increased rates of attention deficit/hyperactivity disorder and special educational needs. Other studies have not found evidence of such outcomes.

PROGNOSIS

Several prognostic scoring systems have been developed to identify patients with meningococcal disease who are least likely to survive. Factors associated with a poorer prognosis are shock; young age (infancy), old age, and adolescence; coma; purpura fulminans; disseminated intravascular coagulation; thrombocytopenia; leukopenia; absence of meningitis; metabolic acidosis; low plasma concentrations of antithrombin and proteins S and C; high blood levels of PAI-1; and a low erythrocyte sedimentation rate or C-reactive protein level. The Glasgow Meningococcal Septicaemia Prognostic Score (GMSPS) performs well and may be clinically useful for severity assessment in meningococcal disease. However, scoring systems do not direct the clinician to specific interventions, and the priority in management should be recognition of compromised airways, breathing, or circulation and direct, urgent intervention. Most patients improve rapidly with appropriate antibiotics and supportive therapy. Fulminant meningococcemia is more likely to result in death or ischemic skin loss than is meningitis; optimal emergency management may reduce mortality rates among the most severely affected patients.

PREVENTION

Since mortality rates in meningococcal disease remain high despite improvements in intensive care management, immunization is the only rational approach to prevention at a population level. Secondary cases are common among household and "kissing" contacts of cases, and secondary prophylaxis with antibiotics is widely recommended for these contacts (see below).

Polysaccharide Vaccines Purified meningococcal capsular polysaccharide has been used for immunization since the 1960s. Meningococcal polysaccharide vaccines are currently formulated as either bivalent (capsular groups A and C) or quadrivalent (capsular groups A, C, Y, and W), with 50 μg of each polysaccharide per dose. Local reactions (erythema, induration, and tenderness) may occur in up to 40% of vaccinees, but serious adverse events (including febrile convulsions in young children) are very rarely reported. In adults, the vaccines are immunogenic, but immunity appears to be relatively short-lived (with antibody levels above baseline for only 2–10 years), and booster doses do not induce a further rise in antibody concentration. Indeed, a state of immunologic hyporesponsiveness has been widely reported to follow booster doses of plain polysaccharide vaccines. The repeating units of these vaccines cross-link B-cell receptors to drive specific memory B cells to become plasma cells and produce antibody. Because meningococcal polysaccharides are T cell–independent antigens, no memory B cells are produced after immunization, and the memory B-cell pool

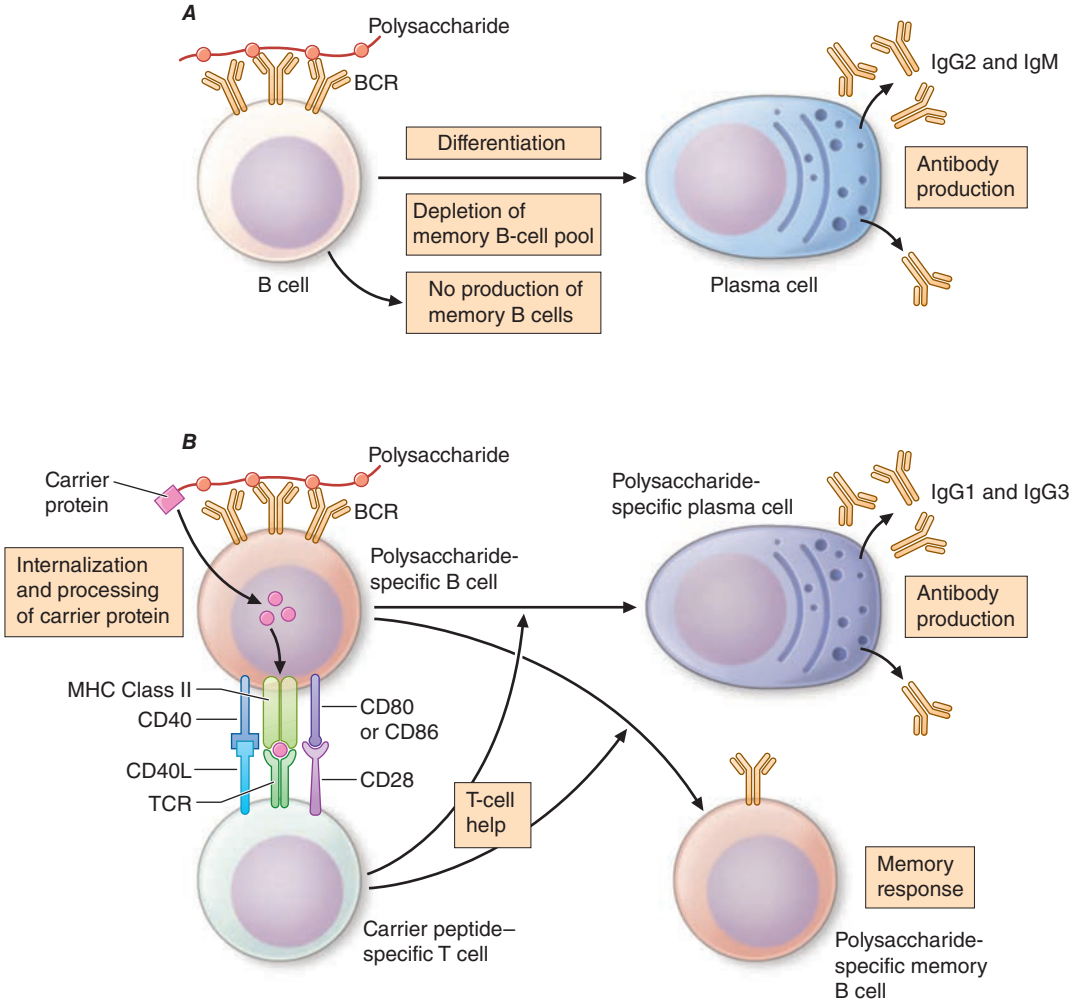

FIGURE 155-6 ***A.*** Polysaccharides from the encapsulated bacteria that cause disease in early childhood stimulate B cells by cross-linking the B-cell receptor (BCR) and driving the production of immunoglobulins. There is no production of memory B cells, and the B-cell pool may be depleted by this process such that subsequent immune responses are decreased. ***B.*** The carrier protein from protein–polysaccharide conjugate vaccines is processed by the polysaccharide-specific B cell, and peptides are presented to carrier peptide–specific T cells, with the consequent production of both plasma cells and memory B cells. MHC, major histocompatibility complex; TCR, T-cell receptor. *(Reproduced with permission from AJ Pollard: Maintaining protection against invasive bacteria with protein–polysaccharide conjugate vaccines. Nat Rev Immunol 9:213, 2009.)*

is depleted such that fewer polysaccharide-specific cells are available to respond to a subsequent dose of vaccine (Fig. 155-6). The clinical relevance of hyporesponsiveness is unknown. Plain polysaccharide vaccines generally are not immunogenic in early childhood, possibly because marginal-zone B cells are involved in polysaccharide responses and maturation of the splenic marginal zone is not complete until 18 months to 2 years of age. The efficacy of the meningococcal capsular group C component is >90% in young adults; no efficacy data are available for the capsular group Y and W polysaccharides in this age group.

Group A meningococcal polysaccharides are exceptional in that they are effective in preventing disease at all ages. Two doses administered 2–3 months apart to children 3–18 months of age or a single dose administered to older children or adults has a protective efficacy rate of >95%. The vaccine was previously used widely in the control of outbreaks of meningococcal disease in the African meningitis belt. The duration of protection appears to be only 3–5 years. The plain polysaccharide vaccines have been largely superseded by protein–polysaccharide conjugate vaccines.

There is no meningococcal capsular group B plain polysaccharide vaccine because α-2,8-*N*-acetylneuraminic acid is expressed on the surface of neural cells in the fetus such that the B polysaccharide is perceived as "self" and therefore is not immunogenic in humans.

Conjugate Vaccines The poor immunogenicity of plain polysaccharide vaccines in infancy has been overcome by chemical conjugation of the polysaccharides to a carrier protein (CRM_{197}, tetanus toxoid, or diphtheria toxoid). Conjugates that contain monovalent capsular group C polysaccharide and quadrivalent vaccines with A, C, Y, and W polysaccharides have been developed, as have vaccines including various other antigen combinations (e.g., tetanus conjugates with capsular group C and/or Y polysaccharide and *Haemophilus influenzae* type b polysaccharide). After immunization, peptides from the carrier protein are conventionally thought to be presented by polysaccharide-specific B cells to peptide-specific T cells in association with major histocompatibility complex (MHC) class II molecules. (Some data suggest that carrier protein peptide may actually be presented in association with an oligosaccharide and MHCII.) The result is a T cell–dependent immune response that allows production of antibody and generation of an expanded B-cell memory pool. Unlike responses to booster doses of plain polysaccharides, responses to booster doses of conjugate vaccines have the characteristics of memory responses. Indeed, conjugate vaccines overcome the hyporesponsiveness induced by plain polysaccharides by replenishing the memory pool. The reactogenicity of conjugate vaccines is similar to that of plain polysaccharide vaccines.

The first widespread use of capsular group C meningococcal conjugate vaccine (MenC) came in 1999 in the United Kingdom after a rise in capsular group C disease. A mass vaccination campaign involving all individuals <19 years of age was undertaken, and the number of laboratory-confirmed capsular group C cases fell from 955 in 1998–1999 to just 29 in 2011–2012. The effectiveness of the immunization program was attributed both to direct protection of immunized persons and to reduced transmission of the organism in the population

as a result of decreased rates of colonization among the immunized (i.e., herd immunity). Data on immunogenicity and effectiveness have shown that the duration of protection is short when the vaccine is administered in early childhood; thus booster doses are needed to maintain population immunity. In contrast, immunity after a dose of vaccine given in adolescence appears to be more prolonged.

In 2005, the first quadrivalent conjugate meningococcal vaccine containing A, C, Y, and W polysaccharides conjugated to diphtheria toxoid was initially recommended for all children >11 years of age in the United States and for persons 2–55 years of age in Canada. Such vaccines are now recommended by the Advisory Committee on Immunization Practices (ACIP) for routine administration to individuals 11–18 years of age, with a booster dose 3 years later; only a single dose is given to persons >16 years of age. These vaccines are also recommended for high-risk persons from 2 months to 55 years of age (see *www.cdc.gov/mmwr/preview/mmwrhtml/mm6324a2.htm*).

Uptake was slow initially, but current U.S. data suggest an efficacy rate of 82% in the first year after vaccination, with waning to 59% at 3–6 years after vaccination. Limited early data from the U.S. Vaccine Adverse Events Reporting System indicated that there might be a short-term increase in the risk of Guillain-Barré syndrome after immunization with the diphtheria conjugate vaccine; however, further investigation has not confirmed this finding. Quadrivalent conjugate vaccines with tetanus or CRM_{197} as carrier protein are now available in many countries and are used for high-risk groups and in routine programs for toddlers and adolescents.

A monovalent capsular group A vaccine, manufactured in India, was licensed in 2010 and rolled out to countries in the sub-Saharan African meningitis belt in a mass immunization campaign. There is strong evidence that this vaccine has been highly effective in controlling epidemic meningococcal disease in the region, with >90% reduction in disease in vaccinated populations. However, disease caused by capsular groups C, X, and W persists, and new-generation vaccines with wider coverage are being developed.

Vaccines Based on Subcapsular Antigens The lack of immunogenicity of the group B capsule has led to the development of vaccines based on subcapsular antigens. Various surface components have been studied in early-phase clinical trials. Outer-membrane vesicles (OMVs) containing outer-membrane proteins, phospholipid, and LPS can be extracted from cultures of *N. meningitidis* by detergent treatment **(Fig. 155-7)**. OMVs prepared in this way were used in efficacy trials with a Norwegian outbreak strain and reduced the incidence of group B disease among 14- to 16-year-old schoolchildren by 53%. Similarly, OMV vaccines constructed from local outbreak strains in Cuba and New Zealand have had reported efficacy rates of >70%. These OMV vaccines appear to produce strain-specific immune responses, with only limited cross-protection, and are therefore best suited to clonal outbreaks (e.g., those in Cuba and New Zealand as well as others in Norway and the province of Normandy in France).

Several purified surface proteins have been evaluated in phase 1 clinical trials but have not yet been developed further because of antigenic variability or poor immunogenicity (e.g., transferrin-binding proteins, neisserial surface protein A). Other vaccine candidates have been identified since sequencing of the meningococcal genome. The combination vaccine 4CMenB, which includes the New Zealand OMV vaccine and three recombinant proteins (neisserial adhesin A, factor H–binding protein, and neisserial heparin-binding antigen), is immunogenic from infancy and has been licensed for use in the United States, Canada, Europe, and Australia. This vaccine has been used with apparent success in the control of several university outbreaks in the United States and in a community outbreak in an area of Quebec, Canada. 4CMenB vaccine has an acceptable safety profile, with fever prominent among infants and injection-site pain frequently reported among older children and adults. The vaccine is also being used in many countries for immunization of high-risk groups. In September 2015, 4CMenB was recommended for routine use in the United Kingdom for all infants born from May 2015 onward; a recent analysis reported a 75% reduction in age groups that were fully eligible for vaccination, with a high coverage rate of 95%. The licensed schedule is 3 priming doses before 6 months of age and a booster dose at 12 months of age. A non-significant vaccine effectiveness of 53% was seen after two doses, and 59% effectiveness was found after the booster dose at 1 year of age.

FIGURE 155-7 Illustration of meningococcal outer-membrane vesicle containing outer-membrane structures.

Because the disease is so rare, the cost-effectiveness of capsular group B vaccine in infant immunization programs, as assessed with conventional thresholds, is borderline in the United Kingdom. Since infants are not commonly colonized with capsular group B meningococci, any impact on the total population burden of carried organisms will be small. It is therefore unlikely that an infant immunization program will provide additional value through induction of herd immunity. Rates of capsular group B carriage are higher among teenagers and young adults than at other ages (apart from infancy). A recent large cluster randomized trial in Australia found no effect of 4CMenB on carriage of disease-causing meningococci, highlighting that the benefit of this vaccine is likely to be via direct protection.

An immunogenic vaccine based on two variants of the lipoprotein factor H–binding protein (fHbp2) has been developed for use in adolescents and is licensed in the United States and Europe. The vaccine is immunogenic against representative indicator strains, inducing fourfold rises in bactericidal antibody titer in 50–92% of individuals. fHbp2 has an acceptable safety profile, with pain at the injection site, fatigue, and headache commonly reported. This vaccine can be used with a range of vaccines routinely administered in adolescence, including Tdap (tetanus–diphtheria–acellular pertussis), human papillomavirus, and MenACWY vaccines. fHbp2 has been used to control outbreaks of meningococcal disease in educational institutions in the United States, but no formal studies of its effectiveness have yet been undertaken. Studies in the UK are currently evaluating the impact of both 4CMenB and fHbp2 against meningococcal carriage amongst teenagers.

Both of the new capsular group B meningococcal vaccines are licensed for use in the United States for persons 10–25 years of age. In addition, ACIP recommends their administration to individuals at high risk of capsular group B disease, with 4CMenB administered as two doses (1–2 months apart) and fHbp2 as two doses (at 0 and 6 months) or three doses (at 0, 1–2, and 6 months).

MANAGEMENT OF CONTACTS

Close (household and kissing) contacts of individuals with meningococcal disease are at increased risk for developing secondary disease (up to 1000 times the rate for the general population); a secondary case

follows as many as 3% of sporadic cases. About one-fifth of secondary cases are actually co-primary cases—i.e., cases that occur soon after the primary case and in which transmission is presumed to have originated from the same third party. The rate of secondary cases is highest during the week after presentation of the index case. The risk falls rapidly but remains above baseline for up to 1 year after the index case; 30% of secondary cases occur in the first week, 20% in the second week, and most of the remainder over the next 6 weeks. In outbreaks of meningococcal disease, mass prophylaxis has been used; however, limited data support population intervention, and significant concerns have arisen about adverse events and the development of resistance. For these reasons, prophylaxis is usually restricted to (1) persons at greatest risk who are intimate and/or household contacts of the index case and (2) health care workers who have been directly exposed to respiratory secretions. In most cases, members of wider communities (e.g., at schools or colleges) are not offered prophylaxis.

The aim of prophylaxis is to eradicate colonization of close contacts with the strain that has caused invasive disease in the index case. Prophylaxis should be given to all contacts at the same time to avoid recolonization by meningococci transmitted from untreated contacts and should also be used as soon as possible to treat early disease in secondary cases. If the index patient is treated with an antibiotic that does not reliably clear colonization (e.g., penicillin), he or she should be given a prophylactic agent at the end of treatment to prevent relapse or onward transmission. Although rifampin has been most widely used and studied, it is not the optimal agent because it fails to eradicate carriage in 15–20% of cases, rates of adverse events have been high, compliance is affected by the need for four doses, and emerging resistance has been reported. Ceftriaxone as a single IM or IV injection is highly (97%) effective in carriage eradication and can be used at all ages and in pregnancy. Reduced susceptibility of isolates to ceftriaxone has occasionally been reported. Ciprofloxacin or ofloxacin is preferred in some countries; these agents are highly effective and can be administered by mouth but are not recommended in pregnancy. Resistance to fluoroquinolones has been reported in some meningococci in North America, Europe, and Asia.

In documented capsular group A, B, C, Y, or W disease, contacts may be offered immunization (with either the MenACWY conjugate vaccine or the MenB vaccine, as appropriate) in addition to chemoprophylaxis to provide protection beyond the duration of antibiotic therapy. Mass vaccination has been used successfully to control disease during outbreaks in closed communities (educational and military establishments) as well as during epidemics in open communities.

156 Gonococcal Infections

Sanjay Ram, Peter A. Rice

DEFINITION

Gonorrhea is a sexually transmitted infection (STI) of epithelium and commonly manifests as cervicitis, urethritis, proctitis, and conjunctivitis. If untreated, infections at these sites can lead to local complications such as endometritis, salpingitis, tuboovarian abscess, bartholinitis, peritonitis, and perihepatitis in female patients; periurethritis and epididymitis in male patients; and ophthalmia neonatorum in newborns. Disseminated gonococcemia is an uncommon event whose manifestations include skin lesions, tenosynovitis, arthritis, and (in rare cases) endocarditis or meningitis.

MICROBIOLOGY

Neisseria gonorrhoeae is a gram-negative, nonmotile, non-spore-forming organism that grows singly and in pairs (i.e., as monococci and diplococci, respectively). Exclusively a human pathogen, the gonococcus contains, on average, three genome copies per coccal unit; this polyploidy permits a high level of antigenic variation and the survival of the organism in its host. Gonococci, like all other *Neisseria* species, are oxidase positive. They are distinguished from other neisseriae by their ability to grow on selective media and to use glucose but not maltose, sucrose, or lactose.

EPIDEMIOLOGY

The incidence of gonorrhea had been declining steadily in the United States, but in 2018, there were ~616,000 newly reported cases—up 56% since 2015. With 87 million cases estimated by the World Health Organization to have occurred globally in 2016, gonorrhea remains a major public health problem worldwide, is a significant cause of morbidity in developing countries, and may play a role in enhancing transmission of HIV.

Gonorrhea predominantly affects young, nonwhite, unmarried, less educated members of urban populations. The number of reported cases probably represents half of the true number of cases—a discrepancy resulting from underreporting, self-treatment, nonspecific treatment without a laboratory-proven diagnosis, and asymptomatic infection. The number of reported new cases of gonorrhea in the United States rose from ~250,000 in the early 1960s to a high of 1.01 million in 1978. The recorded incidence of gonorrhea in modern times peaked in 1975, with 468 reported new cases per 100,000 population in the United States. This peak was attributable to the interaction of several variables, including improved accuracy of diagnosis, changes in patterns of contraceptive use, and changes in sexual behavior. A decline in the overall incidence of gonorrhea in the United States over the past quarter-century may have reflected increased condom use resulting from public health efforts to curtail HIV transmission. Nevertheless, in 2019, 187.8 new cases per 100,000 population were reported in this country, representing a 1-year increase of 5% and a 92% increase since the historic low in 2009; this figure is the highest among industrialized countries. Simultaneously, antibiotic resistance is increasing in the United States and other countries, prompting the U.S. Centers for Disease Control and Prevention (CDC) to name antibiotic-resistant *N. gonorrhoeae* as one of the three most urgent threats of its kind. At present, the attack rate in the United States is highest among 15- to 24-year-old women and 20- to 29-year-old men; >70% of all reported cases occur in these two groups. From the standpoint of ethnicity, rates are highest among African Americans and lowest among persons of Asian descent.

The incidence of gonorrhea is higher in developing countries than in industrialized nations. The exact incidence of any STI is difficult to ascertain in developing countries because of limited surveillance and variable diagnostic criteria. Extremely high rates of gonorrhea have been reported among aboriginal populations in Namibia and Australia. Studies in Africa have clearly demonstrated that nonulcerative STIs

such as gonorrhea (in addition to ulcerative STIs) are an independent risk factor for the transmission of HIV **(Chap. 202)**.

Gonorrhea is transmitted from males to females more efficiently than in the opposite direction. The rate of transmission to a woman during a single unprotected sexual encounter with an infected man is ~50–70%. Oropharyngeal gonorrhea occurs in ~20% of women who practice fellatio with infected partners. Transmission in either direction by cunnilingus is rare.

In any population, there exists a small minority of individuals who have high rates of new-partner acquisition. These "core-group members" or "high-frequency transmitters" are vital in sustaining STI transmission at the population level. Another instrumental factor in sustaining gonorrhea in the population is the large number of infected individuals who are asymptomatic or have minor symptoms that are ignored. These persons, unlike symptomatic individuals, may not cease sexual activity and therefore may continue to transmit the infection. This situation underscores the importance of contact tracing and empirical treatment of the sex partners of index cases.

PATHOGENESIS, IMMUNOLOGY, AND ANTIMICROBIAL RESISTANCE

Outer-Membrane Proteins • **PILI** Fresh clinical isolates of *N. gonorrhoeae* initially form piliated (fimbriated) colonies distinguishable on translucent agar. Pilus expression is rapidly switched off with unselected subculture because of rearrangements in pilus genes. This change is a basis for antigenic variation of gonococci. Piliated strains adhere better to cells derived from human mucosal surfaces and are more virulent in organ culture models and human inoculation experiments than nonpiliated variants. In a fallopian tube explant model, pili mediate gonococcal attachment to nonciliated columnar epithelial cells. This event initiates gonococcal adherence, invasion and transport through these cells to intercellular spaces near the basement membrane or directly into the subepithelial tissue. Pili are also essential for genetic competence and transformation of *N. gonorrhoeae*, which permit horizontal transfer of genetic material between different gonococcal lineages in vivo.

OPACITY-ASSOCIATED PROTEIN Another gonococcal surface protein that is important in adherence to epithelial cells is opacity-associated protein (Opa; formerly called protein II). Opa contributes to intergonococcal adhesion, which is responsible for the opaque nature of gonococcal colonies on translucent agar and the organism's adherence to a variety of eukaryotic cells, including polymorphonuclear leukocytes (PMNs). Certain Opa variants promote invasion of epithelial cells, and this effect has been linked with the ability of Opa to bind vitronectin, heparan sulfate proteoglycans, and several members of the carcinoembryonic antigen–related cell adhesion molecule (CEACAM) receptor family. Epithelial CEACAM-binding gonococci prevent exfoliation of epithelium through a mechanism that involves nitric oxide that is produced during anaerobic bacterial metabolism and upregulation of CD105 (a member of the transforming growth factor-beta receptor family), which may interfere with bacterial clearance. *N. gonorrhoeae* Opa proteins that bind CEACAM1, which is expressed by primary CD4+ T lymphocytes, suppress the activation and proliferation of these lymphocytes. Select Opa proteins can engage CEACAM3, which is expressed on neutrophils, with consequent nonopsonic phagocytosis (i.e., phagocytosis independent of antibody and complement) and killing of bacteria.

PORIN Porin (previously designated protein I) is the most abundant gonococcal surface protein. Porin molecules exist as trimers that provide anion-transporting aqueous channels through the otherwise hydrophobic outer membrane. Porin exhibits stable interstrain antigenic variation and forms the basis for gonococcal serotyping. Two main serotypes have been identified; PorB.1A strains are often associated with disseminated gonococcal infection (DGI), whereas PorB.1B strains usually cause local genital infections only. DGI strains are generally resistant to the killing action of normal human serum and do not incite a significant local inflammatory response; therefore, they may not cause symptoms at genital sites. These characteristics may be related to the ability of PorB.1A strains to bind to complement-inhibitory molecules, resulting in a diminished inflammatory response. Porin can translocate to the cytoplasmic membrane of host cells—a process that could initiate gonococcal endocytosis and invasion. PorB.1B present in outer membrane vesicles shed during bacterial growth inhibits the ability of dendritic cells to induce T-cell proliferation and may contribute to the ability of gonococci to subvert adaptive immunity.

OTHER OUTER-MEMBRANE PROTEINS Other notable outer-membrane proteins include H.8, a lipoprotein that is present in high concentration on the surface of all gonococcal strains and is an excellent target for antibody-based diagnostic testing. Transferrin-binding proteins (Tbp1 and Tbp2), lactoferrin-binding proteins (LbpA and LbpB), and hemoglobin/haptoglobin binding proteins (HpuA and HpuB) are required for scavenging iron from transferrin, lactoferrin, and heme in vivo. Transferrin and iron have been shown to enhance the attachment of iron-deprived *N. gonorrhoeae* to human endometrial cells. TdfH and TdfJ enable gonococci to scavenge host zinc from calprotectin and S100 calcium binding protein A7 (psoriasin). IgA1 protease is produced by *N. gonorrhoeae* and may protect the organism from the action of mucosal IgA.

Lipooligosaccharide Gonococcal lipooligosaccharide (LOS) consists of a lipid A and a core oligosaccharide that lacks the repeating O-carbohydrate antigenic side chain seen in many other gram-negative bacteria. Gonococcal LOS possesses marked endotoxic activity and contributes to the local cytotoxic effect in a fallopian tube model. LOS core sugars undergo a high degree of phase variation under different conditions of growth; this variation reflects genetic regulation and expression of glycotransferase genes that dictate the carbohydrate structure of LOS. These phenotypic changes may affect interactions of *N. gonorrhoeae* with elements of the humoral immune system (antibodies and complement) and may also influence direct binding of organisms to both professional phagocytes and nonprofessional phagocytes (epithelial cells). For example, gonococci that are sialylated at their LOS sites inhibit the classic pathway of complement by reducing binding of IgG and also bind complement factor H to inhibit the alternative pathway of complement. LOS sialylation may also decrease nonopsonic Opa-mediated association with neutrophils and inhibit the oxidative burst in PMNs. The binding of the unsialylated terminal lactosamine residue of LOS to an asialoglycoprotein receptor on male epithelial cells facilitates adherence and subsequent gonococcal invasion of these cells. Moreover, oligosaccharide structures in LOS can modulate host immune responses. For example, the terminal monosaccharide expressed by LOS determines the C-type lectin receptor on dendritic cells that is targeted by the bacteria. In turn, the specific C-type lectin receptor engaged influences whether a T_H1- or T_H2-type response is elicited; the latter response may be less favorable for clearance of gonococcal infection.

Host Factors In addition to gonococcal structures that interact with epithelial cells, host factors seem to be important in mediating entry of gonococci into nonphagocytic cells. Activation of phosphatidylcholine-specific phospholipase C and acidic sphingomyelinase by *N. gonorrhoeae*, which results in the release of diacylglycerol and ceramide, is a requirement for the entry of *N. gonorrhoeae* into epithelial cells. Ceramide accumulation within cells leads to apoptosis, which may disrupt epithelial integrity and facilitate entry of gonococci into subepithelial tissue. Release of chemotactic factors as a result of complement activation contributes to inflammation, as does the toxic effect of LOS in provoking the release of inflammatory cytokines.

The importance of humoral immunity in host defenses against neisserial infections is best illustrated by the predisposition of persons deficient in terminal complement components (C5 through C9) to have recurrent bacteremic gonococcal infections and recurrent meningococcal meningitis or meningococcemia. Gonococcal porin induces T cell–proliferative responses in persons with urogenital gonococcal disease. A significant increase in porin-specific interleukin (IL) 4–producing CD4+ as well as CD8+ T lymphocytes is seen in individuals with mucosal gonococcal disease. A portion of these lymphocytes

that show a porin-specific T_H2-type response could traffic to mucosal surfaces and play a role in immune protection against the disease. Few data clearly indicate that protective immunity is acquired from a previous gonococcal infection, although bactericidal and opsonophagocytic antibodies to porin and LOS may offer partial protection. On the other hand, women who are infected and acquire high levels of antibody to another outer-membrane protein, Rmp (reduction modifiable protein, formerly called protein III), may be especially likely to become reinfected with *N. gonorrhoeae* because Rmp antibodies block the effect of bactericidal antibodies to porin and LOS. Rmp shows little, if any, interstrain antigenic variation; therefore, Rmp antibodies potentially may block antibody-mediated killing of all gonococci. The mechanism of blocking has not been fully characterized, but Rmp antibodies may noncompetitively inhibit binding of porin and LOS antibodies because of the proximity of these structures in the gonococcal outer membrane. In male volunteers who have no history of gonorrhea, the net effect of these events may influence the outcome of experimental challenge with *N. gonorrhoeae*. Because Rmp bears extensive homology to enterobacterial OmpA and meningococcal class 4 proteins, it is possible that these blocking antibodies result from prior exposure to cross-reacting proteins from these species and also play a role in first-time infection with *N. gonorrhoeae*.

Gonococcal Resistance to Antimicrobial Agents It is no surprise that *N. gonorrhoeae*, with its remarkable capacity to alter its antigenic structure and adapt to changes in the microenvironment, has become resistant to numerous antibiotics. The first effective agents against gonorrhea were the sulfonamides, which were introduced in the 1930s and became ineffective within a decade. Penicillin was then used as the drug of choice for the treatment of gonorrhea. By 1965, 42% of gonococcal isolates had developed low-level resistance to penicillin G. Resistance due to the production of penicillinase arose later.

Gonococci become fully resistant to antibiotics either by chromosomal mutations or by acquisition of R factors (plasmids). Two types of chromosomal mutations have been described. The first type, which is drug specific, is a single-step mutation leading to high-level resistance. The second type involves mutations at several chromosomal loci that combine to determine the level as well as the pattern of resistance. Strains with mutations in chromosomal genes were first observed in the late 1950s. As recently as 2007, chromosomal mutations accounted for resistance to penicillin, tetracycline, or both in ~16% of strains surveyed in the United States.

β-Lactamase (penicillinase)–producing strains of *N. gonorrhoeae* (PPNG) carrying β-lactamase plasmids had rapidly spread worldwide by the early 1980s. *N. gonorrhoeae* strains with plasmid-borne tetracycline resistance (TRNG) can mobilize some β-lactamase plasmids, and PPNG and TRNG occur together, sometimes along with strains exhibiting chromosomally mediated resistance (CMRNG). Penicillin, ampicillin, and tetracycline are no longer reliable for the treatment of gonorrhea and should not be used.

Quinolone-containing regimens also were recommended for treatment of gonococcal infections; the fluoroquinolones offered the advantage of antichlamydial activity when administered for 7 days. However, quinolone-resistant *N. gonorrhoeae* (QRNG) appeared soon after these agents were first used to treat gonorrhea. QRNG is particularly common in the Pacific Islands (including Hawaii) and Asia, where, in certain areas, all gonococcal strains are now resistant to quinolones. At present, QRNG is also common in parts of Europe and the Middle East. In the United States, QRNG has been identified in all areas but predominantly in states on the Pacific coast, where resistant strains were first seen. Alterations in DNA gyrase and topoisomerase IV have been implicated as mechanisms of fluoroquinolone resistance.

Resistance to spectinomycin, which has been used in the past as an alternative agent, has been reported. Because this agent usually is not associated with resistance to other antibiotics, spectinomycin can be reserved for use against multidrug-resistant strains of *N. gonorrhoeae*. Nevertheless, outbreaks caused by strains resistant to spectinomycin have been documented in Korea and England when the drug has been used for primary treatment of gonorrhea.

Third-generation cephalosporins have remained highly effective as single-dose therapy for gonorrhea, but the recent isolation of strains highly resistant to ceftriaxone (minimal inhibitory concentrations [MICs], 2 μg/mL) in Japan and some European countries is cause for concern. Even though the MICs of ceftriaxone against certain strains may reach 0.015–0.125 μg/mL (higher than the MICs of 0.0001–0.008 μg/mL for fully susceptible strains), these levels are greatly exceeded in the blood, the urethra, and the cervix when the routinely recommended parenteral dose of ceftriaxone is administered. The rising MICs of oral cefixime (the previously recommended alternative oral third-generation cephalosporin) against *N. gonorrhoeae*, combined with this drug's limited capacity to reach levels sufficiently higher than MICs in the blood, the urethra, the cervix, and especially the pharynx, have resulted in the removal of cefixime from the list of first-line agents for treatment of uncomplicated gonorrhea. *N. gonorrhoeae* strains with reduced susceptibility to ceftriaxone and cefixime (i.e., cephalosporin-intermediate/resistant strains) contain mutations in (1) the *penA* allele, which is the principal resistance determinant and encodes a penicillin-binding protein (PBP2) whose sequence can differ in up to 60–70 amino acids from that of wild-type PBP2; (2) the *m*ultiple *t*ransferable *r*esistance *r*egulator (*mtrR*) gene that results in increased drug efflux through the MtrCDE efflux pump; and (3) *penB*, which decreases drug influx through PorB.

Resistance to azithromycin can result from alterations of the ribosomal binding target by azithromycin and—as with cephalosporins—the over- and underexpression of efflux and influx systems. Combined resistance to cephalosporins and azithromycin has been reported in several instances throughout the world.

CLINICAL MANIFESTATIONS

Gonococcal Infections in Men Acute urethritis is the most common clinical manifestation of gonorrhea in male patients. The usual incubation period after exposure is 2–7 days, although the interval can be longer and most men remain asymptomatic. Strains of the PorB.1A serotype tend to cause a greater proportion of cases of mild and asymptomatic urethritis than do PorB.1B strains. When they occur, urethral discharge and dysuria, usually without urinary frequency or urgency, are the major symptoms. The discharge initially is scant and mucoid but becomes profuse and purulent within a day or two. Gram's staining of the urethral discharge may reveal PMNs and gram-negative intracellular monococci and diplococci **(Fig. 156-1)**. The clinical manifestations of gonococcal urethritis are usually more severe and overt than those of nongonococcal urethritis, including urethritis caused by *Chlamydia trachomatis* **(Chap. 189)**; however, exceptions are common, and it is often impossible to differentiate the causes of urethritis on clinical grounds alone. The majority of cases of urethritis seen in the United States today are not caused by *N. gonorrhoeae* and/or *C. trachomatis*. Although a number of other organisms may be responsible, many cases do not have a specific etiologic agent identified. Certain clones of *Neisseria meningitidis*, the second member of the pathogenic

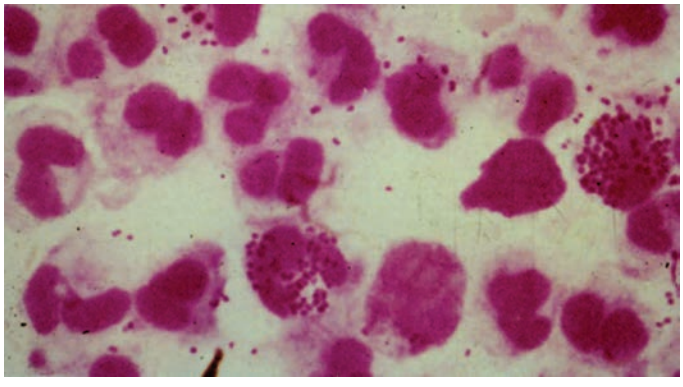

FIGURE 156-1 Gram's stain of urethral discharge from a male patient with gonorrhea shows gram-negative intracellular monococci and diplococci. *(Source: © All rights reserved. Canadian Guidelines on Sexually Transmitted Infections. Public Health Agency of Canada, modified 2020. Adapted and reproduced with permission from the Minister of Health, 2021.)*

Neisseria species, have been associated with urethritis in men who have sex with men (MSM) in Europe and in heterosexual men in the southern and midwestern United States.

Most symptomatic men with gonorrhea seek treatment and cease to be infectious. The remaining men, who are largely asymptomatic, accumulate in number over time and constitute about two-thirds of all infected men at any point in time; together with men incubating the organism who shed the organism but are asymptomatic, they serve as the source of spread of infection. Before the antibiotic era, symptoms of urethritis persisted for ~8 weeks. Epididymitis is now an uncommon complication, and gonococcal prostatitis occurs rarely, if at all. Other unusual local complications of gonococcal urethritis include edema of the penis due to dorsal lymphangitis or thrombophlebitis, submucous inflammatory "soft" infiltration of the urethral wall, periurethral abscess or fistula, inflammation or abscess of Cowper's gland, and seminal vesiculitis. Balanitis may develop in uncircumcised men.

Gonococcal Infections in Women • **GONOCOCCAL CERVICITIS** Mucopurulent cervicitis is a common STI diagnosis in American women and may be caused by *N. gonorrhoeae*, *C. trachomatis*, and other organisms, including *Mycoplasma genitalium* **(Chap. 188)**. Cervicitis may coexist with candidal or trichomonal vaginitis. *N. gonorrhoeae* primarily infects the columnar epithelium of the cervical os. Bartholin's glands occasionally become infected.

Women infected with *N. gonorrhoeae* usually develop symptoms. However, women who either remain asymptomatic or have only minor symptoms may delay seeking medical attention. These minor symptoms may include scant vaginal discharge issuing from the inflamed cervix (without vaginitis or vaginosis per se) and dysuria (often without urgency or frequency) that may be associated with gonococcal urethritis. Although the incubation period of gonorrhea is less well defined in women than in men, symptoms usually develop within 10 days of infection and are more acute and intense than those of chlamydial cervicitis.

The physical examination reveals a mucopurulent discharge (mucopus) issuing from the cervical os or a reddened (inflamed) cervix even in the absence of reported symptoms. Because Gram's stain is not sensitive for the diagnosis of gonorrhea in women, specimens should be submitted for culture or a nonculture assay (see "Laboratory Diagnosis," below). Edematous and friable cervical ectopy and endocervical bleeding induced by gentle swabbing are more often seen in chlamydial infection. Gonococcal infection may extend deep enough to produce dyspareunia and lower abdominal or back pain. In such cases, it is imperative to consider a diagnosis of pelvic inflammatory disease (PID) and to administer treatment for that disease **(Chaps. 136 and 189)**.

N. gonorrhoeae may also be recovered from the urethra and rectum of women with cervicitis, but these are rarely the only infected sites. Urethritis in women may produce symptoms of internal dysuria, which is often attributed to "cystitis." Pyuria in the absence of bacteriuria visible on Gram's stain of unspun urine, accompanied by urine cultures that fail to yield $>10^2$ colonies of bacteria usually associated with urinary tract infection, signifies the possibility of urethritis usually due to *C. trachomatis*. Urethral infection with *N. gonorrhoeae* also may occur in this context, but in this instance, urethral cultures are usually positive.

GONOCOCCAL VAGINITIS The vaginal mucosa of healthy women is lined by stratified squamous epithelium and is rarely infected by *N. gonorrhoeae*. However, gonococcal vaginitis can occur in anestrogenic women (e.g., prepubertal girls and postmenopausal women), in whom the vaginal stratified squamous epithelium is often thinned down to the basilar layer, which can be infected by *N. gonorrhoeae*. The intense inflammation of the vagina makes the physical (speculum and bimanual) examination extremely painful. The vaginal mucosa is red and edematous, and an abundant purulent discharge is often present. Infection in the urethra and in Skene's and Bartholin's glands often accompanies gonococcal vaginitis. Inflamed cervical erosion or abscesses in nabothian cysts may also occur. Coexisting cervicitis may result in pus in the cervical os.

Anorectal Gonorrhea Because the female anatomy permits the spread of cervical exudate to the rectum, *N. gonorrhoeae* is sometimes recovered from the rectum of women with uncomplicated gonococcal cervicitis. The rectum is the sole site of infection in only 5% of women with gonorrhea. Such women are usually asymptomatic but occasionally have acute proctitis manifested by anorectal pain or pruritus, tenesmus, purulent rectal discharge, and rectal bleeding. Among MSM, the frequency of gonococcal infection, including rectal infection, fell by ≥90% throughout the United States in the early 1980s, A resurgence of gonorrhea among MSM has been documented in several cities since the 1990s, the estimated rates of reported cases having more than doubled in a recent 3-year period. Gonococcal isolates from the rectum of MSM tend to be more resistant to antimicrobial agents than are gonococcal isolates from other sites. Gonococcal isolates with a mutation in *mtrR* or in the promoter region of the gene that encodes for this transcriptional regulator develop increased resistance to antimicrobial hydrophobic agents such as bile acids and fatty acids in feces and thus are found with increased frequency in MSM. This situation may have been responsible for higher rates of failure of treatment for rectal gonorrhea with older regimens consisting of penicillin or tetracyclines.

Pharyngeal Gonorrhea Pharyngeal gonorrhea is usually mild or asymptomatic, although symptomatic pharyngitis does occasionally occur with cervical lymphadenitis. The mode of acquisition is oral–genital sexual exposure, with fellatio being a more efficient means of transmission than cunnilingus. In certain female adolescent populations in the United States, pharyngeal gonorrhea has become as common as genital gonorrhea. Most cases resolve spontaneously, and transmission from the pharynx to sexual contacts is rare. Pharyngeal infection almost always coexists with genital infection. Swabs from the pharynx should be plated directly onto gonococcal selective media. Pharyngeal colonization with *N. meningitidis* needs to be differentiated from that with other *Neisseria* species. Because commensal oropharyngeal neisseriae are often resistant to antimicrobials, horizontal gene transfer between these organisms and *N. gonorrhoeae* may be important in the development of antimicrobial resistance of *N. gonorrhoeae.*

Ocular Gonorrhea in Adults Ocular gonorrhea in an adult usually results from autoinoculation of *N. gonorrhoeae* from an infected genital site. As in genital infection, the manifestations range from severe to occasionally mild or asymptomatic disease. The variability in clinical manifestations may be attributable to differences in the ability of the infecting strain to elicit an inflammatory response. Infection may result in a markedly swollen eyelid, severe hyperemia and chemosis, and a profuse purulent discharge. The massively inflamed conjunctiva may be draped over the cornea and limbus. Lytic enzymes from the infiltrating PMNs occasionally cause corneal ulceration and rarely cause perforation.

Prompt recognition and treatment of this condition are of paramount importance. Gram's stain and culture of the purulent discharge establish the diagnosis. Genital cultures also should be performed.

Gonorrhea in Pregnant Women, Neonates, and Children Gonorrhea in pregnancy can have serious consequences for both the mother and the infant. Recognition of gonorrhea early in pregnancy also identifies a population at risk for other STIs, particularly chlamydial infection, syphilis, and trichomoniasis. The risks of salpingitis and PID—conditions associated with a high rate of fetal loss—are highest during the first trimester. Pharyngeal infection, most often asymptomatic, may be more common during pregnancy because of altered sexual practices. Prolonged rupture of the membranes, premature delivery, chorioamnionitis, funisitis (infection of the umbilical cord stump), and sepsis in the infant (with *N. gonorrhoeae* detected in the newborn's gastric aspirate during delivery) are common complications of maternal gonococcal infection at term. Other conditions and microorganisms, including *Mycoplasma hominis*, *Mycoplasma genitalium, Ureaplasma urealyticum*, *C. trachomatis*, and bacterial vaginosis (often accompanied by infection with *Trichomonas vaginalis*), have been associated with similar complications.

The most common form of gonorrhea in neonates is ophthalmia neonatorum, which results from exposure to infected cervical secretions during parturition. Ocular neonatal instillation of a prophylactic agent (e.g., 1% silver nitrate eye drops or ophthalmic preparations containing erythromycin or tetracycline) prevents ophthalmia neonatorum but is not effective for its treatment, which requires systemic antibiotics. The clinical manifestations are acute and usually begin 2–5 days after birth. An initial nonspecific conjunctivitis with a serosanguineous discharge is followed by tense edema of the eyelids, chemosis, and a profuse, thick, purulent discharge. Corneal ulcerations that result in nebulae or perforation may lead to anterior synechiae, anterior staphyloma, panophthalmitis, and blindness. Infections described at other mucosal sites in infants, including vaginitis, rhinitis, and anorectal infection, are likely to be asymptomatic. Pharyngeal colonization has been demonstrated in 35% of infants with gonococcal ophthalmia, and coughing is the most prominent symptom in these cases. Septic arthritis (see below) is the most common manifestation of systemic infection or DGI in the newborn. The onset usually comes at 3–21 days of age, and polyarticular involvement is common. Sepsis, meningitis, and pneumonia are seen in rare instances.

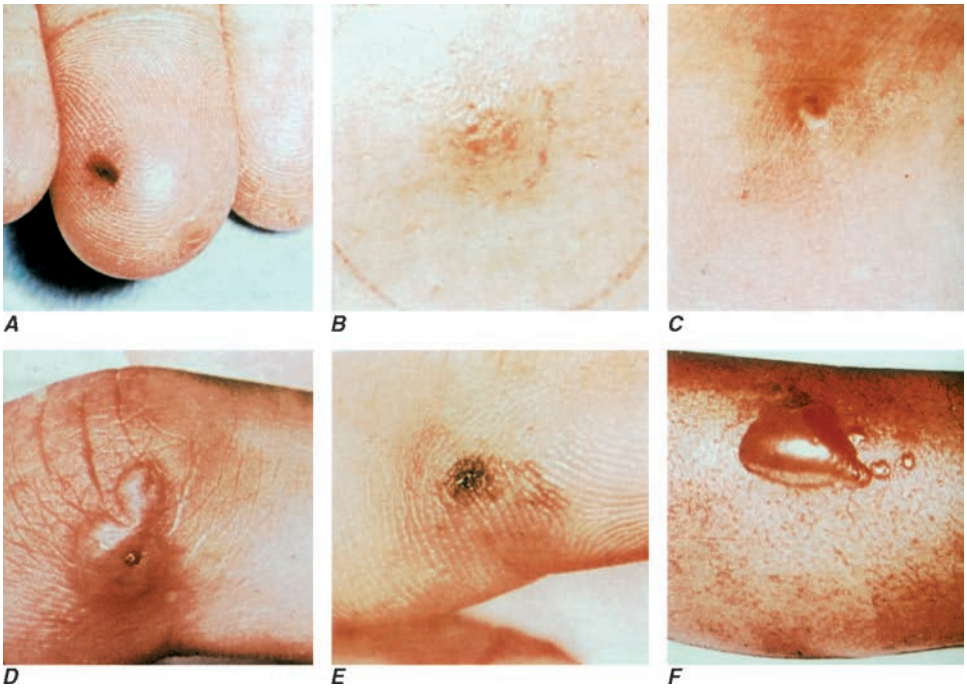

FIGURE 156-2 Characteristic skin lesions in patients with proven gonococcal bacteremia. The lesions are in various stages of evolution. ***A.*** Very early petechia on finger. ***B.*** Early papular lesion, 7 mm in diameter, on lower leg. ***C.*** Pustule with central eschar resulting from early petechial lesion. ***D.*** Pustular lesion on finger. ***E.*** Mature lesion with central necrosis (black) on hemorrhagic base. ***F.*** Bullae on anterior tibial surface. *(Reprinted with permission from TF Murphy, GI Parameswaran: Clin Infect Dis 49:124, 2009, with permission. © 2009 Infectious Diseases Society of America.)*

Any STI in children beyond the neonatal period raises the possibility of sexual abuse. Gonococcal vulvovaginitis is the most common manifestation of gonococcal infection in children beyond infancy. Anorectal and pharyngeal infections are common in these children and are frequently asymptomatic. The urethra, Bartholin's and Skene's glands, and upper genital tract are rarely involved. All children with gonococcal infection should also be evaluated for chlamydial infection, syphilis, and possibly HIV infection.

Gonococcal Arthritis Disseminated gonococcal infection (DGI; gonococcal arthritis) results from gonococcal bacteremia. In the 1970s, DGI occurred in ~0.5–3% of persons with untreated gonococcal mucosal infection. The lower incidence of DGI at present is probably attributable to a decline in the prevalence of particular strains that are likely to disseminate. Nonetheless, sporadic outbreaks of DGI still occur in North America. DGI strains resist the bactericidal action of human serum and generally do not incite inflammation at genital sites, probably because of limited generation of chemotactic factors. Strains recovered from DGI cases in the 1970s were often of the PorB.1A serotype, were highly susceptible to penicillin, and had special growth requirements—including arginine, hypoxanthine, and uracil—that made the organism more fastidious and more difficult to isolate.

Menstruation is a risk factor for dissemination, and approximately two-thirds of cases of DGI are in women. In about half of affected women, symptoms of DGI begin within 7 days of onset of menses. Complement deficiencies, especially of the components involved in the assembly of the membrane attack complex (C5 through C9), predispose to neisserial bacteremia, and persons with more than one episode of DGI should be screened with an assay for total hemolytic complement activity. DGI is also associated with the use of the complement C5–blocking monoclonal antibody eculizumab.

The clinical manifestations of DGI have sometimes been classified into two stages: a bacteremic stage, which is less common today, and a joint-localized stage with suppurative arthritis. A clear-cut progression usually is not evident. Patients in the bacteremic stage have higher temperatures, and chills more frequently accompany their fever. Painful joints are common and often occur together with tenosynovitis and skin lesions. Polyarthralgias usually include the knees, elbows, and more distal joints; the axial skeleton is generally spared. Skin lesions are seen in ~75% of patients and include papules and pustules, often with a hemorrhagic component **(Fig. 156-2; see also Fig. A1-43)**. Other manifestations of noninfectious dermatitis, such as nodular lesions, urticaria, and erythema multiforme, have been described. These lesions are usually on the extremities and number between 5 and 40. The differential diagnosis of the bacteremic stage of DGI includes reactive arthritis, acute rheumatoid arthritis, sarcoidosis, erythema nodosum, drug-induced arthritis, and viral infections (e.g., hepatitis B and acute HIV infection). The distribution of joint symptoms in reactive arthritis differs from that in DGI **(Fig. 156-3)**, as do the skin and genital manifestations **(Chap. 362)**.

Suppurative arthritis involves one or two joints, most often the knees, wrists, ankles, and elbows (in decreasing order of frequency); other joints occasionally are involved. Most patients who develop gonococcal septic arthritis do so without prior polyarthralgias or skin lesions; in the absence of symptomatic genital infection, this disease cannot be distinguished from septic arthritis caused by other pathogens. The differential diagnosis of acute arthritis in young adults is discussed in **Chap. 130**. Rarely, osteomyelitis complicates septic arthritis involving small joints of the hand.

Gonococcal endocarditis, although rare today, was a relatively common complication of DGI in the preantibiotic era, accounting for about one-quarter of reported cases of endocarditis. Another unusual complication of DGI is meningitis.

Gonococcal Infections in HIV-Infected Persons The association between gonorrhea and the acquisition of HIV has been demonstrated in several well-controlled studies, mainly in Kenya and Zaire. The nonulcerative STIs enhance the transmission of HIV three- to fivefold; transmission of HIV-infected immune cells and increased viral shedding by persons with urethritis or cervicitis may contribute **(Chap. 202)**. HIV has been detected by polymerase chain reaction (PCR) more commonly in ejaculates from HIV-positive men with gonococcal urethritis than in those from HIV-positive men with nongonococcal urethritis. PCR positivity diminishes

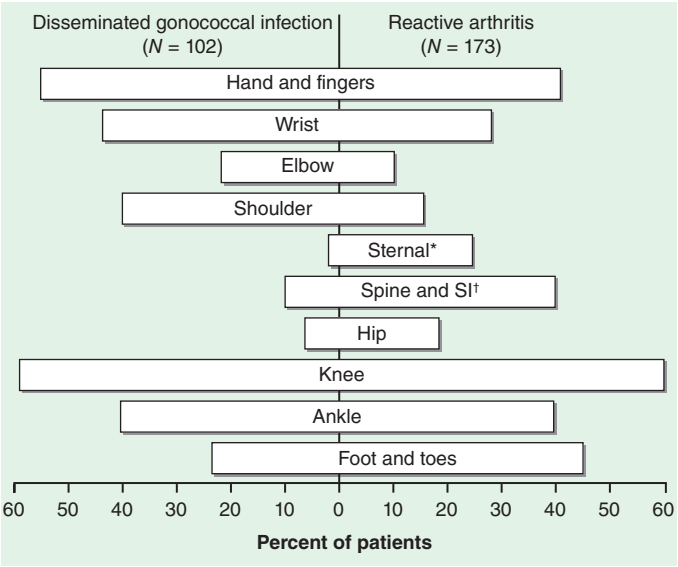

FIGURE 156-3 Distribution of joints with arthritis in 102 patients with disseminated gonococcal infection and 173 patients with reactive arthritis. *Includes the sternoclavicular joints. †SI, sacroiliac joint.

twofold after appropriate therapy for urethritis. Not only does gonorrhea enhance the transmission of HIV, but it may also increase the individual's risk for acquisition of HIV. A proposed mechanism is the significantly greater number of CD4+ T lymphocytes and dendritic cells that can be infected by HIV in endocervical secretions from women with nonulcerative STIs than in those from women with ulcerative STIs.

LABORATORY DIAGNOSIS

A rapid diagnosis of gonococcal infection in men may be obtained by Gram's staining of urethral exudates (Fig. 156-1). The detection of gram-negative intracellular monococci and diplococci is usually highly specific and sensitive in diagnosing gonococcal urethritis in symptomatic males but is only ~50% sensitive in diagnosing gonococcal cervicitis. Samples should be collected with Dacron or rayon swabs. Part of the sample should be inoculated onto a plate of modified Thayer-Martin or other gonococcal selective medium for culture. It is important to process all samples immediately because gonococci do not tolerate drying. If plates cannot be incubated immediately, they can be held safely for several hours at room temperature in candle extinction jars prior to incubation. If processing is to occur within 6 h, transport of specimens may be facilitated by the use of nonnutritive swab transport systems such as Stuart or Amies medium. For longer holding periods (e.g., when specimens for culture are to be mailed), culture media with self-contained CO_2-generating systems (such as the JEMBEC or Gono-Pak systems) may be used. Specimens should also be obtained for the diagnosis of chlamydial infection **(Chap. 189)**.

PMNs are often seen in the endocervix on a Gram's stain, and an abnormally increased number (≥30 PMNs per field in five 1000× oil-immersion microscopic fields) establishes the presence of an inflammatory discharge. Unfortunately, the presence or absence of gram-negative intracellular monococci or diplococci in cervical smears does not accurately predict which patients have gonorrhea, and the diagnosis in this setting should be made by culture or another suitable nonculture diagnostic method. The sensitivity of a single endocervical culture is ~80–90%. If a history of rectal sex is elicited, a rectal wall swab (uncontaminated with feces) should be cultured. A presumptive diagnosis of gonorrhea cannot be made on the basis of gram-negative diplococci in smears from the pharynx, where other *Neisseria* species are components of the normal flora.

Several nucleic acid amplification tests (NAATs), including the Roche COBAS AMPLICOR, Gen-Probe Aptima Combo 2, and BD ProbeTec ET, are now widely available on semiautomated or fully automated platforms and are commonly employed diagnostic tests for gonorrhea. These tests also detect *C. trachomatis* and are more sensitive than culture for identification of either *N. gonorrhoeae* or *C. trachomatis*. The Gen-Probe and BD tests offer the advantage that urine samples can be tested with a sensitivity similar to or greater than that obtained when urethral or cervical swab samples are assessed by other non-NAATs or culture, respectively. A point-of-care NAAT-based test (Binx *io*) for gonorrhea and chlamydia with a 30-minute turnaround time is now approved by the U.S. Food and Drug Administration (FDA). In MSM, it is important to screen the rectum and pharynx because screening urine alone will miss the majority of cases. A disadvantage of non-culture-based assays is that *N. gonorrhoeae* cannot be grown from the transport systems. Thus, a culture-confirmatory test and formal antimicrobial susceptibility testing, if needed, cannot be performed.

Because of the legal implications, the preferred method for the diagnosis of gonococcal infection in children is a standardized culture. Two positive NAATs, each targeting a different nucleic acid sequence, may be substituted for culture of the cervix or the urethra as legal evidence of infection in children. Although nonculture tests for gonococcal infection have not been approved by the FDA for use with specimens obtained from the pharynx and rectum of infected children, NAATs from these sites are preferred for diagnostic evaluation in adult victims of suspected sexual abuse, especially if the NAATs have been evaluated by the local laboratory and found to be superior. Cultures should be obtained from the pharynx and anus of both girls and boys, the urethra of boys, and the vagina of girls; cervical specimens are not recommended for prepubertal girls. For boys with a urethral discharge, a meatal specimen of the discharge is adequate for culture. Presumptive colonies of *N. gonorrhoeae* should be identified definitively by at least two independent methods.

Blood should be cultured in suspected cases of DGI. The use of Isolator blood culture tubes may enhance the yield. The probability of positive blood cultures decreases after 48 h of illness. Synovial fluid should be inoculated into blood culture broth medium and plated onto chocolate agar rather than selective medium because this fluid is not likely to be contaminated with commensal bacteria. Gonococci are infrequently recovered from early joint effusions containing <20,000 leukocytes/μL but may be recovered from effusions containing >80,000 leukocytes/μL. The organisms are seldom recovered from blood and synovial fluid of the same patient.

TREATMENT

Gonococcal Infections

Treatment failure can lead to continued transmission and the emergence of antibiotic resistance. The importance of adequate treatment with a regimen that the patient will adhere to cannot be overemphasized. Single-dose regimens have been developed for uncomplicated gonococcal infections. Treatment guidelines for gonococcal infections from the Centers for Disease Control and Prevention (CDC) were revised in 2020, and are summarized in **Table 156-1**. The third-generation cephalosporin ceftriaxone is now recommended as the first-line regimen for use at twice the previous dose (now, 500 mg IM, single dose) based on doubling of mean inhibitory concentrations (MICs) of current strains compared with MICs 20 years ago. The development of decreased sensitivity to ceftriaxone throughout the world will require the development of new effective regimens. Azithromycin, which had been recommended to provide additional treatment of gonorrhea (also to include treatment of chlamydial infection) is no longer recommended as part of a first line regimen. Resistance to azithromycin of U.S. isolates of *N. gonorrhoeae*, which had been less than 0.6% over a number of years, has increased more than sevenfold to 4.6% in the most recent year in which it was reported. If chlamydial infection cannot be excluded, concurrent treatment with doxycycline (100 mg orally twice a day for 7 days) is recommended. The recommendations for uncomplicated gonorrhea apply to HIV-infected as well as HIV-uninfected patients.

TABLE 156-1 Recommended Treatment for Gonococcal Infections: Adapted from the 2020 Guidelines for Gonococcal Infection of the Centers for Disease Control and Prevention

DIAGNOSIS	TREATMENT OF CHOICE[a]
Uncomplicated gonococcal infection of the cervix, urethra, pharynx[b], or rectum	
First-line regimen	Ceftriaxone (500 mg IM, single dose)
	plus
	Doxycycline (100 mg orally twice a day for 7 days) for treatment of chlamydial infection if chlamydial infection cannot be excluded
Alternative regimens if ceftriaxone is not available	Gentamicin (240 mg IM, single dose) plus azithromycin (2 g orally as a single dose)[c]
	Cefixime (800 mg PO, single dose) *or* spectinomycin (2 g IM, single dose)[d,e]
	plus
	Doxycycline (100 mg orally twice a day for 7 days) for treatment of chlamydial infection if chlamydial infection cannot be excluded
Epididymitis	**See Chap. 136**
Pelvic inflammatory disease	**See Chap. 136**
Gonococcal conjunctivitis in an adult	Ceftriaxone (1 g IM, single dose)[f]
Ophthalmia neonatorum[g]	Ceftriaxone (25–50 mg/kg IV, single dose, not to exceed 125 mg)
Disseminated gonococcal infection[h]	
Initial therapy[i]	
Patient tolerant of β-lactam drugs	Ceftriaxone (1 g IM or IV q24h; recommended) *or* cefotaxime (1 g IV q8h) *or* ceftizoxime (1 g IV q8h)
Patients allergic to β-lactam drugs	Spectinomycin (2 g IM q12h)[d]
Continuation therapy[i]	Cefixime (400 mg PO bid)
Meningitis or endocarditis	See text for specific recommendations[k]

[a]True failure of treatment with a recommended regimen is rare and should prompt an evaluation for reinfection, infection with a drug-resistant strain, or an alternative diagnosis. [b]Ceftriaxone is the most reliable agent recommended for treatment of pharyngeal infection. [c]*In vitro* synergistic killing of *N. gonorrhoeae* of gentamicin plus azithromycin is mild to moderate; azithromycin is for treatment chlamydial infection, primarily. [d]Spectinomycin is unavailable in the United States; in uncomplicated gonococcal infection it should be used at a higher dose (4 g IM, single dose) in areas of the world where increased resistance to spectinomycin exists. [e]Spectinomycin may be ineffective for the treatment of pharyngeal gonorrhea. [f]Plus lavage of the infected eye with saline solution (once). [g]Prophylactic regimens are discussed in the text. [h]Hospitalization is indicated if the diagnosis is uncertain, if the patient has the joint-localized stage with suppurative arthritis, or if the patient cannot be relied on to adhere to treatment. [i]All initial regimens should also include doxycycline (100 mg orally twice a day for 7 days) for treatment of chlamydial infection if chlamydial infection cannot be excluded; [j]gonococcal therapy should be continued for 24–48 h after clinical improvement begins, at which time the switch may be made to an oral agent (e.g., cefixime) if antimicrobial susceptibility can be documented by culture of the causative organism. If no organism is isolated and the diagnosis is secure, then treatment with ceftriaxone should be continued for at least 1 week. [k]Hospitalization is indicated to exclude suspected meningitis or endocarditis.

The currently recommended regimen for the treatment of uncomplicated gonococcal infection of the urethra, cervix, rectum, or pharynx (a single IM dose of ceftriaxone) almost always results in an effective cure. Quinolone-containing regimens are no longer recommended in the United States as first-line treatment because of widespread resistance. Rising MICs of cefixime worldwide have led the CDC to discontinue its recommendation of this agent as first-line treatment for uncomplicated gonorrhea. Multicenter trials of treatment for uncomplicated gonorrhea in the United States have shown ≥99.5% efficacy of two combination regimens and 96% efficacy in one single-agent regimen: gemifloxacin (320 mg, single oral dose) plus azithromycin (2 g, single oral dose); gentamicin (a single IM dose of 240 mg or, in individuals who weigh ≤45 kg, 5 mg/kg) plus azithromycin (2 g, single oral dose), and zoliflodacin (2 or 3 g, single oral dose). At this time, however, none of these regimens is recommended by CDC as first-line treatment; gentamicin plus azithromycin is recommended as an alternative regimen.

Co-infection with *C. trachomatis* occurs frequently; concurrent treatment with doxycycline (100 mg orally twice daily for 7 days) is effective against chlamydial infection. Spectinomycin has been used as an alternative agent for the treatment of uncomplicated gonococcal infections in penicillin-allergic persons outside the United States but is not currently available in the United States. Of note, the limited effectiveness of spectinomycin for the treatment of pharyngeal infection reduces its utility in populations among whom such infection is common, such as MSM.

Persons with uncomplicated genital or rectal infections who receive ceftriaxone or an alternative regimen do not need a test of cure; however, cultures for *N. gonorrhoeae* should be performed if symptoms persist after therapy with an established regimen, and any gonococci isolated should be tested for antimicrobial susceptibility. Persons with pharyngeal infection should undergo a test of cure regardless of the treatment regimen, 7–14 days after treatment to ensure eradication or detection of a possible treatment failure. Symptomatic gonococcal pharyngitis is more difficult to eradicate than genital infection. Persons who cannot tolerate cephalosporins may be treated with an alternative regimen. Treatment with spectinomycin results in a cure rate of ≤52%; persons given spectinomycin should have a subsequent pharyngeal sample cultured early (3–5 days) following treatment as a test of cure. A single 2-g dose of azithromycin may be used if the infecting organism is known to be sensitive or in areas where rates of resistance to azithromycin are low. Quinolones may be used if the infecting organism is known to be sensitive. If culture is not readily available and NAAT is positive, every effort should be made to perform a confirmatory culture. All isolates from test-of-cure cultures should undergo antimicrobial susceptibility testing. Because of high rates of reinfection with *N. gonorrhoeae* (and *C. trachomatis*) within 6–12 months, persons previously treated for gonorrhea should be retested 3 months after treatment.

Treatments for gonococcal epididymitis and PID are discussed in **Chap. 136**. Ocular gonococcal infections in older children and adults should be managed with a single dose of ceftriaxone combined with saline irrigation of the conjunctivae (both undertaken expeditiously), and patients should undergo a careful ophthalmologic evaluation that includes a slit-lamp examination.

DGI, particularly the joint-localized stage with suppurative arthritis, may require higher dosages and longer durations of therapy (Table 156-1). Hospitalization is indicated if the diagnosis is uncertain, if the patient has localized suppurative arthritis that requires aspiration, or if the patient cannot be relied on to comply with treatment. Open drainage is necessary only occasionally—e.g., for management of hip infections that may be difficult to drain percutaneously. Nonsteroidal anti-inflammatory agents may be indicated to alleviate pain and hasten clinical improvement of affected joints.

Gonococcal meningitis and endocarditis should be treated in the hospital with high-dose IV ceftriaxone (1–2 g IV every 12–24 h); therapy should continue for 10–14 days for meningitis and for at least 4 weeks for endocarditis. All persons who experience more than one episode of DGI should be evaluated for complement deficiency.

PREVENTION AND CONTROL

Condoms, if properly used, provide effective protection against the transmission and acquisition of gonorrhea as well as other infections that are transmitted to and from genital mucosal surfaces. Spermicidal preparations used with a diaphragm or cervical sponges impregnated with nonoxynol-9 offer some protection against gonorrhea and chlamydial infection. However, the frequent use of preparations that contain nonoxynol-9 is associated with mucosal disruption that paradoxically may enhance the risk of HIV infection in the event of exposure. All patients should be instructed to refer sex partners for evaluation and treatment. All sex partners of persons with gonorrhea

should be evaluated and treated for *N. gonorrhoeae* and *C. trachomatis* infections if their last contact with the patient took place within 60 days before the onset of symptoms or the diagnosis of infection in the patient. If the patient's last potential sexual exposure to infection was >60 days before onset of symptoms or diagnosis, the patient's most recent sex partner should be treated. Partner-delivered medications or prescriptions for medications to treat gonorrhea and chlamydial infection diminish the likelihood of reinfection (or relapse) in the infected patient. In states where it is not prohibited, this approach is an option for partner management. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms. Greater emphasis must be placed on prevention by public health education, individual patient counseling, and behavior modification, particularly the use of condoms. Sexually active persons, especially adolescents, should be offered screening for STIs. For most male patients, NAAT of urine or a urethral swab may be used for screening. Preventing the spread of gonorrhea may help reduce the transmission of HIV. No effective vaccine for gonorrhea is yet available, but efforts to test several candidates are underway including a field trial of a licensed group B meningococcal vaccine (Bexsero), which in prototype form had been shown to reduce the incidence of gonorrhea in a population given the vaccine to control a group B meningococcal epidemic.

157 *Haemophilus* and *Moraxella* Infections

Timothy F. Murphy

HAEMOPHILUS INFLUENZAE

MICROBIOLOGY

Haemophilus influenzae was first recognized in 1892 by Pfeiffer, who erroneously concluded that the bacterium was the cause of influenza. *H. influenzae* is a small (1- × 0.3-μm) gram-negative organism of variable shape; thus, it is often described as a pleomorphic coccobacillus. In clinical specimens such as cerebrospinal fluid (CSF) and sputum, *H. influenzae* frequently stains only faintly with safranin and therefore can easily be overlooked.

H. influenzae grows both aerobically and anaerobically. Its aerobic growth requires two factors: hemin (X factor) and nicotinamide adenine dinucleotide (V factor). These requirements are used in the clinical laboratory to identify the bacterium. However, using phenotypic methods for differentiating among *Haemophilus* species has limitations, as the growing number of whole-genome sequences of *Haemophilus* isolates from the human respiratory tract is revealing complex genetic relationships among *Haemophilus* species (see "Diagnosis," below).

TABLE 157-1 Characteristics of Type b and Nontypable Strains of *Haemophilus influenzae*

FEATURE	TYPE b STRAINS	NONTYPABLE STRAINS
Capsule	Ribosyl-ribitol phosphate	Unencapsulated
Pathogenesis	Invasive infections due to hematogenous spread	Mucosal infections due to contiguous spread
Clinical manifestations	Meningitis and invasive infections in incompletely immunized infants and children	Otitis media in infants and children; lower respiratory tract infections in adults with chronic bronchitis
Evolutionary history	Basically clonal	Genetically diverse
Vaccine	Highly effective conjugate vaccines	Protein D used as carrier protein in pneumococcal vaccine approved in Europe: GSK Synflorix. Others under development

Six major serotypes of *H. influenzae* have been identified; designated *a* through *f*, they are based on antigenically distinct polysaccharide capsules. In addition, some strains lack a polysaccharide capsule and are referred to as *nontypable* strains. Type b and nontypable strains are the most relevant strains clinically **(Table 157-1)**, although encapsulated strains other than type b can cause disease. *H. influenzae* was the first free-living organism to have its entire genome sequenced.

The antigenically distinct type b capsule is a linear polymer composed of ribosyl-ribitol phosphate. Strains of *H. influenzae* type b (Hib) cause disease primarily in infants and children <6 years of age. Nontypable strains are primarily mucosal pathogens but occasionally cause invasive disease.

EPIDEMIOLOGY AND TRANSMISSION

H. influenzae, an exclusively human pathogen, is spread by airborne droplets or by direct contact with secretions or fomites. Colonization with nontypable *H. influenzae* is a dynamic process; new strains are acquired and other strains are replaced periodically.

The widespread use of Hib conjugate vaccines in many industrialized countries has resulted in striking decreases in the rate of nasopharyngeal colonization by Hib and in the incidence of Hib infection **(Fig. 157-1)**. Worldwide, invasive Hib disease occurs predominantly in unimmunized children and in those who have not completed the primary immunization series. Most World Health Organization member countries have introduced Hib conjugate vaccination, but a large number of the world's children remain unimmunized, principally in countries without national vaccine programs. Certain groups have a higher incidence of invasive Hib disease than the general population,

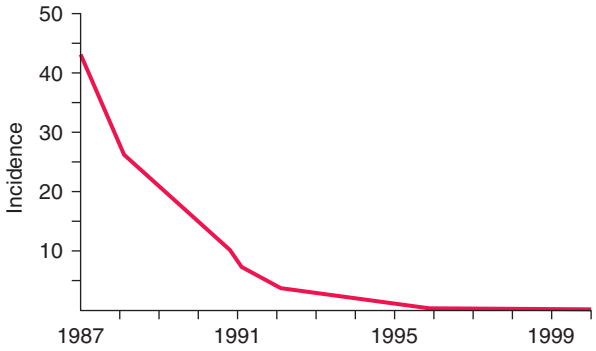

FIGURE 157-1 Estimated incidence (rate per 100,000) of invasive disease due to *Haemophilus influenzae* type b among children <5 years of age: 1987–2000. Fewer than 40 cases per year have been reported since 2000. *(Data from the Centers for Disease Control and Prevention.)*

including African-American and Australian Aboriginal children and Native American groups. Although this increased incidence has not yet been accounted for, several factors may be relevant, including age at exposure to the bacterium, socioeconomic conditions, and genetic differences.

PATHOGENESIS

Hib strains cause systemic disease by invasion and hematogenous spread from the respiratory tract to distant sites such as the meninges, bones, and joints. The type b polysaccharide capsule is an important virulence factor affecting the bacterium's ability to avoid opsonization and cause systemic disease.

Nontypable strains cause disease by local invasion of mucosal surfaces. Otitis media results when bacteria reach the middle ear by way of the eustachian tube. Adults with chronic obstructive pulmonary disease (COPD) experience recurrent lower respiratory tract infection due to nontypable strains. In addition, nontypable *H. influenzae* persist in the lower airways of adults with COPD in both extracellular and intracellular locations, contributing to the airway inflammation that is a hallmark of the disease. Nontypable strains that cause infection in adults with COPD differ in pathogenic potential and genome content from strains that cause otitis media. In the middle ear, nontypable strains form biofilms. More resistant to host clearance mechanisms and to antibiotics than are planktonic bacteria, biofilms are associated with chronic and recurrent otitis media. Nontypable *H. influenzae* persist in the human respiratory tract and cause infection by altering expression of genes through slipped-strand mispairing and through phase-variable expression of DNA methylase genes that control the expression of multiple genes that play a role in virulence.

The incidence of invasive disease caused by nontypable strains is low but appears to be increasing over the past decade. Most strains that cause invasive disease are genetically and phenotypically diverse.

IMMUNE RESPONSE

Antibody to the capsule is important in protection from infection by Hib strains. The level of (maternally acquired) serum antibody to the capsular polysaccharide, which is a polymer of polyribitol ribose phosphate (PRP), declines from birth to 6 months of age and, in the absence of vaccination, remains low until ~2 or 3 years of age. The age at the antibody nadir correlates with that of the peak incidence of type b disease. Antibody to PRP then appears partly as a result of exposure to Hib or cross-reacting antigens. Systemic Hib disease is unusual after the age of 6 years because of the presence of protective antibody. Vaccines in which PRP is conjugated to protein carrier molecules have been developed and are now used widely. These vaccines generate an antibody response to PRP in infants and effectively prevent invasive infections in infants and children.

Since nontypable strains lack a capsule, the immune response to infection is directed at noncapsular antigens. These antigens have generated considerable interest as immune targets and potential vaccine components. The human immune response to nontypable strains appears to be strain-specific, a characteristic that accounts in part for the propensity of these strains to cause recurrent otitis media and recurrent exacerbations of chronic bronchitis in immunocompetent hosts.

CLINICAL MANIFESTATIONS

Hib The most serious manifestation of infection with Hib is *meningitis* **(Chap. 138)**, which primarily affects children <2 years of age. The clinical manifestations of Hib meningitis are similar to those of meningitis caused by other bacterial pathogens. Fever and altered central nervous system function are the most common features at presentation. Nuchal rigidity may or may not be evident. Subdural effusion, the most common complication, is suspected when, despite 2 or 3 days of appropriate antibiotic therapy, the infant has seizures, hemiparesis, or continued obtundation. The overall mortality rate from Hib meningitis is ~5%, and the morbidity rate is high. Of survivors, 6% have permanent sensorineural hearing loss, and about one-fourth have a significant disability of some type. If more subtle disabilities are sought, up to half of survivors are found to have some neurologic sequelae, such as partial hearing loss and delayed language development.

Epiglottitis **(Chap. 35)** is a life-threatening Hib infection involving cellulitis of the epiglottis and supraglottic tissues. It can lead to acute upper-airway obstruction. Its unique epidemiologic features are its occurrence in an older age group (2–7 years old) than other Hib infections and its absence among Navajo Native Americans and Alaskan Eskimos. Sore throat and fever rapidly progress to dysphagia, drooling, and airway obstruction. Epiglottitis also occurs in adults.

Cellulitis **(Chap. 129)** due to Hib occurs in young children. The most common location is on the head or neck, and the involved area sometimes takes on a characteristic bluish-red color. Most patients have bacteremia, and 10% have an additional focus of infection.

Hib causes *pneumonia* in infants. The infection is clinically indistinguishable from other types of bacterial pneumonia (e.g., pneumococcal pneumonia) except that Hib is more likely to involve the pleura. Several less common invasive conditions can be important clinical manifestations of Hib infection in children. These include osteomyelitis, septic arthritis, pericarditis, orbital cellulitis, endophthalmitis, urinary tract infection, abscesses, and bacteremia without an identifiable focus.

Non–type b encapsulated strains of *H. influenzae* (types a, c, d, e, and f) are unusual causes of invasive infection manifested predominantly by bacteremia and pneumonia. *H. influenzae* type a infections are seen with increased frequency in indigenous populations of North America, and these strains are predominantly clonal. Most infections due to non–type b encapsulated strains occur in the setting of underlying conditions.

Nontypable *H. influenzae* Nontypable *H. influenzae* is the most common bacterial cause of exacerbations of COPD; these exacerbations are characterized by increased cough, sputum production, and shortness of breath. Fever is low-grade, and no infiltrates are evident on chest x-ray. Nontypable strains also cause community-acquired bacterial pneumonia in adults, especially among patients with COPD or AIDS. The clinical features of *H. influenzae* pneumonia are similar to those of other types of bacterial pneumonia, including pneumococcal pneumonia.

Nontypable *H. influenzae* is one of the three most common causes of childhood otitis media (the other two being *Streptococcus pneumoniae* and *Moraxella catarrhalis*) **(Chap. 35)**. Infants are febrile and irritable, while older children report ear pain. Symptoms of viral upper-respiratory infection often precede otitis media. The diagnosis is made by pneumatic otoscopy. An etiologic diagnosis, although not routinely sought, can be established by tympanocentesis and culture of middle-ear fluid. Clinical features associated with *H. influenzae* otitis media include a history of recurrent episodes, treatment failure, concomitant conjunctivitis, bilateral otitis media, and recent antimicrobial therapy. The increasing use of pneumococcal polysaccharide conjugate vaccines in many countries has resulted in an overall decrease in otitis media and its complications. However, a relative increase in the proportion of otitis media caused by *H. influenzae* in children failing initial antimicrobial therapy or with recurrent episodes has occurred. Continued monitoring of the incidence and etiology of otitis media will be important.

Nontypable *H. influenzae* also causes puerperal sepsis and is an important cause of neonatal bacteremia. These nontypable strains, provisionally named *Haemophilus quentini*, are closely related to but distinct from *H. haemolyticus*, tend to be of biotype IV and cause invasive disease after colonizing the female genital tract.

Nontypable *H. influenzae* causes sinusitis **(Chap. 35)** in adults and children. In addition, the bacterium is a less common cause of various invasive infections. These infections include bacteremia, empyema, adult epiglottitis, pericarditis, cellulitis, septic arthritis, osteomyelitis, endocarditis, cholecystitis, intraabdominal infections, urinary tract infections, mastoiditis, and aortic graft infection. Most *H. influenzae* invasive infections in countries where Hib vaccines are used widely are caused by nontypable strains, and a recent increased incidence of such infections has been observed. Although most strains of nontypable *H. influenzae* that cause invasive infections are genetically diverse, recent

localized clusters of infections have been caused by clonally related strains. Continued monitoring will be important. Many patients with *H. influenzae* bacteremia have an underlying condition, such as HIV infection, cardiopulmonary disease, alcoholism, or cancer.

DIAGNOSIS

The most reliable method for establishing a diagnosis of invasive *H. influenzae* infection is recovery of the organism in culture in a normally sterile body site, such as blood, CSF, or joint fluid.

H. influenzae isolated from the respiratory tract must be distinguished from a complex flora and from other *Haemophilus* species. Particular caution must be used to distinguish *H. influenzae* from *Haemophilus haemolyticus*, a respiratory tract commensal that has identical growth requirements. *H. haemolyticus* has classically been distinguished from *H. influenzae* by the hemolysis of the former species on horse blood agar. However, a significant proportion of isolates of *H. haemolyticus* have now been recognized as nonhemolytic. Analysis of various genotypic markers, including 16S ribosomal sequences, superoxide dismutase, outer-membrane protein P6, protein D, and fuculose kinase, can be used to distinguish these two species. The availability of whole-genome sequences of an increasing number of *Haemophilus* isolates from the human upper respiratory tract has revealed complex genomic relationships among *Haemophilus* species, suggesting a genetic continuum between some *Haemophilus* species.

The presence of gram-negative coccobacilli in Gram-stained CSF is strong evidence for Hib meningitis. Recovery of the organism from CSF confirms the diagnosis. Cultures of other normally sterile body fluids, such as blood, joint fluid, pleural fluid, pericardial fluid, and subdural effusion, are confirmatory in other infections.

Detection of PRP is an important adjunct to culture in rapid diagnosis of Hib meningitis. Immunoelectrophoresis, latex agglutination, coagglutination, and enzyme-linked immunosorbent assay are effective in detecting PRP. These assays are particularly helpful when patients have received prior antimicrobial therapy and thus are especially likely to have negative cultures.

Because nontypable *H. influenzae* is primarily a mucosal pathogen, it is a component of a mixed flora; thus etiologic diagnosis is challenging. Nontypable *H. influenzae* infection is strongly suggested by the predominance of gram-negative coccobacilli among abundant polymorphonuclear leukocytes in a Gram-stained sputum specimen from a patient in whom pneumonia is suspected. Although bacteremia is detectable in a small proportion of patients with pneumonia due to nontypable *H. influenzae*, most such patients have negative blood cultures.

A diagnosis of otitis media is based on the detection by pneumatic otoscopy of fluid in the middle ear. An etiologic diagnosis requires tympanocentesis but is not routinely sought. An invasive procedure is also required to determine the etiology of sinusitis; thus, treatment is often empirical once the diagnosis is suspected in light of clinical symptoms and sinus radiographs.

TREATMENT

Haemophilus influenzae

Initial therapy for meningitis due to Hib should consist of a cephalosporin such as ceftriaxone or cefotaxime. For children, the dosage of ceftriaxone is 75–100 mg/kg daily given in two doses 12 h apart. The pediatric dosage of cefotaxime is 200 mg/kg daily given in four doses 6 h apart. Adult dosages are 2 g every 12 h for ceftriaxone and 2 g every 4–6 h for cefotaxime. An alternative regimen for initial therapy is ampicillin (200–300 mg/kg daily in four divided doses) plus chloramphenicol (75–100 mg/kg daily in four divided doses). Therapy should continue for a total of 1–2 weeks.

Administration of glucocorticoids to patients with Hib meningitis reduces the incidence of neurologic sequelae. The presumed mechanism is reduction of the inflammation induced by bacterial cell-wall mediators of inflammation when cells are killed by antimicrobial agents. Dexamethasone (0.6 mg/kg per day intravenously in four divided doses for 2 days) is recommended for the treatment of Hib meningitis in children >2 months of age.

Invasive infections other than meningitis are treated with the same antimicrobial agents. For epiglottitis, the dosage of ceftriaxone is 50 mg/kg daily, and the dosage of cefotaxime is 150 mg/kg daily, given in three divided doses 8 h apart. Epiglottitis constitutes a medical emergency, and maintenance of an airway is critical. The duration of therapy is determined by the clinical response. A course of 1–2 weeks is usually appropriate.

Many infections caused by nontypable strains of *H. influenzae*, such as otitis media, sinusitis, and exacerbations of COPD, can be treated with oral antimicrobial agents. Approximately 20–35% of nontypable strains produce β-lactamase (with the exact proportion depending on geographic location), and these strains are resistant to ampicillin. Several agents have excellent activity against nontypable *H. influenzae*, including amoxicillin/clavulanic acid, various extended-spectrum cephalosporins, and the macrolides azithromycin and clarithromycin. Fluoroquinolones are highly active against *H. influenzae* and are useful in adults with exacerbations of COPD. However, fluoroquinolones are not currently recommended for the treatment of children or pregnant women because of possible effects on articular cartilage.

In addition to β-lactamase production, alteration of penicillin-binding proteins—a second mechanism of ampicillin resistance—has been detected in isolates of *H. influenzae*. Although rare in the United States, these β-lactamase-negative ampicillin-resistant strains are common in Japan and are increasing in prevalence in Europe. Resistance to macrolides is also being observed with increasing frequency globally. Continued monitoring of the evolving antimicrobial susceptibility patterns of *H. influenzae* will be important.

PREVENTION

Vaccination (See also **Chap. 123**) Three conjugate vaccines that prevent invasive infections with Hib in infants and children are licensed in the United States. In addition to eliciting protective antibody, these vaccines prevent disease by reducing rates of pharyngeal colonization with Hib. The widespread use of conjugate vaccines has dramatically reduced the incidence of Hib disease in developed countries. Even though the manufacture of Hib vaccines is costly, vaccination is cost-effective. The Global Alliance for Vaccines and Immunizations has recognized the underuse of Hib conjugate vaccines.

The disease burden has been reduced in developing countries that have implemented routine vaccination (e.g., The Gambia, Chile). An important obstacle to more widespread vaccination is the lack of data on the epidemiology and burden of Hib disease in many developing countries.

All children should be immunized with an Hib conjugate vaccine, receiving the first dose at ~2 months of age, the rest of the primary series at 2–6 months of age, and a booster dose at 12–15 months of age. Specific recommendations vary for the different conjugate vaccines. The reader is referred to the recommendations of the American Academy of Pediatrics (**Chap. 123** and *www.cispimmunize.org*).

Currently, no vaccines are available specifically for the prevention of disease caused by nontypable *H. influenzae*. However, a vaccine that contains protein D—a surface protein of *H. influenzae*—conjugated to pneumococcal polysaccharides is licensed in other countries and is used widely throughout the world. The vaccine has shown partial efficacy in preventing *H. influenzae* otitis media in clinical trials. Vaccine formulations that include surface protein antigens are currently in clinical trials, and additional progress in the development of vaccines against nontypable *H. influenzae* is anticipated.

Chemoprophylaxis The risk of secondary disease is greater than normal among household contacts of patients with Hib disease. Therefore, all children and adults (except pregnant women) in households with an index case and at least one incompletely immunized contact <4 years of age should receive prophylaxis with oral rifampin. When two or more cases of invasive Hib disease have occurred within 60 days

at a child-care facility attended by incompletely vaccinated children, administration of rifampin to all attendees and personnel is indicated, as it is for household contacts. Chemoprophylaxis is not indicated in nursery and child-care contacts of a single index case. The reader is referred to the recommendations of the American Academy of Pediatrics.

HAEMOPHILUS DUCREYI

Haemophilus ducreyi is the etiologic agent of chancroid **(Chap. 136)**, a sexually transmitted disease characterized by genital ulceration and inguinal adenitis. In addition to being a cause of morbidity in itself, chancroid is associated with HIV infection because of the role played by genital ulceration in HIV transmission. Chancroid increases the efficiency of transmission of and the degree of susceptibility to HIV infection. *H. ducreyi* has also been recognized as an important cause of non-sexually transmitted cutaneous ulcers.

MICROBIOLOGY

H. ducreyi is a highly fastidious coccobacillary gram-negative bacterium whose growth requires X factor (hemin). Although, in light of this requirement, the bacterium has been classified in the genus *Haemophilus*, DNA homology and chemotaxonomic studies have established substantial differences between *H. ducreyi* and other *Haemophilus* species. Taxonomic reclassification of the organism is likely in the future but awaits further study. Ulcers contain predominantly T cells. The fact that patients who have had chancroid may have repeated infections indicates that infection does not confer protection.

EPIDEMIOLOGY AND PREVALENCE

The prevalence of chancroid has steadily declined in the United States and worldwide over the past decade and a half. The infection appears to be more common in developing countries. Transmission is predominantly heterosexual, and cases in males have outnumbered those in females by ratios of 3:1 to 25:1 during outbreaks. Contact with commercial sex workers and illicit drug use are strongly associated with chancroid. Most cases in developed countries are sporadic.

H. ducreyi has emerged as a major cause of cutaneous ulcers in children in developing countries, particularly in the South Pacific and Africa. Strains that cause cutaneous ulcers have genome sequences that are nearly identical to class I strains (of two related classes) of *H. ducreyi* that cause genital ulcers.

CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

Infection is acquired as the result of a break in the epithelium during sexual contact with an infected individual. After an incubation period of 4–7 days, the initial lesion—a papule with surrounding erythema—appears. In 2 or 3 days, the papule evolves into a pustule, which spontaneously ruptures and forms a sharply circumscribed ulcer that generally is not indurated **(Fig. 157-2)**. The ulcers are painful and bleed easily; little or no inflammation of the surrounding skin is evident. Approximately half of patients develop enlarged, tender inguinal lymph nodes, which frequently become fluctuant and spontaneously rupture. Patients usually seek medical care after 1–3 weeks of painful symptoms.

The presentation of chancroid does not usually include all of the typical clinical features and is sometimes atypical. Multiple ulcers can coalesce to form giant ulcers. Ulcers can appear and then resolve, with inguinal adenitis (Fig. 157-2) and suppuration following 1–3 weeks later; this clinical picture can be confused with that of lymphogranuloma venereum **(Chap. 189)**. Multiple small ulcers can resemble folliculitis. Other differential diagnostic considerations include the various infections causing genital ulceration, such as primary syphilis, secondary syphilis (condyloma latum), genital herpes, and donovanosis. In rare cases, chancroid lesions become secondarily infected with bacteria; the result is extensive inflammation.

Non-sexually transmitted cutaneous ulcers caused by *H. ducreyi* resemble those of yaws caused by *Treponema pallidum* subspecies *pertenue*, which is endemic in regions where *H. ducreyi* cutaneous ulcers are seen. Ulcers caused by *H. ducreyi* are less likely than those of yaws to show central granulating tissue and less likely to have indurated edges, but substantial overlap in clinical characteristics exists.

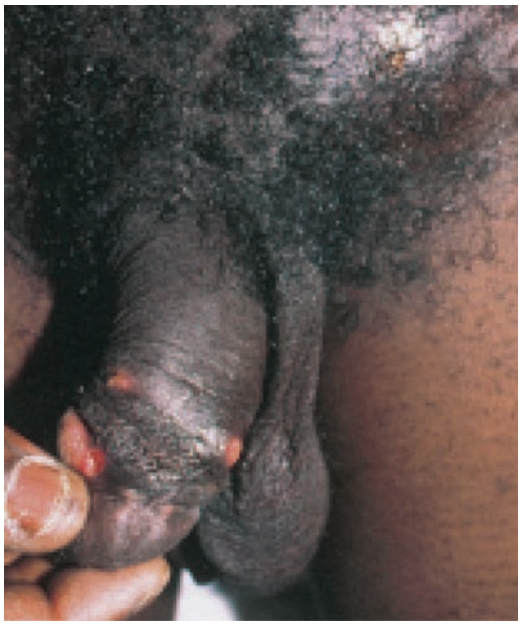

FIGURE 157-2 Chancroid with characteristic penile ulcers and associated left inguinal adenitis (bubo).

DIAGNOSIS

Clinical diagnosis of chancroid is often inaccurate, and laboratory confirmation should be attempted in suspected cases. An accurate diagnosis of chancroid relies on culture of *H. ducreyi* from the lesion or from an aspirate of suppurative lymph nodes. Since the organism can be difficult to grow, the use of selective and supplemented media is necessary. No polymerase chain reaction (PCR) assay for *H. ducreyi* is commercially available; such tests can be performed by Clinical Laboratory Improvement Amendment (CLIA)–certified clinical laboratories that have developed their own assays.

A probable diagnosis of sexually transmitted chancroid can be made when the following criteria are met: (1) one or more painful genital ulcers; (2) no evidence of *T. pallidum* infection by dark-field examination of ulcer exudate or by a negative serologic test for syphilis performed at least 7 days after ulcer onset; (3) a typical clinical presentation for chancroid; and (4) a negative test for herpes simplex virus in the ulcer exudate.

A serologic test for syphilis does not distinguish cutaneous ulcers due to *H. ducreyi* from those due to yaws. A PCR assay has been used in clinical studies to establish an *H. ducreyi* etiology, but, as stated above, no such assay is commercially available.

TREATMENT

Haemophilus ducreyi

Treatment regimens for both genital and cutaneous infections include (1) a single 1-g oral dose of azithromycin; (2) ceftriaxone (250 mg intramuscularly in a single dose); (3) ciprofloxacin (500 mg by mouth twice a day for 3 days); and (4) erythromycin base (500 mg by mouth three times a day for 7 days). Isolates from patients who do not respond promptly to treatment should be tested for antimicrobial resistance. In patients with HIV infection, healing may be slow and longer courses of treatment may be necessary. Clinical treatment failure in HIV-seropositive patients may reflect co-infection, especially with herpes simplex virus. Contacts of patients with chancroid should be identified and treated, whether or not symptoms are present, if they have had sexual contact with the patient during the 10 days preceding the patient's onset of symptoms.

MORAXELLA CATARRHALIS

MICROBIOLOGY

M. catarrhalis is an unencapsulated gram-negative diplococcus whose ecologic niche is the human respiratory tract. The organism was initially designated *Micrococcus catarrhalis*. Its name was changed to *Neisseria catarrhalis* in 1970 because of phenotypic similarities to commensal *Neisseria* species. On the basis of more rigorous analysis of genetic relatedness, *Moraxella catarrhalis* is now the widely accepted name for this species.

EPIDEMIOLOGY

Nasopharyngeal colonization by *M. catarrhalis* is common in infancy, with colonization rates ranging between 33% and 100% and depending on geographic location. Several factors probably account for this geographic variation, including living conditions, day-care attendance, hygiene, household smoking, and population genetics. The prevalence of colonization decreases steadily with age.

The widespread use of pneumococcal conjugate vaccines in some countries has resulted in alterations in patterns of nasopharyngeal colonization in resident populations. A relative increase in colonization by nonvaccine pneumococcal serotypes, nontypable *H. influenzae*, and *M. catarrhalis* has occurred. These changes in colonization patterns may be altering the distribution of pathogens of both otitis media and sinusitis in children.

PATHOGENESIS

M. catarrhalis causes mucosal infections of the respiratory tract by contiguous spread from its colonizing site in the upper airway. A preceding viral upper respiratory tract infection is a common inciting event for otitis media. In exacerbations of COPD, the acquisition of new strains is critical for pathogenesis. Strains exhibit substantial genetic diversity and differences in virulence properties.

The expression of several adhesin molecules with differing specificities for various host cell receptors reflects the importance of adherence to the respiratory epithelial surface in the pathogenesis of infection. *M. catarrhalis* invades multiple cell types. Its intracellular residence in lymphoid tissue provides a potential reservoir for persistence in the human respiratory tract. Like many gram-negative bacteria, *M. catarrhalis* sheds vesicles into the surrounding environment. The vesicles are internalized by host cells and mediate several virulence mechanisms, including induction of inflammation and delivery of β-lactamase, that can promote the survival of co-pathogens.

CLINICAL MANIFESTATIONS

In children, *M. catarrhalis* causes predominantly mucosal infections when the bacterium migrates from the nasopharynx to the middle ear or the sinuses **(Chap. 35)**. The inciting event for both otitis media and sinusitis is often a preceding viral infection. Overall, cultures of middle-ear fluid obtained by tympanocentesis indicate that *M. catarrhalis* causes 15–20% of cases of acute otitis media. More sensitive molecular analysis of middle ear fluid detects *M. catarrhalis* alone or with other pathogens in 30 to 50% of middle ear fluid samples from children with otitis media. Acute otitis media caused by *M. catarrhalis* or nontypable *H. influenzae* is clinically milder than otitis media caused by *S. pneumoniae*, with less fever and a lower prevalence of a red bulging tympanic membrane. However, substantial overlap makes it impossible to predict etiology in an individual child on the basis of clinical features.

A small proportion of viral upper respiratory tract infections are complicated by bacterial sinusitis. Cultures of sinus puncture aspirates show that *M. catarrhalis* accounts for ~20% of cases of acute bacterial sinusitis in children and for a smaller proportion in adults.

M. catarrhalis is a common cause of exacerbations in adults with COPD. The bacterium has been overlooked in this clinical setting because it has long been considered to be a commensal and because it is easily mistaken for commensal *Neisseria* species in cultures of respiratory secretions (see "Diagnosis," below). Several independent lines of evidence have established *M. catarrhalis* as a pathogen in COPD. These include (1) the demonstration of *M. catarrhalis* in the lower airways during exacerbations, (2) the association of exacerbation with acquisition of new strains, (3) elevations of inflammatory markers in association with *M. catarrhalis*, and (4) the development of specific immune responses following infection. *M. catarrhalis* is the second most common bacterial cause of COPD exacerbations (after *H. influenzae*), as shown in a 10-year prospective study; the distribution of exacerbations associated with new-strain acquisitions is shown in **Fig. 157-3**. Not included are culture-negative cases or cases from which a pathogen had been previously isolated. With the application of rigorous clinical criteria for defining the etiology of exacerbations (both culture-positive and culture-negative), ~10% of all exacerbations in the same study were caused by *M. catarrhalis*. The clinical features of an exacerbation due to *M. catarrhalis* are similar to those of exacerbations due to other bacterial pathogens, including *H. influenzae* and *S. pneumoniae*. The cardinal symptoms are cough with increased sputum production, sputum purulence, and dyspnea in comparison with baseline symptoms.

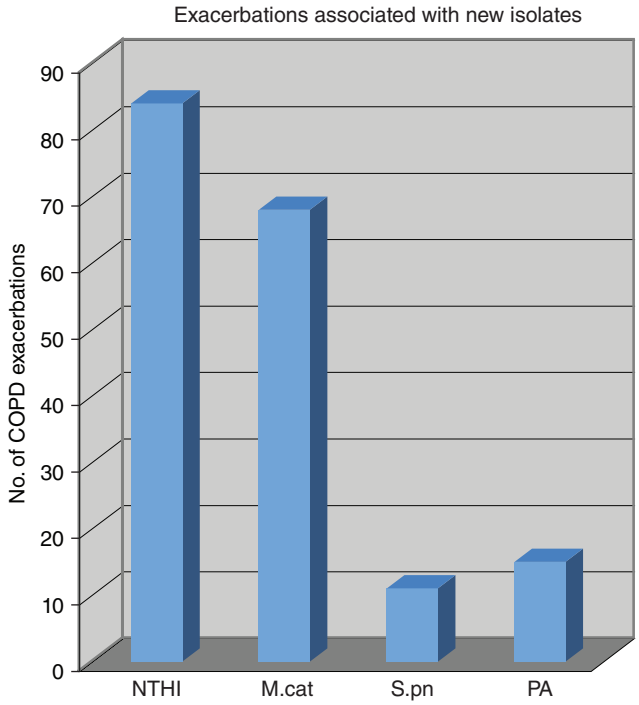

FIGURE 157-3 Cumulative results of a prospective study (1994–2004) of bacterial infection in chronic obstructive pulmonary disease (COPD) showing etiology of exacerbations. The numbers of exacerbations shown indicate the acquisition of a new strain simultaneous with clinical symptoms of an exacerbation. NTHI, nontypable *H. influenzae*; M.cat, *M. catarrhalis*; S.pn, *Streptococcus pneumoniae*; PA, *Pseudomonas aeruginosa*. *(Reproduced with permission from JC Goldstein, TF Murphy: Moraxella catarrhalis, a human respiratory tract pathogen. Clin Infect Dis 49:124, 2009.)*

Pneumonia due to *M. catarrhalis* occurs in the elderly, particularly in the setting of underlying cardiopulmonary disease, but is infrequent. Invasive infections, such as bacteremia, endocarditis, neonatal meningitis, and septic arthritis, are rare.

DIAGNOSIS

Tympanocentesis is required for etiologic diagnosis of otitis media, but this procedure is not performed routinely. Therefore, treatment of otitis media is generally empirical. Similarly, an etiologic diagnosis of sinusitis requires an invasive procedure and thus is usually not available to the clinician. Isolation of *M. catarrhalis* from an expectorated sputum sample from an adult experiencing clinical symptoms of an exacerbation is suggestive, but not diagnostic, of *M. catarrhalis* as the cause.

Upon culture, colonies of *M. catarrhalis* resemble those of commensal neisseriae that are part of the normal upper airway flora. As mentioned above, the difficulty in distinguishing colonies of *M. catarrhalis* from neisserial colonies in cultures of respiratory secretions explains in part why *M. catarrhalis* has been overlooked as a pathogen. In contrast to these *Neisseria* species, *M. catarrhalis* colonies can be slid across the

agar surface without disruption (the "hockey puck sign"). In addition, after 48 h of growth, *M. catarrhalis* colonies take on a pink color and tend to be larger than neisserial colonies. A variety of biochemical tests can distinguish *M. catarrhalis* from neisseriae. Kits that rely on these biochemical reactions are commercially available.

TREATMENT

Moraxella catarrhalis

M. catarrhalis rapidly acquired β-lactamases during the 1970s and 1980s; antimicrobial susceptibility patterns have remained relatively stable since that time, with >90% of strains now producing β-lactamase and thus resistant to amoxicillin. Otitis media in children and exacerbations of COPD in adults are generally managed empirically with antimicrobial agents that are active against *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Most strains of *M. catarrhalis* are susceptible to amoxicillin/clavulanic acid, extended-spectrum cephalosporins, newer macrolides (azithromycin, clarithromycin), trimethoprim-sulfamethoxazole, and fluoroquinolones. However, recent reports from several centers in Asia show substantial resistance to macrolides and fluoroquinolones, indicating emerging resistance. Continued monitoring of global antimicrobial susceptibility patterns of *M. catarrhalis* will be critical.

158 Infections Due to the HACEK Group and Miscellaneous Gram-Negative Bacteria

Tamar F. Barlam

THE HACEK GROUP

HACEK organisms are a group of fastidious, slow-growing, gram-negative bacteria whose growth requires an atmosphere of carbon dioxide. These organisms do not grow on media routinely used for enteric bacteria (e.g., MacConkey agar). Species belonging to this group include several *Haemophilus* species, *Aggregatibacter* (formerly *Actinobacillus*) species, *Cardiobacterium* species, *Eikenella corrodens*, and *Kingella kingae*. HACEK bacteria normally reside in the oral cavity and have been associated with local infections in the mouth. They are also known to cause severe systemic infections—such as bacteremia and bacterial endocarditis, which can develop on either native or prosthetic valves (Chap. 128). In a nationwide survey in Denmark, HACEK bacteremias were most often due to *Haemophilus species*, followed by *Aggregatibacter* species. HACEK bacteremia is strongly predictive of underlying infective endocarditis (overall positive predictive value, 60%). However, this association varies significantly by organism. For example, in one study, infective endocarditis was diagnosed in 100% of patients with *Aggregatibacter actinomycetemcomitans* bacteremia, 55% with *Haemophilus parainfluenzae* bacteremia, but in no patients with *Eikenella* bacteremia.

In large series, 0.8–6% of cases of infective endocarditis are attributable to HACEK organisms, most often *Aggregatibacter* species, *Haemophilus* species, and *Cardiobacterium hominis*. Invasive infection typically occurs in patients with a history of cardiac valvular disease or prosthetic valves, often in the setting of a recent dental procedure or nasopharyngeal infection. The aortic and mitral valves are most commonly affected. The clinical course of HACEK endocarditis tends to be subacute, particularly with *Aggregatibacter* or *Cardiobacterium*. However, *K. kingae* endocarditis may have a more aggressive presentation. Compared with non-HACEK endocarditis, HACEK endocarditis occurs in younger patients and has been more frequently associated with embolic, vascular, and immunologic manifestations. Systemic embolization is common. The overall prevalence of major emboli associated with HACEK endocarditis ranges from 28% to 71% in different series. On echocardiography, valvular vegetations are seen in up to 85% of patients. *Aggregatibacter* and *Haemophilus* species cause mitral valve vegetations most often; *Cardiobacterium* is associated with aortic valve vegetations.

The microbiology laboratory should be alerted when a HACEK organism is being considered. Most cultures that ultimately yield a HACEK organism become positive within the first week, especially with improved culture systems such as BACTEC. Studies have not shown that prolonged incubation increases laboratory recovery of clinically significant HACEK isolates. Polymerase chain reaction (PCR) techniques, such as gene amplification of 16S rRNA, can facilitate the diagnosis of HACEK infection of blood or cardiac valves. Other tools, such as matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry performed directly on agar colonies, can increase the accuracy and speed of diagnosis of HACEK infections.

Because of HACEK organisms' slow growth, antimicrobial susceptibility testing may be difficult, and β-lactamase production may not be detected. Resistance is most commonly noted in *Haemophilus* and *Aggregatibacter* species. Etest methodology may increase the accuracy of susceptibility testing. In recent studies, ceftriaxone and levofloxacin have been active against all isolates. The overall prognosis in both native-valve and prosthetic-valve HACEK endocarditis is excellent and is significantly better than that in endocarditis caused by non-HACEK pathogens.

***Haemophilus* Species** *Haemophilus parainfluenzae* is the most common *Haemophilus* species isolated from cases of HACEK endocarditis. Of patients with HACEK endocarditis due to *Haemophilus* species, 60% have been ill for <2 months before presentation, and 19–50% develop congestive heart failure. Mortality rates as high as 30–50% were reported in older series; however, more recent studies have documented mortality rates of <5%. *H. parainfluenzae* has been isolated from other infections, such as meningitis; brain, dental, pelvic, and liver abscess; pneumonia; urinary tract infection; and septicemia.

***Aggregatibacter* Species** *Aggregatibacter* species are the most common cause of HACEK endocarditis; the species most frequently involved are *A. actinomycetemcomitans*, *A.* (formerly *Haemophilus*) *aphrophilus*, and *A. paraphrophilus*. *Aggregatibacter* is associated with prosthetic-valve endocarditis more often than are *Haemophilus* species. *A. actinomycetemcomitans* can be isolated from soft tissue infections and abscesses in association with *Actinomyces israelii*. Typically, patients who develop *Aggregatibacter* endocarditis have periodontal disease or have recently undergone dental procedures in the setting of underlying cardiac valvular damage. The disease is insidious; patients may be sick for several months before diagnosis. Frequent complications include embolic phenomena, congestive heart failure, and renal failure.

A. actinomycetemcomitans has been isolated from patients with brain abscess, meningitis, endophthalmitis, parotitis, osteomyelitis, urinary tract infection, pneumonia, and empyema, among other infections. *A. aphrophilus* is often associated with bone and joint infection and is an important cause of brain abscess. In one series, *A. aphrophilus* was isolated from brain abscesses in 10% of cases—a rate that is disproportionate to its isolation from oral flora. This species has also been described as a cause of abscess in other organ systems.

***Cardiobacterium* Species** *Cardiobacterium* species, most often *C. hominis*, cause endocarditis primarily in patients with underlying valvular heart disease or with prosthetic valves. These organisms most frequently affect the aortic valve. Many patients have signs and symptoms of long-standing infection before diagnosis, with evidence of arterial embolization, vasculitis, cerebrovascular accidents, immune complex glomerulonephritis, or arthritis at presentation. Embolization, mycotic aneurysms, and congestive heart failure are common complications. A second species, *C. valvarum*, has been described in association with endocarditis.

Eikenella corrodens *E. corrodens* is most frequently recovered from sites of infection in conjunction with other bacterial species. Clinical sources of *E. corrodens* include sites of human bite wounds (clenched-fist injuries), endocarditis, soft tissue infections, osteomyelitis, head and neck infections, respiratory infections, chorioamnionitis, gynecologic infections associated with intrauterine devices, meningitis, brain abscesses, and visceral abscesses. This organism is the least common cause of HACEK endocarditis.

Kingella kingae More than half of cases of *K. kingae* infection are bone and joint infections; the majority of the remaining infections are infective endocarditis, bacteremia, and meningitis. Invasive *K. kingae* infections with bacteremia are associated with upper respiratory tract infections and stomatitis in 80% of cases. Rates of oropharyngeal colonization with *K. kingae* are highest in the first 3 years of life (detected in ~5–10% of children) and appear higher in children regularly attending daycare; colonization coincides with an increased incidence of skeletal infections and other invasive infections due to this organism from the age of 6 months to 4 years. *K. kingae* can be transmitted from child to child and has been the cause of outbreaks among young children. *K. kingae* bacteremia can present with a petechial rash similar to that seen in *Neisseria meningitidis* sepsis.

Because of improved microbiologic methodology and molecular methods such as real-time PCR, the isolation of *K. kingae* is increasingly common. Inoculation of clinical specimens (e.g., synovial fluid) into aerobic blood culture bottles enhances recovery of this organism. PCR studies of blood or joint fluid can identify *K. kingae* in culture-negative cases. Some studies have demonstrated that *K. kingae* has surpassed *Staphylococcus aureus* as the leading cause of septic arthritis and osteomyelitis in children.

Infective endocarditis, unlike other infections with *K. kingae*, occurs in older children and adults. The majority of patients have preexisting valvular disease. There is a high incidence of complications, including arterial emboli, cerebrovascular accidents, tricuspid insufficiency, and congestive heart failure with cardiovascular collapse.

TREATMENT

HACEK Endocarditis

(Table 158-1) Ceftriaxone (2 g/d) is first-line therapy for HACEK endocarditis, with a favorable outcome in 80–90% of cases. Data on the use of levofloxacin (750 mg/d) for HACEK endocarditis remain limited, but this drug can be considered an alternative for treatment of patients intolerant of β-lactam therapy. Of note, *Eikenella* is resistant to clindamycin, metronidazole, and aminoglycosides.

Native-valve endocarditis should be treated for 4 weeks with antibiotics, whereas prosthetic-valve endocarditis requires 6 weeks of therapy. The cure rates for HACEK prosthetic-valve endocarditis appear to be high. Unlike prosthetic-valve endocarditis caused by other gram-negative organisms, HACEK endocarditis is often cured with antibiotic treatment alone—i.e., without surgical intervention. In a recent case-control study, 1-year mortality was significantly lower than infective endocarditis caused by viridans group *Streptococcus*.

OTHER FASTIDIOUS GRAM-NEGATIVE BACTERIA

***Capnocytophaga* Species** Like HACEK organisms, this genus of fastidious, fusiform, gram-negative coccobacilli is facultatively anaerobic and requires an atmosphere enriched in carbon dioxide for optimal growth. *Capnocytophaga* species such as *C. ochracea*, *C. gingivalis*, *C. haemolytica*, and *C. sputigena* are part of the oral flora; most infections are contiguous with the oropharynx (e.g., periodontal disease, respiratory tract infections, cervical abscesses, endophthalmitis). These organisms have also been associated with sepsis in immunocompromised hosts, particularly neutropenic patients with oral ulcerations, meningitis, endocarditis, cellulitis, osteomyelitis, and septic arthritis. *Capnocytophaga* species have been isolated from many other sites as well, usually as part of a polymicrobial infection. There is a high prevalence of resistance to β-lactams and macrolides in *Capnocytophaga*; the oral cavity serves as a reservoir for resistance genes to those agents.

C. canimorsus and *C. cynodegmi* are endogenous to the canine and feline mouth **(Chap. 141)**. Patients infected with these species frequently have a history of dog or cat bites or of exposure without scratches or bites. Asplenia, glucocorticoid therapy, and alcohol abuse are predisposing conditions that can be associated with severe sepsis with shock and disseminated intravascular coagulation. Patients typically have a petechial rash that can progress from purpuric lesions to gangrene.

TABLE 158–1 Treatment of Infections Caused by HACEK-Group and Other Fastidious Gram-Negative Organisms

ORGANISMS	PREFERRED THERAPY	ALTERNATIVE AGENTS	COMMENTS
Haemophilus spp. *Aggregatibacter* spp. *Cardiobacterium* spp. *Eikenella corrodens* *Kingella kingae*	Ceftriaxone (2 g/d)	Ampicillin/sulbactam (3 g of ampicillin q6h) Levofloxacin (750 mg/d)	Ampicillin/sulbactam resistance has been described in *Haemophilus* and *Aggregatibacter* spp. Data on use of levofloxacin for endocarditis therapy are limited. Fluoroquinolones are not recommended for treatment of patients <18 years of age. Penicillin (16–18 million units q4h) or ampicillin (2 g q4h) can be used if the organism is susceptible. However, because of the slow growth of HACEK bacteria, antimicrobial testing may be difficult, and β-lactamase production may not be detected.
Capnocytophaga spp.	Ampicillin/sulbactam (1.5–3 g of ampicillin q6h)	Ceftriaxone (2 g/d q12–24h)	Penicillin (12–18 million units q4h) should be used if the isolate is known to be susceptible.
Pasteurella multocida	Ampicillin/sulbactam (1.5–3 g of ampicillin q6h)	Ceftriaxone (1–2 g/d q12–24h)	Penicillin should be used if the isolate is known to be susceptible. *P. multocida* is also susceptible to tetracyclines and fluoroquinolones.

TREATMENT

Capnocytophaga Infections

(Table 158-1) Because of increasing β-lactamase production, a penicillin derivative plus a β-lactamase inhibitor—such as ampicillin/sulbactam (1.5–3.0 g of ampicillin every 6 h)—is currently recommended for empirical treatment of infections caused by *Capnocytophaga* species. If the isolate is known to be susceptible, infections with *C. canimorsus* should be treated with penicillin (12–18 million units every 4 h). *Capnocytophaga* is also susceptible to clindamycin (600–900 mg every 6–8 h) and third-generation cephalosporins such as ceftriaxone (2 g every 12–24 h). Antibiotics should be given prophylactically to asplenic patients who have sustained dog-bite injuries.

Pasteurella multocida *P. multocida* is a fastidious, bipolar-staining, gram-negative coccobacillus that colonizes the respiratory and gastrointestinal tracts of domestic animals; oropharyngeal colonization rates are 70–90% in cats and 50–65% in dogs. *P. multocida* can be transmitted to humans through bites or scratches, via the respiratory tract from contact with contaminated dust or infectious droplets, or via deposition of the organism on injured skin or mucosal surfaces during licking. Most human infections affect skin and soft tissue; almost two-thirds of these infections are caused by cats. Patients at the extremes of age or with serious underlying disorders (e.g., cirrhosis, diabetes) are at increased risk for systemic manifestations, including meningitis, peritonitis, osteomyelitis and septic arthritis, endocarditis, septic shock, ecthyma, necrotizing fasciitis, and purpura fulminans, and are more likely not to have evidence of an animal bite. However, cases have also occurred in healthy individuals of all ages. If inhaled, *P. multocida* can cause acute respiratory tract infection, particularly in patients with underlying sinus and pulmonary disease.

TREATMENT

Pasteurella multocida Infections

(Table 158-1) *P. multocida* is susceptible to penicillin, ampicillin, ampicillin/sulbactam, second- and third-generation cephalosporins, tetracyclines, and fluoroquinolones. β-Lactamase–producing strains have been reported.

OTHER GRAM-NEGATIVE BACTERIA

Achromobacter xylosoxidans *Achromobacter* (previously *Alcaligenes*) *xylosoxidans* is an aerobic nonfermenting gram-negative organism that is probably part of the endogenous intestinal flora. It has been isolated from a variety of water sources, including well water, IV fluids, and humidifiers. Immunocompromised hosts, including patients with cancer and postchemotherapy neutropenia, cirrhosis, chronic renal failure, and cystic fibrosis, are at increased risk for infection. Nosocomial outbreaks and pseudo-outbreaks of *A. xylosoxidans* infection have been attributed to contaminated fluids, and clinical illness has been associated with isolates from many sites, including blood (often in the setting of intravascular devices). Community-acquired *A. xylosoxidans* bacteremia usually occurs in the setting of pneumonia. Metastatic skin lesions are present in one-fifth of cases. The reported mortality rate is as high as 67%—a figure similar to rates for other bacteremic gram-negative pneumonias.

TREATMENT

Achromobacter xylosoxidans Infections

(Table 158-2) Treatment is based on in vitro susceptibility testing of all clinically relevant isolates; multidrug resistance is common. Carbapenems, tigecycline, and colistin are typically the most active agents.

TABLE 158-2 Treatment Options for Other Selected Gram-Negative Bacteria[a]

ORGANISM	TREATMENT OPTIONS
Achromobacter xylosoxidans	Carbapenems, tigecycline, colistin
Aeromonas spp.	Fluoroquinolones, third- and fourth-generation cephalosporins, carbapenems, aminoglycosides
Elizabethkingia/Chryseobacterium spp.	Fluoroquinolones, minocycline, tigecycline, piperacillin/tazobactam
Rhizobium radiobacter	Fluoroquinolones, third- and fourth-generation cephalosporins, carbapenems
Shewanella spp.	Fluoroquinolones, third- and fourth-generation cephalosporins, β-lactam/β-lactamase inhibitors, carbapenems, aminoglycosides
Chromobacterium violaceum	Carbapenems, fluoroquinolones, trimethoprim-sulfamethoxazole

[a]Treatment should be based on in vitro susceptibility testing; multidrug resistance is common among these organisms.

***Aeromonas* Species** *Aeromonas* is a facultative anaerobic gram-negative bacterium. *Aeromonas* infections are most often caused by *A. hydrophila*, *A. caviae*, *A. veronii*, and *A. dhakensis*. *Aeromonas* proliferates in potable water, freshwater, and soil. It remains controversial whether *Aeromonas* is a cause of bacterial gastroenteritis; asymptomatic colonization of the intestinal tract with *Aeromonas* occurs frequently, and no clonally related diarrheal outbreak has been documented. However, rare cases of hemolytic-uremic syndrome following bloody diarrhea have been shown to be secondary to the presence of *Aeromonas*.

Aeromonas causes health care–associated sepsis and bacteremia in infants with multiple medical problems and in immunocompromised hosts, particularly those with cancer or hepatobiliary disease, including cirrhosis. *A. caviae* is associated with health care–related bacteremia. Community-acquired infections include bacteremia, spontaneous bacterial peritonitis, biliary tract infections, and skin and soft tissue infections. Severe soft tissue infections such as necrotizing fasciitis are more common in Taiwan than in Western countries; *Aeromonas* was the most common pathogen associated with skin and soft tissue infections after the tsunami in Thailand. Along with other gram-negative organisms such as *Shewanella* and *Chromobacterium*, *Aeromonas* infections are associated with floods and other hydrologic disasters. *Aeromonas* infection and sepsis can occur in patients with trauma (including severe trauma with myonecrosis), patients with seawater-contaminated wounds, and burn patients exposed to the organism by environmental (freshwater or soil) wound contamination. Reported mortality rates range from 25% among immunocompromised adults with sepsis to >90% among patients with myonecrosis. Patients with *A. dhakensis* bacteremia have higher 14-day mortality rates than do those whose bacteremia is attributable to other species. *Aeromonas* can produce ecthyma gangrenosum (hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration; **see Fig. A1-34**) resembling the lesions seen in *Pseudomonas aeruginosa* infection. This organism causes nosocomial infections related to catheters, surgical incisions, or use of leeches. Other manifestations include meningitis, peritonitis, pneumonia, and ocular infections.

TREATMENT

Aeromonas Infections

(Table 158-2) *Aeromonas* species are generally susceptible to fluoroquinolones (e.g., ciprofloxacin at a dosage of 500 mg every 12 h PO or 400 mg every 12 h IV), third- and fourth-generation cephalosporins, carbapenems, and aminoglycosides, but resistance to all those agents has been described. Because *Aeromonas* can produce various β-lactamases, including carbapenemases, susceptibility testing must be used to guide therapy. Antibiotic prophylaxis (e.g., with ciprofloxacin) is indicated when medicinal leeches are used.

***Elizabethkingia/Chryseobacterium* Species** *Elizabethkingia meningoseptica* (formerly *Chryseobacterium meningosepticum*), a nonfastidious aerobic nonfermentative gram-negative bacillus, is an important cause of nosocomial infections, including outbreaks due to contaminated fluids (e.g., contaminated sinks, disinfectants, and aerosolized antibiotics) and sporadic infections due to indwelling devices, feeding tubes, and other fluid-associated apparatuses. Most published reports have originated from Asia, particularly Taiwan. A report from South Korea described infections with a high case-fatality rate associated with mechanical ventilation. Outbreaks due to this organism have persisted until extensive cleaning of environmental surfaces and equipment has been performed. Nosocomial *E. meningoseptica* infection usually involves preterm neonates, patients with underlying immunosuppression (e.g., related to malignancy or diabetes), or patients exposed to antibiotics in intensive care. *E. meningoseptica* has been reported to cause meningitis (primarily in neonates), pneumonia, sepsis, endocarditis, bacteremia, eye infections, and soft tissue infections. Other species of *Elizabethkingia* are emerging, identified using MALDI-TOF and 16s rRNA sequencing. In a report of 86 clinical isolates, only 12 (19.8%) of the isolates were *E. meningoseptica;* the majority were *E. anophelis* (51 isolates; 59.3%). More than three-quarters of the isolates were from the lower respiratory tract, and 9.3% were from blood cultures. In a U.S. study of 11 patients with *E. anophelis* infection, all had bloodstream infections. In that series, the patients had comorbidities and recent health care exposure; there was a mortality rate of 18.2%.

Chryseobacterium indologenes has caused bacteremia, sepsis, peritonitis, meningitis, and pneumonia, typically in immunocompromised patients with indwelling devices. Mortality rates have been as high as 50% in some reports; it is unclear whether a poor prognosis is related to underlying comorbidities or to the multidrug-resistant phenotype of the organism.

TREATMENT

Elizabethkingia/Chryseobacterium Infections

(Table 158-2) These organisms are often susceptible to fluoroquinolones, minocycline, tigecycline, and rifampin. They may be susceptible to β-lactam/β-lactamase inhibitor combinations such as piperacillin/tazobactam, but multidrug-resistant isolates are increasing and can possess extended-spectrum β-lactamases and metallo-β-lactamases. In vitro susceptibility testing often indicates activity of agents used against gram-positive bacteria (e.g., vancomycin), but it is unclear that those agents are reliable clinically. Combination therapy may be needed for successful treatment. Susceptibility testing should be performed to guide the choice of optimal agents.

MISCELLANEOUS ORGANISMS

Rhizobium (formerly *Agrobacterium) radiobacter* has usually been associated with infection in the presence of medical devices, including intravascular catheter–related infections, prosthetic-joint and prosthetic-valve infections, and peritonitis caused by dialysis catheters. Cases of endophthalmitis after cataract surgery also have been described. Most *R. radiobacter* infections occur in immunocompromised hosts, especially individuals with malignancy or HIV infection. Elderly patients with septic shock, watery diarrhea, and acute renal failure also have been reported. Strains are usually susceptible to fluoroquinolones, third- and fourth-generation cephalosporins, and carbapenems (Table 158-2).

Shewanella species are ubiquitous nonfermentative gram-negative organisms found in seawater and marine environments. Human disease is caused primarily by *S. putrefaciens* and *S. algae*; *S. algae* may be the more virulent species. Most infections involve skin and soft tissue, ranging from impetigo to necrotizing fasciitis. Patients are exposed to the organism through contact of bites, open wounds, or devitalized tissue with seawater, marine animals, or fresh seafood or through ingestion of seawater or of raw or undercooked seafood, especially shellfish. *Shewanella* species also cause chronic ulcers of the lower extremities, osteomyelitis, biliary tract infections, pneumonia, bacteremia, sepsis, and potentially chronic otitis media. A fulminant course is associated with cirrhosis, hemochromatosis, diabetes mellitus, malignancy, or other severe underlying conditions. In one series of cases from Martinique, 13% of infections were fatal. These organisms are often susceptible to fluoroquinolones, third- and fourth-generation cephalosporins, β-lactam/β-lactamase inhibitors, carbapenems, and aminoglycosides (Table 158-2).

Chromobacterium violaceum is a facultative anaerobic organism found in soil and water in tropical or subtropical regions. After exposure, it can cause rare but serious—often fatal—skin and soft tissue infections of limbs although several recent reports suggest a more benign course with lower mortality. Life-threatening infections with severe sepsis and metastatic abscesses occur most often in patients with underlying illness, particularly in children with defective neutrophil function (e.g., those with chronic granulomatous disease). *C. violaceum* is frequently resistant to multiple drugs; carbapenems are most often used empirically. Fluoroquinolones and trimethoprim-sulfamethoxazole also can be active (Table 158-2).

Ochrobactrum anthropi causes infections related to central venous catheters in compromised hosts; other invasive infections such as bacteremia have been described. *Pseudomonas* (formerly *Flavimonas*) *oryzihabitans* can cause catheter-related bloodstream infections in immunocompromised patients. *Sphingobacterium* is a rare cause of human infection in immunocompromised hosts. It can colonize hospital water systems, respiratory tract equipment, and laboratory instruments. *Sphingomonas paucimobilis* is found in soil and water sources and is a rare cause of infection in both healthy and immunocompromised patients. This organism can cause bloodstream infections, respiratory distress, and sepsis. It has a predilection for bone and soft tissue infection, osteomyelitis, and septic arthritis. A different species, *Sphingomonas koreensis,* was associated with a small cluster of nosocomial cases at one hospital and was traced to a reservoir in the plumbing system. *Ralstonia* species also can contaminate water supplies, including hospital water systems. Cases of bacteremia, osteomyelitis, pneumonia, and meningitis have been described. Other organisms implicated in human infections include *Weeksella* species; *Bergeyella* species; various CDC groups; and *Oligella urethralis.* The reader is advised to consult subspecialty texts and references for further guidance on these organisms.

159 *Legionella* Infections

Steven A. Pergam, Thomas R. Hawn

Bacteria of *Legionella* species cause two primary human diseases: *Legionella* pneumonia (often referred to as Legionnaires' disease) and Pontiac fever; collectively, these diseases are referred to as *legionellosis*. Legionnaires' disease was first described in 1976 in an outbreak among members of the American Legion participating in a conference at a hotel in Philadelphia, Pennsylvania. Since their original description,

Legionella-related infections have increased in frequency throughout the world as techniques to diagnose them have improved, clinical awareness has increased, cities have grown, and water systems have both aged and become more complex. Most cases of legionellosis are linked to waterborne exposures. These infections can be either sporadic or due to common-source community or nosocomial exposures. Outbreaks of legionellosis are well described. After exposure, legionellosis occurs primarily among persons with risk factors for disease, including older adults and those with primary organ dysfunction, immunocompromise, or other chronic illnesses. Clinical awareness is important, as the similarity of signs and symptoms of legionellosis to those of other respiratory illnesses can lead to delayed treatment. Despite appropriate therapy, *Legionella* pneumonia is associated with significant morbidity and mortality.

PATHOGEN AND PATHOGENICITY

Legionellae are aerobic gram-negative bacteria that are ubiquitous in aquatic environments, damp soil, and compost. Of the more than 60 *Legionella* species, approximately half have been documented to lead to clinical disease, but most clinical disease is driven by *Legionella pneumophila*, primarily serotype 1. The primary habitats for growth and replication of *Legionella* are amoebae and other free-living protozoa, in which these bacterial species can thrive intracellularly; humans are accidental hosts. Legionellae are reliant on host-derived amino acids and nutrients for intracellular replication. The organisms have a biphasic life cycle: a replicative phase in nutrient-rich conditions (e.g., in their protozoal hosts) and a noninfective transmissive phase under scarcity of resources. Therefore, they can persist in complex biofilms in both natural and engineered water systems (e.g., premise plumbing—a building's hot and cold water piping systems) and are phagocytized by waterborne protozoa. In premise plumbing systems, where temperature and nutrients support the protozoal hosts of legionellae, the bacteria can replicate to concentrations sufficient to cause human infection.

After exposure to *Legionella* through inhalation or aspiration of small aerosol particles, the organisms attach to immune cells and are phagocytized. After phagocytosis, they can evade intracellular defenses and replicate in human alveolar macrophages and monocytes. Pathogenic *Legionella* species have numerous virulence systems that they use to evade the human immune system, including the development of *Legionella*-containing vacuoles within immune cells, downregulation of cytokine receptors, inhibition of host protein synthesis, and avoidance of lysosomal degradation. Despite their ability to replicate and persist in the intracellular environment, innate immune components that target intracellular pathogens—specifically, pattern recognition receptors, including Toll-like receptors and nucleotide-binding oligomerization domain–like receptors—activate immune responses. Adaptive CD4 and CD8 cytotoxic T-cell involvement and these innate immune responses eventually lead to the production of interferon γ and tumor necrosis factor, the promotion of neutrophil recruitment into the lung, and other proinflammatory responses. This cascade can be beneficial and result in clearance of the pathogen. However, these inflammatory responses can also cause immunopathology and adverse outcomes. *L. pneumophila* is more cytopathogenic than most non-*pneumophila Legionella* species, a characteristic that may be partially responsible for its association with severe disease.

EPIDEMIOLOGY

Legionella species are responsible for >50% of all waterborne outbreaks and >10% of disease related to drinking water in the United States. A National Academies of Sciences, Engineering, and Medicine report estimates that 50,000–70,000 Americans develop Legionnaires' disease per year. Incidence rates of legionellosis in the United States are reportedly 2–3 cases per 100,000 persons, but higher rates have been reported in other parts of the world. Numerous global epidemiologic studies assessing legionellosis have shown an increasing prevalence over the past few decades; this increase has been hypothesized to be due to a variety of causes, including an aging population, improved diagnostics, global temperature changes, and an aging water infrastructure. Legionellosis is associated with substantial health care costs.

Legionella species are found throughout the world, but most epidemiologic data focus on legionellosis in large metropolitan areas in Australia/New Zealand, Europe, and North America. Rates of infection in other parts of the world are unknown, as surveillance systems and laboratory testing are less readily available in large portions of Africa and Asia. More than 80% of cases of Legionnaires' disease are linked to *L. pneumophila*—in particular to serotype 1, which is the most frequently isolated *Legionella* pathogen. Although *L. pneumophila* predominates as a cause of disease, species predilection varies regionally. In Australia and New Zealand, for example, the rate of disease due to *Legionella longbeachae* approaches or exceeds that for *L. pneumophila*.

As previously mentioned, most reported cases are due to *L. pneumophila* serotype 1—a reflection of its pathogenicity. However, this predominance is also due to the frequency and ease of use of urinary antigen testing that targets this pathogen and allows more effective diagnosis in the community. It is unclear how large a role non-*pneumophila* species and non–serotype 1 *L. pneumophila* play in disease. However, in studies in Europe, where respiratory cultures are more frequently collected, nearly 10% of Legionnaires' disease patients were infected with species other than *L. pneumophila.* In the United States, nearly 10% of culture-confirmed cases are due to non–serogroup 1 *L. pneumophila.* Immunosuppressed patients, such as cancer patients and transplant recipients, may be more likely to develop pneumonia caused by non-*pneumophila* species such as *Legionella micdadei, Legionella bozemanii,* and *L. longbeachae.*

Despite increases in cases in the United States **(Fig. 159-1)** and throughout the world, incident cases are still thought to be underreported. Many cohort studies of community-acquired pneumonia do not require routine testing for *Legionella* or assess only for *L. pneumophila* serotype 1 (by urinary antigen testing) and therefore may underestimate true prevalence. For example, a large administrative database of studies shows that, of patients with clinically proven community-acquired pneumonia, only 26% underwent *Legionella*-specific testing; even patients with documented risk factors for legionellosis are not always tested for *Legionella*. In studies that routinely assess for legionellosis, the prevalence of *Legionella* pneumonia ranges between 2 and 10% of all community-acquired pneumonia cases. In addition, extrapulmonary presentations and Pontiac fever are less likely to be identified or to result in presentation for health care, and this trend leads to further underestimation of the true burden of legionellosis.

Seasonality and Climate Geoclimatic changes, storms, and seasonality are thought to be important components of *Legionella*'s epidemiology. The incidence of *Legionella* disease increases in the summer and fall—specifically, in warmer weather and with increased rain and humidity. Studies that screen all respiratory samples for *Legionella* find that legionellosis is indeed diagnosed most frequently in the United States during warmer summer/fall months and periods of greater humidity. Furthermore, seasonal storms, which may disrupt water pipes or cause increased flooding, can result in contamination of water systems with soil and lead to *Legionella* exposures. There is concern that, with ongoing climate shifts and rising global temperatures, cases of legionellosis may continue to increase.

Community and Health Care–Associated Outbreaks Small and large clusters and point-source outbreaks of *Legionella* cases lead to public health investigations, but these situations account for only ~5–10% of all *Legionella* cases yearly. Outbreaks occur when two or more people become ill after shared exposures in a community. In health care systems, a single proven case should trigger a *Legionella* investigation. The Centers for Disease Control and Prevention (CDC) recommends an outbreak investigation if a singular patient with *Legionella* is identified who did not leave the facility/campus for the 10 days prior to illness onset. Additionally, an outbreak investigation within a health care system is warranted if there are at least two possible *Legionella* patients who spent any time in the hospital/long-term care facility within 12 months of each other (see "Clinical Presentations" below).

Most common outbreaks are linked to water sources dispersing aerosol droplets that increase the area of particle spread (e.g., cooling

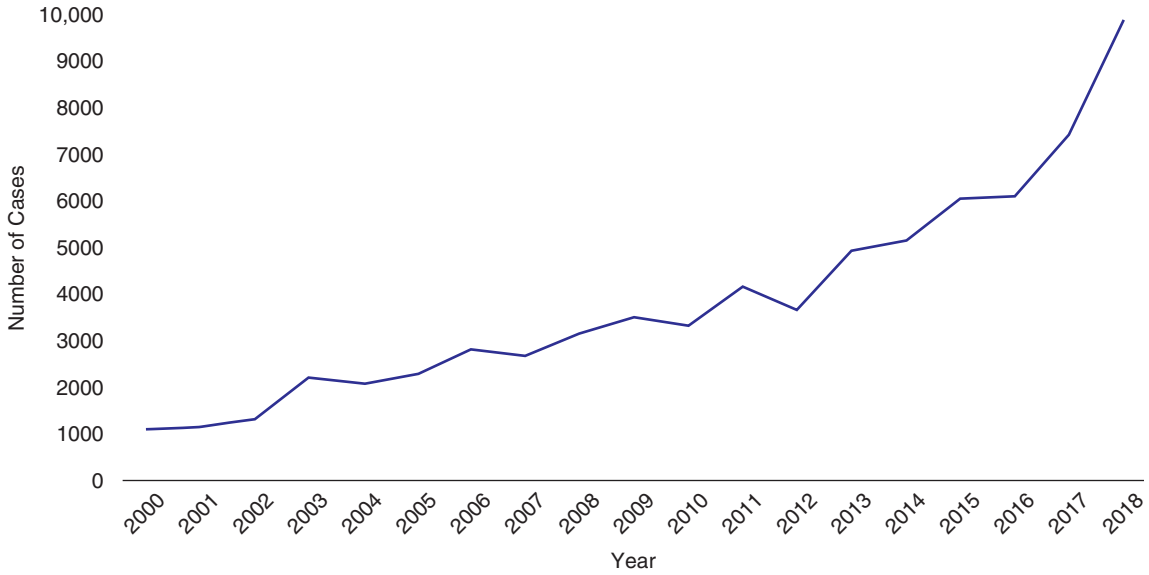

FIGURE 159-1 Increasing *Legionella* disease incidence in the United States over the past two decades (2000–2018). *(From https://www.cdc.gov/legionella/about/history.html.)*

towers or fountains) or to large building structural water systems that cause multiple prolonged exposures (e.g., those in hospitals, hotels, or apartments). The most commonly reported sources include not only cooling towers and fountains but also water misters; centralized heating, ventilation, and air-conditioning systems; hot tubs/spas; pools; ice machines; and showerheads and sinks in large premise plumbing structures **(Fig. 159-2)**. When used as primary sources of water, groundwater and wells have also been associated with *Legionella* exposures. The majority of exposures are related to engineered hot-water systems, which are often maintained at temperatures that limit scalding but are ideally suited for *Legionella*'s growth. *Legionella* can also be found in cold water, particularly in warmer summer months, as a consequence of the warming water temperature; engineering issues (e.g., heating lamps in fountains); or unexpected breaks in plumbing systems (e.g., malfunctioning thermostatic mixing valves), which can lead to hot-water contamination of cold-water systems.

Buildings with inconsistent use patterns, such as hotels in seasonal travel destinations, can be linked to outbreaks of legionellosis, as water stagnation leads to low chlorine/disinfectant levels and organism proliferation can reach high enough levels to cause disease. Outbreaks have also been linked to cruise ships and boats. Because of stay-at-home orders related to the SARS-CoV-2 pandemic, there is concern that, once the affected buildings (e.g., hotels) are reopened, limited water movement and stagnation could lead to increases in cases of legionellosis. Modern buildings with water-saving devices, which aim to limit water and energy use, may increase the risk of legionellosis, as they can decrease water temperatures and limit water flow.

Outbreaks in health care and long-term care facilities are identified more frequently than outbreaks in other facilities, as they often bring together at-risk patients, prolonged water exposures, accessible testing, elevated awareness, and regulations that help ensure that cases are more easily linked to common sources. The outbreak examples listed in **Table 159-1** demonstrate the wide variety of common sources and the number of cases associated with such factors. As previously mentioned, most large outbreaks involve cooling towers, which can spread aerosol droplets over a wide area. The largest outbreak reported to date

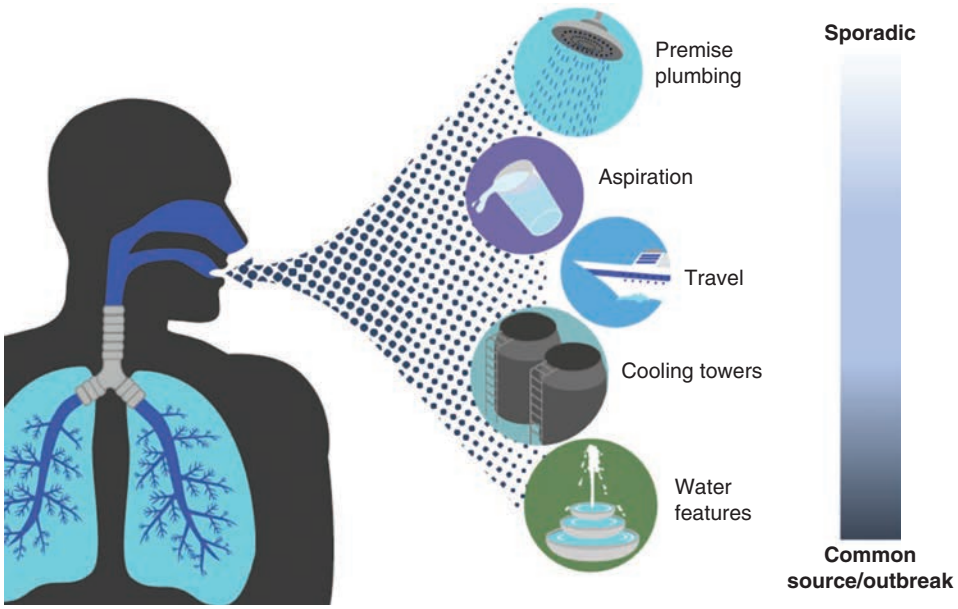

FIGURE 159-2 Sources of waterborne *Legionella* exposures and spectrum of presentation. The spectrum of sporadic to common-source outbreaks is a continuum. For example, premise plumbing in a large office building can lead to a large outbreak, and travel exposures can be related to large outbreaks. Most sporadic cases have no documented source of exposure, while outbreaks often involve mechanisms that spread water aerosol droplets over long distances (e.g., cooling towers), with a consequent ability to infect more individuals. *(Reproduced with permission from Kyoko Kurosawa.)*

TABLE 159-1 Examples of Common-Source Outbreaks of *Legionella pneumophila* Infections Indicate the Wide Variety of Sources and Cases

SITE	YEAR	SPECIES/SEROTYPE	REPORTED SOURCE(S)	CASES
Hotel[a]	2012	*L. pneumophila* serotype 1	Potable water, fountain, spa	85 (plus 29 suspected)
Hospital[b]	2012	*L. pneumophila*	Potable water	22
Community[c]	2014	*L. pneumophila* serotype 1	Cooling tower	334
Hospital/community[d]	2014–2015	*L. pneumophila*	Potable water, household, cooling towers	86
Long-term care facility[e]	2015	*L. pneumophila*	Potable water	74
Community[f]	2015	*L. pneumophila*	Hotel cooling towers	128
Hospital[g]	2018	*L. pneumophila* serotype 1	Potable water, showers	13
Hotel[h]	2019	*L. pneumophila*	Fountain	13 (plus 66 suspected)
Community[i]	2019	*L. pneumophila*	Hot tub display	141

Note: Large community outbreaks were most commonly linked to cooling towers. Not all serotypes reported.

involved a cooling tower in Spain that was linked to 449 documented cases of Legionnaires' disease. Outbreaks are increasingly discussed in the media, such as outbreaks linked to cooling towers in the Bronx neighborhood of New York City, a large hotel outbreak in Atlanta, and outbreaks associated with the Flint, Michigan, water crisis. It is not uncommon for lawsuits to be initiated when deaths are linked to outbreaks.

Sporadic Cases The vast majority of cases of Legionnaires' disease occur sporadically in the community, manifesting as community-acquired pneumonia. Identification of the transmission source is more difficult in community-acquired cases than in nosocomial cases, despite reporting and review by local public health jurisdictions. In nearly 90% of all cases of legionellosis, a source of exposure is never identified. Since the spectrum of water exposures in the community is so broad and incubation periods can be long, identifying individual exposures often is not possible. Transient exposures to common sources, travel-related exposures, and exposures to less commonly linked sources (e.g., potting soil and compost) may also be hard to identify. Furthermore, studies of domestic hot water have demonstrated that 5–30% of households may have *Legionella* species detected, but the role that households play in clinical legionellosis is hard to determine, as home water testing is infrequently a part of usual contact investigations. Because of underdiagnosis, it is likely that diagnosed sporadic community-acquired cases represent only patients who are ill enough to present to health care for evaluation.

Risk Factors A number of epidemiologic and demographic risk factors are associated with legionellosis. Older age is a risk factor; most studies suggest that risk begins to increase at an age of ~40 years. Furthermore, elderly patients are at the highest risk for major complications. Males are at approximately three times greater risk for *Legionella* disease than are females in most large epidemiologic studies. Children are thought to be less likely to develop severe infections. However, since routine testing is less common among children, cases may be underreported.

Smoking has been strongly linked to legionellosis. Inhalation of smoke leads to anatomic changes in the airway epithelium, impairs neutrophil and monocyte phagocytosis, and has negative effects on airway ciliary clearance—all of which can increase the risk of pneumonia. Studies have shown that cigarette smoking is a dose-dependent risk factor. Smoking cannabis has also been associated with increased risk. Risk and severity of illness are further associated with smoking-related pulmonary diseases such as chronic obstructive pulmonary disease or emphysema, which in turn lead to increased risk for complications. Patients with other organ dysfunction/failure, such as those with renal disease (including those on dialysis), hepatic disease, nonsmoking pulmonary disease, and cardiac disease, are at increased risk for legionellosis, although it is unclear whether these factors are related to disease severity or to greater awareness and consequent recognition by health care providers.

Immunosuppressed patients are at increased risk for legionellosis and *Legionella*-related complications. Patients undergoing treatment for cancer (including recipients of hematopoietic cell transplantation) and solid organ transplant recipients are at high risk for legionellosis due to immunosuppression as well as disease- and treatment-related comorbidities. Use of prednisone and other glucocorticoids is strongly associated with legionellosis; however, in light of the heterogeneity of immunosuppressive agents and their use, it remains unclear whether most other single agents are as strongly associated with the disease. Combination immunosuppressive regimens increase risk. Patients treated with these regimens are more likely to develop non-*pneumophila* legionellosis and non–serotype 1 *L. pneumophila* infections that may be missed by routine urinary antigen testing. Patients with autoimmune diseases receiving tumor necrosis factor inhibitors, either with or without concomitant glucocorticoid use, are also at increased risk for legionellosis. Furthermore, studies suggest a possible association of legionellosis with genetic polymorphisms in components of the innate immune system that are important in recognizing and responding to intracellular pathogens (e.g., Toll-like receptors and interferon genes).

Transmission The *Legionella* species involved in human disease are usually waterborne pathogens. However, disease development requires sufficient levels of the organism at the exposure site, the formation of small particles that can be inhaled or aspirated into pulmonary alveoli, and an at-risk host. *Legionella*-containing aerosol particles <10 μm in diameter are needed for deposition into the alveoli. The infective dose during exposures is unknown but likely depends on the host: disease development in at-risk individuals may require a more limited exposure. Strain virulence is also thought to be important in disease development: *L. pneumophila* serotype 1 is more apt to lead to outbreaks and disease than, for example, *Legionella anisa*, which has only rarely been associated with disease in high-risk patients. Because of the necessity for these various factors, estimated attack rates during an exposure are only ~5% for pneumonic presentations. Attack rates for Pontiac fever are thought to be higher—up to 90% among those exposed.

Most exposures occur through the inhalation of contaminated aerosols from mists, sprays, or other mechanisms that produce small water droplets that can be inhaled into the distal alveoli. In homes, the most common sites of exposure are showerheads and sinks, which are especially apt to produce particles small enough for inhalation. The role played by aspiration or microaspiration in exposures is more controversial but is hypothesized to be a secondary route for

developing pneumonia. Although human-to-human transmission is not a common pathway, a single presumptive case has been reported. After exposure, *L. pneumophila* has an incubation period of ~2–10 days; this period has been reported to be longer in immunosuppressed hosts. In contrast, symptoms of Pontiac fever occur within 24–48 h after exposure.

CLINICAL PRESENTATIONS

***Legionella* Pneumonia** *Legionella* pneumonia is the most common manifestation of legionellosis. In clinical practice, *Legionella* pneumonia is often referred to by clinicians as an "atypical pneumonia" (i.e., pneumonia that lacks the classic signs and symptoms of bronchopneumonia), and other bacterial pathogens, such as *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*, are also considered as etiologic agents. Initial symptoms of *Legionella* pneumonia are nonspecific and include fever, myalgias, headache, shortness of breath, and either a dry or a productive cough (Table 159-2). Patients with pneumonia who present with neurologic or gastrointestinal symptoms such as anorexia, nausea, or vomiting may be more likely than others to have legionellosis. Immunosuppressed patients may present without typical symptoms such as fever. Patients who have recently traveled, who present during a known or possible *Legionella* outbreak, or who develop pneumonia while hospitalized should undergo testing for legionellosis. Patients with severe pneumonia presentations, including acute respiratory failure, and those with pneumonia and sepsis-like presentations should undergo testing for *Legionella* as per current community-acquired pneumonia guidelines.

On clinical examination, patients with *Legionella* pneumonia classically present with rales, rhonchi, and—when consolidation is present—egophony and dullness to percussion. Not all patients, particularly immunosuppressed patients, present with pulmonary findings on clinical examination. Initial laboratory findings in patients with *Legionella* pneumonia include leukocytosis or leukopenia, thrombocytopenia, and elevated liver enzyme levels; hyponatremia and/or renal dysfunction are frequent findings. Levels of nonspecific laboratory markers of inflammation, such as C-reactive protein, can also be elevated; however, procalcitonin levels may not be as useful as a diagnostic tool. Although clinical symptoms and laboratory findings tend to be nonspecific, a number of clinical prediction tools, such as the Winthrop-University Hospital Criteria and the *Legionella* Score, have been developed to assist with the diagnosis of *Legionella* pneumonia. These scoring systems may be more useful for their negative than for their positive predictive value.

An important subset of *Legionella* pneumonia cases are those that are linked to health care systems—i.e., nosocomial cases. Although cases of hospital-acquired legionellosis are rare, their identification is necessary as they may be harbingers of contamination of water systems, devices, and/or potable water sources. Because of the rarity of nosocomial cases, outbreaks have sometimes occurred over years before the source is identified within the health care system. In this regard, the CDC offers the following definitions: (1) A *presumptive* health care–associated case of Legionnaires' disease is one developing in a patient with *Legionella* pneumonia after ≥10 days of continuous stay at a health care facility during the 14 days before onset of symptoms. (2) A *possible* case is one that develops in a patient with *Legionella* pneumonia who has spent a portion of the 14 days before symptom onset in one or more health care facilities but not enough time to meet the criteria for a presumptive case. To ensure that singular cases lead to more system-wide evaluations, the CDC also recommends an investigation if a health care system detects one or more cases of presumptive health care–associated Legionnaires' disease at any time or two or more possible cases within 12 months of one another.

TABLE 159-2 Clinical and Epidemiologic Features of *Legionella* Pneumonia (Legionnaires' Disease) and Pontiac Fever

FEATURE	*LEGIONELLA* PNEUMONIA	PONTIAC FEVER
Incubation period	2–10 days[a]	24–72 h
Pathogenesis	*Legionella* infection	*Legionella* infection or exposure
Common symptoms	Abdominal or chest pain Anorexia Cough, sputum production Confusion[b] Diarrhea[b] Fatigue Fever/chills Headache Myalgias Nausea/vomiting[b] Shortness of breath	Cough Diarrhea Fatigue Fever/chills Headache Myalgias Nausea/vomiting Vertigo
Risk factors	Age >40 years Male Smoker Immunosuppressed host Neurologic disease Chronic lung disease Organ dysfunction/ chronic illness	Factors associated with increased exposure
Attack rate among exposed individuals	~5%[c]	~90%
Hospitalization rate	>90%	<1%
ICU admission rate	30–50%	Extremely low
Treatment	Antibiotics (macrolide or fluoroquinolone)	Supportive care
Case-fatality rate[d]	10%	Extremely low

[a]Incubation period in immunosuppressed hosts may be longer than 14 days. [b]This symptom is strongly associated with *Legionella* pneumonia. [c]Attack rates are highly dependent on method of exposure, level of the pathogen in source water, and host's level of risk. [d]Case-fatality rates are much higher among immunosuppressed patients and those with severe underlying lung disease, ranging from 30 to 50%.

Abbreviation: ICU, intensive care unit.

PONTIAC FEVER

Pontiac fever is described as an influenza-like illness whose primary symptoms are fever, headache, myalgias, chills, vertigo, nausea, vomiting, and diarrhea (Table 159-2). Compared with *Legionella* pneumonia, Pontiac fever is a milder, self-limited illness that is defined by the absence of pneumonia. Although studies have shown that Pontiac fever is associated with exposure to higher counts of colony-forming units in water sources, the role of the pathogen in the disease is not clear. Symptoms usually develop 24–48 h after exposure and can last for 2–5 days. Since many other illnesses resemble Pontiac fever, the diagnosis usually relies on the recognition of typical clinical features during an outbreak situation; therefore, cases are likely to be missed even when patients present for health care. Studies documenting specific *Legionella* species as the cause of Pontiac fever clusters find that most are due to *L. pneumophila* exposure; however, non-*pneumophila* species such as *L. anisa* have also been associated with this presentation.

Extrapulmonary Disease A number of rare presentations for legionellosis have been described. Skin and soft tissue infections that resemble cellulitis, including cases due to tap water contamination of postsurgical wounds, have been reported. Endocarditis, primarily culture-negative prosthetic valve endocarditis, and myocarditis and pericarditis have also been reported. Rarely, *Legionella* species have been associated with septic arthritis and sinusitis.

DIAGNOSIS

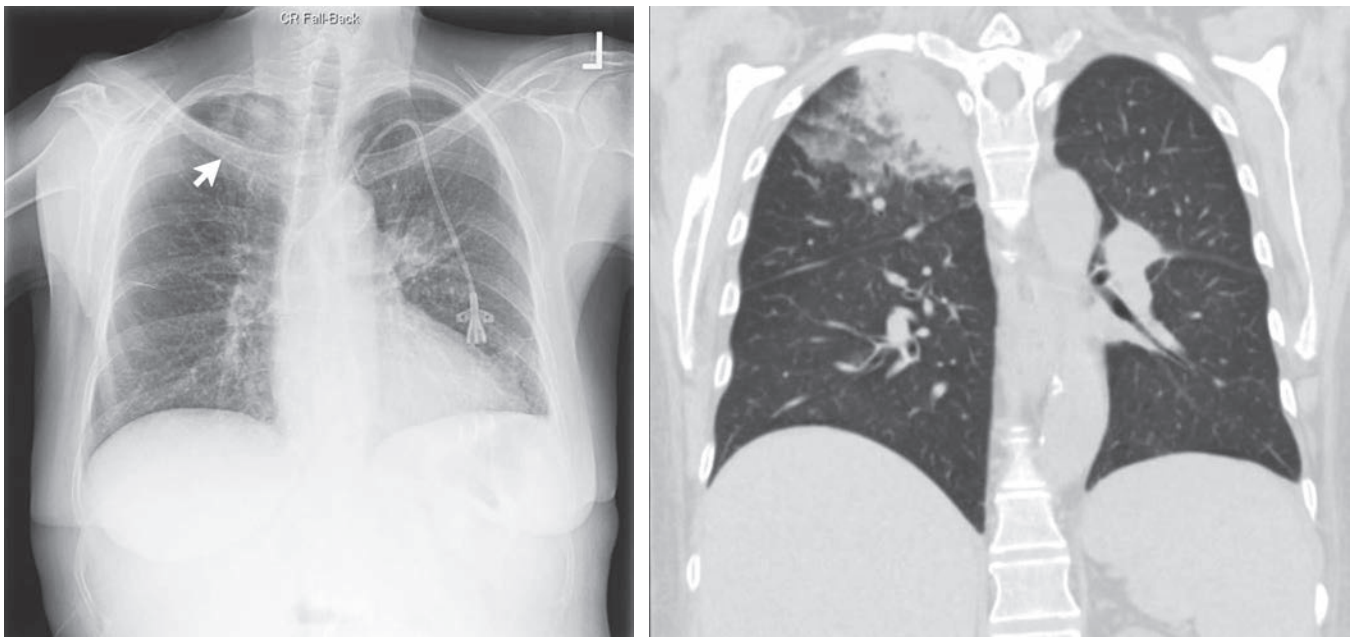
The diagnosis of legionellosis on the basis of clinical findings alone is difficult. Additional workup is needed to make a definitive diagnosis, even when cases are potentially linked to a possible outbreak. To make

FIGURE 159-3 Chest x-ray of a patient with *Legionella* pneumonia and right-lower-lobe consolidation. A 64-year-old woman presented with fever, dry cough, and shortness of breath 7 days after returning from international travel. *Legionella* urinary antigen testing was positive for *L. pneumophila* serotype 1.

a diagnosis, laboratory confirmation is needed, and invasive procedures may be required—e.g., bronchoscopy, particularly for patients whose results on urinary antigen testing are negative and who cannot produce sufficient sputum for testing or for patients with severe disease requiring intensive care unit (ICU) admission. As current treatment guidelines for community-acquired pneumonia recommend empirical coverage that includes antibiotics active against *Legionella* species, diagnostic testing is not routine even among persons who meet the criteria for *Legionella*-specific testing. Furthermore, not all currently available diagnostic laboratory assays are accessible or rapidly available in primary care clinics, urgent care facilities, and emergency rooms where patients may present with their initial symptoms.

Radiologic Findings On chest radiography, *Legionella* pneumonia presents as focal infiltrates or consolidations, most frequently in the lower lobes, that are indistinguishable from those due to other causes of pneumonia **(Fig. 159-3)**. On CT, air-space disease in one or more lobes is often with associated ground-glass opacities **(Fig. 159-4)**; pleural effusions and lymphadenopathy are less frequently seen. In immunocompromised patients, *Legionella* can present with similar lower-lobe consolidations or atypically as pulmonary nodules—with or without cavitation—that mimic fungal infections **(Fig. 159-5)** or even as lung abscesses. Progression during early therapy is not uncommon in immunosuppressed patients.

Laboratory Diagnostics • **CULTURE** Cultures—of sputum, bronchoalveolar lavage fluid, lung tissue, or extrapulmonary sites—are the gold standard for diagnosis of *Legionella* pneumonia because they are critical for epidemiologic investigations. *Legionella* species require special nutrients, such as cysteine, for growth and therefore require specialized media, such as buffered charcoal yeast extract (BCYE) agar. Legionellae grow slowly, usually over 3–5 days, with non-*pneumophila* species often requiring longer incubation times. Once growth is seen, *Legionella* can be stained with standard Gram's stain, and colonies often fluoresce blue or white under ultraviolet light. *L. micdadei* is the only *Legionella* species that is also modified-acid-fast positive. Sensitivity varies with the sample but is highest among lower respiratory tract samples. At some referral centers, lower-tract samples from high-risk immunosuppressed patient populations are routinely sent for culture. Unfortunately, because of current community-acquired pneumonia guidelines, patients are often treated empirically, and many either never have samples sent for *Legionella*-specific cultures or have such samples collected only after antibiotic administration, which decreases sensitivity. Respiratory cultures from patients with legionellosis are crucial during outbreak investigations, as clinical and environmental cultures can be compared by pulsed-gel electrophoresis or molecular sequencing to help identify common-source outbreaks; cultures are also used for serotyping of *L. pneumophila*.



A ***B***

FIGURE 159-4 Right-upper-lobe infiltrate in a patient with *L. pneumophila* pneumonia on chest x-ray and CT. An immunosuppressed patient from a long-term care facility presented with cough, sputum production, fever, and chills. New renal insufficiency and hyponatremia were documented. A chest x-ray (***A***) was consistent with a small right-upper-lobe infiltrate (*white arrow*), which was confirmed by CT (***B***). Urinary antigen testing for *L. pneumophila* serotype 1 was negative, but polymerase chain reaction on bronchoaveolar lavage fluid was positive for *L. pneumophila*.

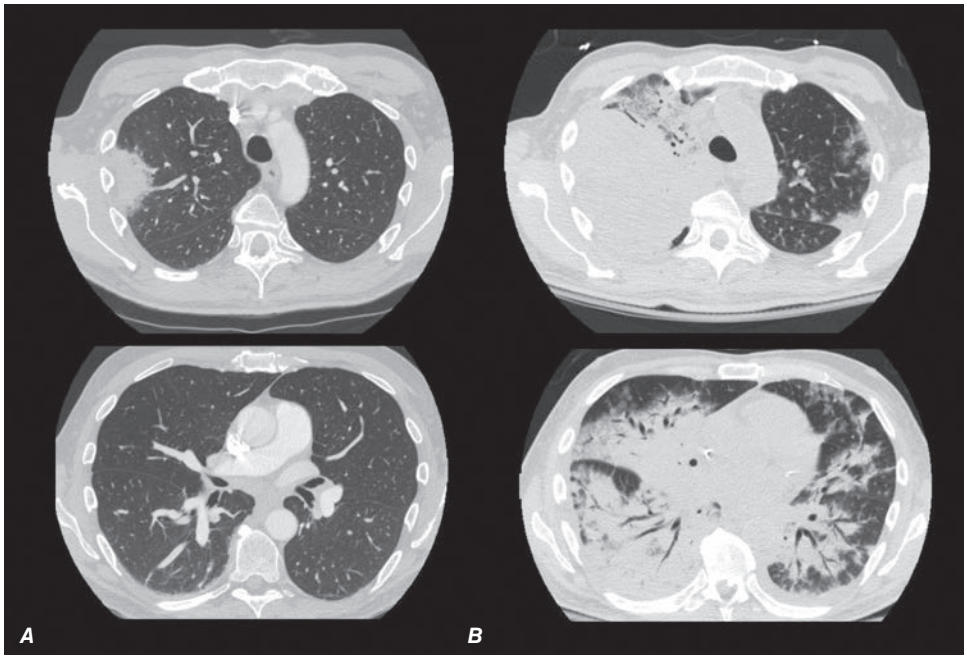


FIGURE 159-5 Nodular disease presentation on CT in an immunosuppressed patient infected with *L. micdadei*. *A.* Presenting CT scan in a hematopoietic cell transplant recipient presenting with fever and cough. A pulmonary nodule was noted in the right upper lobe. Bronchoscopy was performed; cultures were positive on day 5 for small white colonies on buffered charcoal yeast extract plates, and these colonies were eventually identified as *L. micdadei*. ***B.*** Repeat CT scan at day 12 demonstrated an enlarging nodule, diffuse infiltrates, and possible cavitation. The patient required intensive care unit admission and intubation despite appropriate targeted antibiotic therapy.

URINARY ANTIGEN TESTING *Legionella* urinary antigen tests are widely available at many hospitals and commercial laboratories and are characterized by ease of use, simple specimen collection, rapid turnaround time, high sensitivity, and the ability to detect the most prevalent *Legionella* species associated with clinical disease—*L. pneumophila* serotype 1. Urinary antigen testing has limitations, however: it detects only *L. pneumophila* serotype 1 and gives false-negative results in most cases caused by clinically important non–serotype 1 *L. pneumophila* and non-*pneumophila* species. Sensitivity for *L. pneumophila* serotype 1 is ~70% for most assays, but specificity is very high. The urinary antigen test can be negative very early in the disease and can remain positive for months after an infection, particularly in immunosuppressed patient populations; it cannot be used for patients who are anuric. Urinary antigen testing is not recommended for routine use in screening for exposures among asymptomatic patients in outbreak investigations.

SEROLOGY Acute- and convalescent-phase titers of antibody to *Legionella* have limited sensitivity in diagnosing acute Legionnaires' disease but can be useful during outbreak investigations. A case is *confirmed* by documenting a fourfold or greater rise in titer of specific serum antibody to *L. pneumophila* serogroup 1. A case is *suspected* in tests using pooled antigens by (1) a fourfold or greater rise in antibody titer to specific species (e.g., *L. longbeachae*) or non–serogroup 1 *L. pneumophila* or (2) a fourfold or greater rise in antibody titer to multiple species of *Legionella*. Some experts think that a single antibody level of ≥1:256 may be an adequate basis for diagnosing a presumptive case, but most prefer paired serology for confirmation. Serology is an imperfect tool; data suggest that as many as 20–30% of patients with proven legionellosis may not mount an antibody response that is sufficient for diagnosis, and the sensitivity and specificity of seroconversion with regard to non-*pneumophila Legionella* species are unclear among patients with altered immunity. Serology can provide important information for epidemiologic investigations, helping to identify additional cases missed by other diagnostic methods. In addition, the use of serologic testing during outbreak studies allows the investigation of patients without severe disease (e.g., those with Pontiac fever).

DIRECT FLUORESCENT ANTIBODY TESTING The sensitivity of direct fluorescent antibody (DFA) testing of sputum is lower than that of other testing modalities, ranging from 20 to 70% depending on the assay used. Most available assays target specific species (e.g., *L. pneumophila*) or serotypes. DFA testing may have a higher positive predictive value in patients with severe pneumonia or symptoms consistent with Legionnaires' disease, but it is not recommended for screening of low-risk patients because of the frequency of false-positive results.

MOLECULAR TESTING Polymerase chain reaction (PCR), loop-mediated isothermal amplification (LAMP), and other nucleic acid amplification tests are highly sensitive for lower respiratory tract specimens (e.g., sputum) and are becoming more widely available. Molecular methods can detect *Legionella* from multiple sources but are most commonly used for respiratory specimens such as sputum and bronchoalveolar lavage fluid. PCR is more sensitive than culture; in some studies, up to two to four times as many cases of lower tract disease were detected only by molecular methods. Molecular techniques also are useful in diagnosing infection in patients during antibiotic therapy. However, PCR methods are not used to determine *L. pneumophila* serotypes—information that is needed for epidemiologic investigations—and most commercially available assays target only *L. pneumophila*. Multiplex PCR tests for pneumonia and other respiratory pathogens are increasingly available and may include *L. pneumophila*.

TREATMENT

Legionella Pneumonia

Treatment of *Legionella* pneumonia involves antibiotics that target intracellular pathogens, whereas patients with Pontiac fever do not require antibiotic therapy. Macrolides and fluoroquinolones are the first-line agents for *Legionella* pneumonia according to guidelines in the United States and Europe **(Table 159-3)**. Macrolides disrupt protein production critical for survival of the organism. Although erythromycin or clarithromycin is effective, azithromycin is the preferred agent, as it is easier to tolerate and is involved

		or
		Combination therapy[c]

[a]Agents in bold type are considered first-line treatments. [b]All immunosuppressed patients should be considered to have moderate or severe disease and should be started on IV therapy if possible. All patients requiring inpatient care should receive IV therapy until their condition improves, at which point they can be switched to an oral agent. [c]Can consider combination therapy despite limited data demonstrating improved outcomes in severely ill patients. Combinations include either (1) a fluoroquinolone plus a macrolide or (2) a fluoroquinolone or a macrolide with a secondary agent. Secondary agents include doxycycline, minocycline, rifampin, and trimethoprim-sulfamethoxazole, all with varying efficacy for treatment.

Abbreviation: N/A, not applicable.

in fewer drug-drug interactions. Azithromycin and clarithromycin also reach higher intracellular concentrations than erythromycin.

Fluoroquinolones are potent agents against *Legionella* species. Data from both in vitro and in vivo models of infection suggest that fluoroquinolones may be more effective than macrolides, but no randomized clinical trials have yet compared the two drug classes for treatment of legionellosis. In nonrandomized observational studies, fluoroquinolones have been shown to be more effective than macrolides (erythromycin and clarithromycin) in terms of fever resolution and decreased duration of hospitalization; other such studies have shown no difference in outcome.

Both macrolides and fluoroquinolones are available as IV and oral formulations. Most experts prefer IV therapy during the first few days of treatment for patients with severe *Legionella* pneumonia. Secondary agents, such as rifampin, doxycycline, minocycline, and, less frequently, trimethoprim-sulfamethoxazole, have also been used, with mixed responses. Tigecycline, a third-generation glycylcycline related to tetracyclines, has been used for treatment of patients with significant antibiotic allergies. The novel aminomethylcycline antibiotic omadacycline appears to be efficacious in vitro, but its clinical efficacy has not been studied to date, and it is not currently recommended for routine use. Although data are limited, combination therapy does not appear to improve outcomes.

The duration of treatment for patients with mild disease is usually 10–14 days, but most symptoms will improve within the first 3–5 days of therapy. For immunosuppressed patients and patients with severe disease, a 3-week course of therapy is recommended. The duration of therapy for extrapulmonary manifestations of *Legionella* infection is unknown and depends on the site involved and clinical improvement. Resistance to macrolides and fluoroquinolones has been reported only rarely. Susceptibility testing is not routinely performed but is available in specialized laboratories and public health departments.

OUTCOMES

Legionella infections are associated with significant morbidity and mortality, leading to hospitalization and ICU admission of most patients who develop pneumonia. Case-fatality rates of *Legionella* pneumonia are reported to be ~10%, with death more likely among patients who are admitted to the ICU or have major comorbidities. Among patients in whom antibiotic treatment is delayed, mortality rates are approximately three times higher than among those treated earlier. Patients who develop nosocomial pneumonia attributable to health care–associated exposures, particularly those due to *L. pneumophila*, have case-fatality rates of ~25%. Death is a much more common outcome among immunocompromised hosts, whose mortality rates can reach ~30–50%. Assessment of long-term follow-up among patients who survive *Legionella* pneumonia demonstrates that more than one-quarter have ongoing complications after recovery, including recurrent hospitalizations, acute renal failure, respiratory complications, and recurrent pneumonias, among those who recover from severe disease. In contrast, recovery from Pontiac fever usually takes place within 3–5 days, as the disease is self-limiting; hospitalization, complications, and death related to Pontiac fever are extremely rare.

PREVENTION

Prevention of legionellosis starts with addressing water systems. Large municipal water systems provide water throughout the globe, but the quality of these systems varies regionally; many areas have limited access to potable water. Only limited regions have the resources to address *Legionella* water contamination; most water-monitoring agencies focus on control of enteric pathogens, such as *Escherichia coli* and other coliform bacteria, and do not have an adequate infrastructure to address *Legionella*. Even in countries and cities with more complex water systems, there is wide variation in how waterborne pathogens are addressed, and rules and regulations are often country dependent. In the Netherlands, for example, chlorination is not routine, whereas the United Kingdom and most countries in the European Union use chlorine routinely as the primary mode of disinfection for public water systems. Although regulated by the Environmental Protection Agency, management and treatment strategies in the United States vary by state and, in some instances, by city.

Prevention in the United States focuses on health care organizations and hospitals, where water-based exposures are more often linked to case fatalities. Federal requirements to reduce *Legionella* risk in the United States were first established in June 2017, when the Centers for Medicare and Medicaid Services required that all health care organizations develop and adhere to water management plans. These plans require the development of multidisciplinary teams, an understanding of the organization's water system, identification of high-risk areas (e.g., transplant units, oncology floors), identification of at-risk structures for *Legionella* growth, implementation and monitoring of control measures, methods for intervention if control measures fail, and procedures to assure documentation that policies are followed. All medical centers are required to have an awareness of water quality and to have systems in place to help prevent nosocomial *Legionella* pneumonia. Such policies leave water quality assessment, including testing for *Legionella*, up to the individual facility. In addition to hospitals, an increasing number of cities, including New York City, require similar water-management plans for cooling towers, with registration, testing, and mitigation options.

Even if detected in regional water systems, *Legionella* becomes a human pathogen only after replication in premise plumbing systems. In buildings, *Legionella* finds the ideal environment for logarithmic growth, which leads to exposures and subsequent disease. An important first step in prevention within hospitals is a review of plumbing systems to identify areas of concern and a review of impact areas such as dental clinics, ICUs, rehabilitation units, and units that house high-risk patients. Specific water features, such as therapy pools, ice machines, and decorative fountains, need policies for cleaning and disinfection. Targeted approaches to management of cooling towers,

such as high-efficiency drift eliminators and routine maintenance, are important considerations. In addition, areas that have undergone recent construction or renovation should be flagged, with prevention policies in place to address the associated risks. New construction or structural updates can lead to water stagnation, while modifications to plumbing can disrupt biofilms. Units with older premise plumbing are thought to be at higher risk, but even brand new facilities can become colonized during construction, with consequent outbreaks.

Testing for *Legionella* is an important step when presumptive or possible nosocomial pneumonia cases occur and can help address a facility's potential risks. There are a number of methods for environmental testing for *Legionella*, but environmental cultures are used in most hospitals because they quantify *Legionella* levels, allow species identification/serotyping, and can link environmental sources to nosocomial outbreaks. Testing usually focuses on locations where the index patient(s) may have had potential waterborne exposures (e.g., at showers and sinks). Other adjacent areas, along with those noted to be high-risk locations within the hospital, should be considered for additional testing; positive results should widen the testing area. Proactive testing is increasingly being used to preclude nosocomial cases; however, if testing is planned, it should be coupled with a management plan that addresses how *Legionella* will be dealt with if it is found in the water system and where and how frequently testing should be done; we recommend biannual or quarterly testing of select sites within hospital systems.

If a common-source outbreak is discovered, a number of approaches can be used to address *Legionella*. Regardless of source, immediate limitation of ongoing water exposures for patients in the affected room, unit, or floor is a crucial step in avoiding additional cases. Removing or replacing water features associated with exposures, such as decorative fountains and affected equipment or plumbing devices, may be needed. Immediate interventions such as heat shock (increasing water temperatures for a limited period) and hyperchlorination may also be useful as short-term steps in addressing an outbreak.

The addition of a disinfectant to the water system is one of the most common ways to address the presence of *Legionella*. Chemical disinfection with agents such as chlorine or monochloramine and copper and silver ionization are commonly used for secondary disinfection. Use of disinfectants requires routine maintenance and monitoring of chemical or ion levels to assure that they are sufficient for prevention. Lack of monitoring and system failures have led to breakthrough nosocomial *Legionella* cases. Another option is water filtration, which either can serve as a primary method for prevention or can be used in combination with secondary disinfection. Filters—either in-line with plumbing or at point-of-use sites—can be considered for either short- or long-term prevention during an outbreak. However, filters have a limited life span, can weaken water pressure, and are costly to maintain.

160 Pertussis and Other *Bordetella* Infections

Karina A. Top, Scott A. Halperin

Pertussis is an acute infection of the respiratory tract caused by *Bordetella pertussis*. The word *pertussis* means "violent cough," which aptly describes the most consistent and prominent feature of the illness. The inspiratory sound made at the end of an episode of paroxysmal coughing gives rise to the common name for the illness, "whooping cough." However, this feature is variable: it is uncommon among infants ≤6 months of age and is frequently absent in older children and adults. The Chinese name for pertussis is "the 100-day cough," which describes the clinical course of the illness accurately. The identification of *B. pertussis* was first reported by Bordet and Gengou in 1906, and vaccines were produced over the following two decades.

MICROBIOLOGY

Of the 10 identified species in the genus *Bordetella*, only four are of major medical significance. *B. pertussis* infects only humans and is the most important *Bordetella* species causing human disease. *B. parapertussis* causes an illness in humans that is similar to pertussis but is typically milder; co-infections with *B. parapertussis* and *B. pertussis* have been documented. With improved polymerase chain reaction (PCR) diagnostic methodology, up to 20% of patients with a pertussis-like syndrome have been found to be infected with *B. holmesii*, formerly thought to be an unusual cause of bacteremia. *B. bronchiseptica* is an important pathogen of domestic animals that causes kennel cough in dogs, atrophic rhinitis and pneumonia in pigs, and pneumonia in cats. Both respiratory infection and opportunistic infection due to *B. bronchiseptica* are reported occasionally in humans. *B. petrii*, *B. hinzii*, and *B. ansorpii* have been isolated from patients who are immunocompromised.

Bordetella species are gram-negative pleomorphic aerobic bacilli that share common genotypic characteristics. *B. pertussis* and *B. parapertussis* are the most similar of the species, but *B. parapertussis* does not express the gene coding for pertussis toxin. *B. pertussis* is a slow-growing fastidious organism that requires selective medium and forms small, glistening, bifurcated colonies. Suspicious colonies are presumptively identified as *B. pertussis* by direct fluorescent antibody testing or by agglutination with species-specific antiserum. *B. pertussis* is further differentiated from other *Bordetella* species by biochemical and motility characteristics.

B. pertussis produces a wide array of toxins and biologically active products that are important in its pathogenesis and in immunity. Most of these virulence factors are under the control of a single genetic locus that regulates their production, resulting in antigenic modulation and phase variation. Although these processes occur both in vitro and in vivo, their importance in the pathobiology of the organism is unknown; they may play a role in intracellular persistence and person-to-person spread. The organism's most important virulence factor is *pertussis toxin*, which is composed of a B oligomer–binding subunit and an enzymatically active A protomer that ADP-ribosylates a guanine nucleotide–binding regulatory protein (G protein) in target cells, producing a variety of biologic effects. Pertussis toxin has important mitogenic activity, affects the circulation of lymphocytes, and serves as an adhesin for bacterial binding to respiratory ciliated cells. Other important virulence factors and adhesins are *filamentous hemagglutinin*, a component of the cell wall, and *pertactin*, an outer-membrane protein. *Fimbriae*, bacterial appendages that play a role in bacterial attachment, are the major antigens against which agglutinating antibodies are directed. These agglutinating antibodies have historically been the primary means of serotyping *B. pertussis* strains. Other virulence factors include tracheal cytotoxin, a peptidoglycan fragment, which causes inflammatory respiratory epithelial damage; adenylate

cyclase-hemolysin toxin, which impairs host phagocytic cell function; dermonecrotic toxin, which may contribute to respiratory mucosal damage; and lipooligosaccharide, which has properties similar to those of other gram-negative bacterial endotoxins. Since 2010, the emergence of pertactin-negative strains has been observed worldwide, and these strains now predominate in some regions, perhaps from immune pressure resulting from the use of pertactin-containing acellular pertussis vaccines.

EPIDEMIOLOGY

Pertussis is a highly communicable disease, with attack rates of 80–100% among unimmunized household contacts and 20% within households in well-immunized populations. The infection has a worldwide distribution, with cyclical outbreaks every 3–5 years (a pattern that has persisted despite widespread immunization). Pertussis occurs in all months; however, in North America, its activity peaks in autumn and winter.

In developing countries, pertussis remains an important cause of infant morbidity and death. The reported incidence of pertussis worldwide has decreased as a result of improved vaccine coverage **(Fig. 160-1)**. However, coverage rates are still <60% in many developing nations; the World Health Organization (WHO) estimates that 90% of the burden of pertussis is in developing regions. In addition, over-reporting of immunization coverage and under-reporting of disease result in substantial underestimation of the global burden of pertussis. The WHO estimates that there were 161,000 deaths from pertussis among children <5 years of age in 2014.

Before the institution of widespread immunization programs in the developed world, pertussis was one of the most common infectious causes of morbidity and death. In the United States before the 1940s, between 115,000 and 270,000 cases of pertussis were reported annually, with an average yearly rate of 150 cases per 100,000 population. With universal childhood immunization, the number of reported cases fell by >90%, and mortality rates decreased even more dramatically. Only 1010 cases of pertussis were reported in 1976 **(Fig. 160-2)**. After that historic low, rates of pertussis increased slowly. In recent years, pertussis epidemics have been reported with increasing frequency in high-income countries, including Australia, the United Kingdom, and the United States. The United States experienced widespread outbreaks of pertussis in 2005, 2010, 2012, and 2014 at levels not seen in 40–50 years (48,000 reported cases in 2012).

Although thought of as a disease of childhood, pertussis can affect people of all ages and is a known cause of prolonged coughing illness in adolescents and adults. In unimmunized populations, pertussis incidence peaks during the preschool years, and well over half of children have the disease before reaching adulthood. In highly immunized populations such as those in North America, the peak incidence is among infants <1 year of age who have not completed the three-dose primary immunization series. An increase in pertussis incidence among adolescents and adults began in the late 1990s and led to the introduction of an adolescent booster dose across North America by 2006. While the disease burden among adolescents decreased initially, children 7–10 years of age emerged as a high-risk group during a major outbreak in 2010. Most of the affected children were fully immunized. Subsequent outbreaks in 2012 and 2014 showed a shift in epidemiology, with pertussis incidence increasing among adolescents while still remaining elevated among 10-year-olds. The most highly affected cohorts were those who received acellular pertussis vaccines in infancy. Although adults contribute a smaller proportion of reported cases of pertussis than do children and adolescents, this difference may be related to a greater degree of under-recognition and under-reporting. A number of studies of prolonged coughing illness suggest that *B. pertussis* may be the etiologic agent in 12–30% of adults with cough that does not improve within 2 weeks. In one study of the efficacy of an acellular pertussis vaccine in adolescents and adults, the incidence of pertussis in the placebo group was 3.7–4.5 cases per 1000 person-years. Although this prospective cohort study yielded a lower estimate than the studies of cough illness, its results still translate to ~1 million cases of pertussis annually among adults in the United States. In addition, asymptomatic pertussis infection is common and appears to contribute to disease transmission.

Severe morbidity and high mortality rates, however, are restricted almost entirely to infants. In the United States between 2008 and 2011, 83% of pertussis deaths involved infants ≤3 months and >35% of infants with pertussis required hospitalization. Although school-age children are the source of infection for most households, adults are

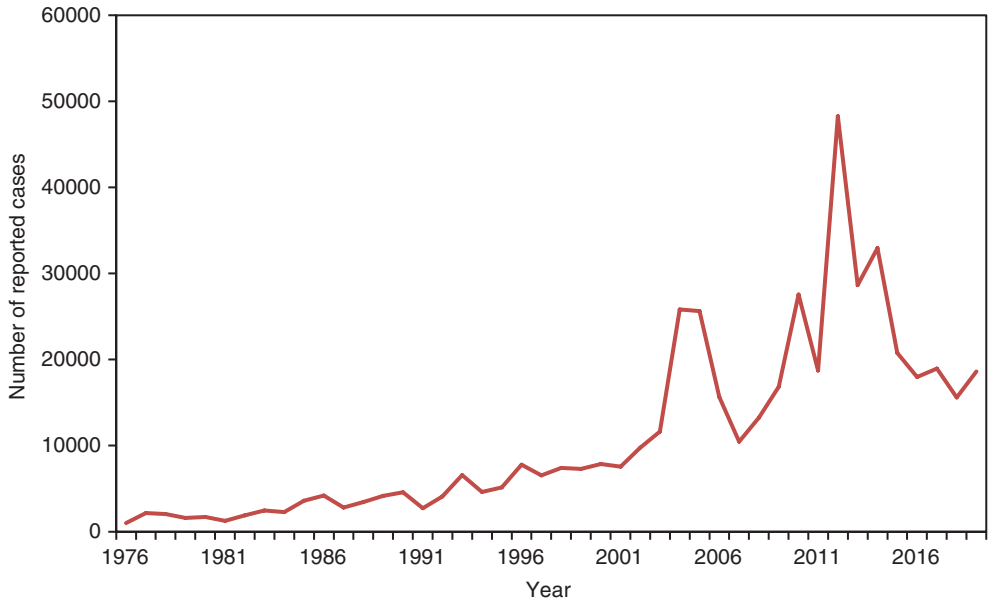

FIGURE 160-2 Reported cases of pertussis by year—United States, 1976–2019. *(From the Centers for Disease Control and Prevention, www.cdc.gov/pertussis/surv-reporting/cases-by-year.html. Accessed June 4, 2021.)*

often the source for cases in high-risk infants and may serve as the reservoir of infection between epidemic years.

PATHOGENESIS

Infection with *B. pertussis* is initiated by attachment of the organism to the ciliated epithelial cells of the nasopharynx. Attachment is mediated by surface adhesins (e.g., pertactin and filamentous hemagglutinin), which bind to the integrin family of cell-surface proteins, probably in conjunction with pertussis toxin. The role of fimbriae in adhesion and in maintenance of infection has not been fully delineated. Perhaps the result of redundancy of adhesins, no differences in virulence or clinical manifestations have been detected with the emergence of pertactin-negative strains. At the site of attachment, the organism multiplies, producing a variety of other toxins that cause local mucosal damage (tracheal cytotoxin, dermonecrotic toxin). Impairment of host defense by *B. pertussis* is mediated by pertussis toxin and adenylate cyclase-hemolysin toxin. There is local cellular invasion, with intracellular bacterial persistence; however, systemic dissemination does not occur. Systemic manifestations (lymphocytosis) result from the effects of the toxins.

The pathogenesis of the clinical manifestations of pertussis is poorly understood. It is not known what causes the hallmark paroxysmal cough. A pivotal role for pertussis toxin has been proposed but has not been confirmed. It is thought that neurologic events in pertussis, such as seizures and encephalopathy, are due to hypoxia from coughing paroxysms or apnea rather than to the effects of specific bacterial products. *B. pertussis* pneumonia, which occurs in up to 10% of infants with pertussis, is usually a diffuse bilateral primary infection. In older children and adults with pertussis, pneumonia is often due to secondary bacterial infection with streptococci or staphylococci. Deaths from pertussis among young infants are frequently associated with very high levels of leukocytosis and pulmonary hypertension.

IMMUNITY

Both humoral and cell-mediated immunity are thought to be important in pertussis. Although immunity after natural infection was thought to be lifelong, seroepidemiologic evidence demonstrates that it is not and that subsequent episodes of clinical pertussis are prevented by intermittent subclinical infection. Pertussis agglutinins were correlated with protection in early studies of whole-cell pertussis vaccines. Antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae are all protective in animal models. Serologic correlates of protection conferred by acellular pertussis vaccines have not been established, although antibody to pertactin, fimbriae, and (to a lesser degree) pertussis toxin correlated best with protection in two efficacy trials. The duration of immunity after whole-cell pertussis vaccination is short-lived, with little protection remaining after 10–12 years. Waning of immunity is even more rapid in adolescents and children who have received all of their immunizations with acellular vaccines—i.e., within 2–4 years after the fifth or sixth dose. The type of immune response elicited may have an effect on duration of protection; natural infection and whole-cell pertussis vaccine elicit a TH1/TH17-predominant response whereas acellular pertussis vaccines stimulate a TH2-biased response.

CLINICAL MANIFESTATIONS

Pertussis is a prolonged coughing illness with clinical manifestations that vary by age (Table 160-1). Although not uncommon among adolescents and adults, classic pertussis is most often seen in preschool and school-age children. After an incubation period averaging 7–10 days, an illness develops that is indistinguishable from the common cold and is characterized by coryza, lacrimation, mild cough, low-grade fever, and malaise. After 1–2 weeks, this *catarrhal phase* evolves into the *paroxysmal phase*: the cough becomes more frequent and spasmodic with repetitive bursts of 5–10 coughs, often within a single expiration. Post-tussive vomiting is frequent, with a mucous plug occasionally expelled at the end of an episode. The episode may be terminated by an audible whoop, which occurs upon rapid inspiration against a closed glottis at the end of a paroxysm. During a spasm, there may be impressive neck-vein distension, bulging eyes, tongue protrusion, and cyanosis. Paroxysms may be precipitated by noise, eating, or physical contact.

TABLE 160-1 Clinical Features of Pertussis, by Age Group and Diagnostic Status

FEATURE	PERCENTAGE OF PATIENTS	
	ADOLESCENTS AND ADULTS	INFANTS AND CHILDREN
Cough		
Paroxysmal	70–99	89–93
Worse at night	61–87	41
Whoop	8–82	69–92
Post-tussive vomiting	17–65	48–60

Source: Republished with permission of American Society for Microbiology from Pertussis: Microbiology, disease, treatment, and prevention, PE Kilgore et al: 29:449, 2016; permission conveyed through Copyright Clearance Center, Inc.

Between attacks, the patient's appearance is normal, but increasing fatigue is evident. The frequency of paroxysmal episodes varies widely, from several per hour to 5–10 per day. Episodes are often worse at night and interfere with sleep. Most complications occur during the paroxysmal stage. Fever is uncommon and suggests bacterial superinfection.

After 2–4 weeks, the coughing episodes become less frequent and less severe—changes heralding the onset of the *convalescent phase*. This phase can last 1–3 months and is characterized by gradual resolution of coughing episodes. For 6–12 months, intercurrent viral infections may be associated with a recrudescence of paroxysmal cough.

Not all individuals who develop pertussis have classic disease. The clinical manifestations in adolescents and adults are more often atypical. The cough is severe, prolonged, and often paroxysmal. Though uncommon, a whoop and vomiting with cough are more specific signs of pertussis in adults with prolonged cough. Other suggestive features are a cough at night, sweating episodes between paroxysms of coughing, and exposure to other individuals with a prolonged coughing illness.

COMPLICATIONS

Complications are frequently associated with pertussis and are more common among infants than among older children or adults. Subconjunctival hemorrhages, abdominal and inguinal hernias, pneumothoraces, and facial and truncal petechiae can result from increased intrathoracic pressure generated by severe fits of coughing. Weight loss can follow decreased caloric intake. Urinary incontinence, rib fracture, carotid artery aneurysm, and cough syncope have also been reported in adolescents and adults with pertussis. In a series of more than 1100 children <2 years of age who were hospitalized with pertussis, 27.1% had apnea, 9.4% had pneumonia, 2.6% had seizures, and 0.4% had encephalopathy; 10 children (0.9%) died. Pneumonia is reported in <5% of adolescents and adults and increases in frequency after 50 years of age. In contrast to the primary *B. pertussis* pneumonia that develops in infants, pneumonia in adolescents and adults with pertussis is usually caused by a secondary infection with encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*.

DIAGNOSIS

If the classic symptoms of pertussis are present, clinical diagnosis is not difficult. However, particularly in older children and adults, it is difficult to differentiate infections caused by *B. pertussis* and *B. parapertussis* from other respiratory tract infections on clinical grounds. Therefore, laboratory confirmation should be attempted in all cases. Lymphocytosis (absolute lymphocyte count $>10^8$–10^9/L) is common among young children, in whom it is unusual with other infections, but not among adolescents and adults. Culture of nasopharyngeal secretions remains the gold standard of diagnosis because of its 100% specificity, although DNA detection by PCR has replaced culture in many laboratories because of substantially increased sensitivity and quicker results. Appropriate PCR methodology must include primers to differentiate among *B. pertussis*, *B. parapertussis*, and *B. holmesii*. The best specimen is collected by nasopharyngeal aspiration, in which a fine flexible plastic catheter attached to a 10-mL syringe is passed into the nasopharynx and withdrawn while gentle suction is applied. Since *B. pertussis* is highly sensitive to drying, secretions for culture should be inoculated without delay onto appropriate medium (Bordet-Gengou or Regan-Lowe), or the catheter should be flushed with a phosphate-buffered saline solution for culture and/or PCR. An alternative to the aspirate is a Dacron or rayon nasopharyngeal swab; again, inoculation of culture plates should be immediate or an appropriate transport medium (e.g., Regan-Lowe charcoal medium) should be used. Results of PCR can be available within hours; cultures become positive by day 5 of incubation.

Nasopharyngeal cultures in untreated pertussis remain positive for a mean of 3 weeks after the onset of illness; these cultures become negative within 5 days of the institution of appropriate antimicrobial therapy. The duration of a positive PCR in untreated pertussis or after therapy is not known but exceeds that of positive cultures. Since much of the period during which the organism can be recovered from the nasopharynx falls into the catarrhal phase, when the etiology of the infection is not suspected, there is only a small window of opportunity for culture-proven diagnosis. Cultures from infants and young children are more frequently positive than those from older children and adults; this difference may reflect earlier presentation of the former age group for medical care. Direct fluorescent antibody tests of nasopharyngeal secretions for direct diagnosis may still be available in some laboratories but should not be used because of poor sensitivity and specificity.

As a result of the difficulties with laboratory diagnosis of pertussis in adolescents, adults, and patients who have been symptomatic for >4 weeks, increasing attention is being given to serologic diagnosis. Enzyme immunoassays detecting IgA and IgG antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae have been developed and assessed for reproducibility. Two- or fourfold increases in antibody titer are suggestive of pertussis, although cross-reactivity of some antigens (such as filamentous hemagglutinin and pertactin) among *Bordetella* species makes it difficult to depend diagnostically on seroconversion involving a single type of antibody. Criteria for serologic diagnosis based on comparison of results for a single serum specimen with established population values are gaining acceptance, and serologic measurement of antibody to pertussis toxin is becoming more widely standardized and available for diagnostic purposes, particularly in outbreak settings and for surveillance.

DIFFERENTIAL DIAGNOSIS

A child presenting with paroxysmal cough, post-tussive vomiting, and whoop is likely to have an infection caused by *B. pertussis* or *B. parapertussis*; lymphocytosis increases the likelihood of a *B. pertussis* etiology. Viruses such as respiratory syncytial virus, rhinovirus, and adenovirus have been isolated from patients with clinical pertussis but probably represent co-infection, particularly in children <1 year of age.

In adolescents and adults, who often do not have paroxysmal cough or whoop, the differential diagnosis of a prolonged coughing illness is more extensive. Pertussis should be suspected when any patient has a cough that does not improve within 14 days, a paroxysmal cough of any duration, a cough followed by vomiting (adolescents and adults), or any respiratory symptoms after contact with a laboratory-confirmed case of pertussis. Other etiologies to consider include infections caused by *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, adenovirus, influenza virus, and other respiratory viruses. Use of angiotensin-converting enzyme (ACE) inhibitors, reactive airway disease, and gastroesophageal reflux disease are well-described noninfectious causes of prolonged cough in adults.

TREATMENT

Pertussis

ANTIBIOTICS

The purpose of antibiotic therapy for pertussis is to eradicate the infecting bacteria from the nasopharynx; therapy does not substantially alter the clinical course unless given early in the catarrhal phase. Macrolide antibiotics are the drugs of choice for treatment of pertussis **(Table 160-2)**; macrolide-resistant *B. pertussis* strains have been reported but are rare. Trimethoprim-sulfamethoxazole is recommended as an alternative for individuals allergic to macrolides.

SUPPORTIVE CARE

Young infants have the highest rates of complication and death from pertussis; therefore, most infants (and older children with severe disease) should be hospitalized. A quiet environment may decrease the stimulation that can trigger paroxysmal episodes. Use of β-adrenergic agonists and/or glucocorticoids has been advocated by some authorities but has not been proven to be effective. Cough suppressants are not effective and play no role in the management of pertussis.

INFECTION CONTROL MEASURES

Hospitalized patients with pertussis should be placed in respiratory isolation, with the use of precautions appropriate for pathogens

TABLE 160-2 Antimicrobial Therapy for Pertussis

DRUG	ADULT DAILY DOSE	FREQUENCY	DURATION, DAYS	COMMENTS
Erythromycin estolate	500 mg	3–4 times per day	7–14	Frequent gastrointestinal side effects
Clarithromycin	500 mg	Twice a day	7	—
Azithromycin	500 mg on day 1, 250 mg subsequently	1 daily dose	5	—
Trimethoprim-sulfamethoxazole	160 mg of trimethoprim, 800 mg of sulfamethoxazole	Twice a day	14	For patients allergic to macrolides; data on effectiveness limited

spread by large respiratory droplets. Isolation should continue for 5 days after initiation of macrolide therapy or, in untreated patients, for 3 weeks (i.e., until nasopharyngeal cultures are consistently negative).

PREVENTION

Chemoprophylaxis Because the risk of transmission of *B. pertussis* within households is high, chemoprophylaxis is widely recommended for household contacts of pertussis cases regardless of their immunization status and should be initiated within 21 days of cough onset in the index case. The effectiveness of chemoprophylaxis is supported by several epidemiologic studies of institutional and community outbreaks. In the only randomized, placebo-controlled study, erythromycin estolate (50 mg/kg per day; maximum dose, 1 g/d) was effective in reducing the incidence of bacteriologically confirmed pertussis by 67%; however, there was no decrease in the incidence of clinical disease. Despite these results, authorities continue to recommend chemoprophylaxis, particularly in households with members at high risk of severe disease (children <1 year of age, pregnant women). Data on the use of the newer macrolides for chemoprophylaxis are not available, but these drugs are commonly used because of their increased tolerability and their effectiveness.

Immunization **(See also Chap. 123)** The mainstay of pertussis prevention is active immunization. Pertussis vaccine became widely used in North America after 1940; the reported number of pertussis cases subsequently fell by >90%. Whole-cell pertussis vaccines are prepared through the heating, chemical inactivation, and purification of whole *B. pertussis* organisms. Despite their efficacy (average estimate, 85%; range for different products, 30–100%), whole-cell pertussis vaccines are associated with adverse events—both common (fever; injection-site pain, erythema, and swelling; irritability) and uncommon (febrile seizures, hypotonic-hyporesponsive episodes). Alleged associations of whole-cell pertussis vaccine with encephalopathy, sudden infant death syndrome, and autism, although not substantiated, spawned an active anti-immunization lobby. The development of acellular pertussis vaccines, which are effective and less reactogenic, has greatly alleviated concerns about the inclusion of pertussis vaccine in the combined infant immunization series.

Although a wide variety of acellular pertussis vaccines were developed, only a few are still marketed widely; all contain pertussis toxoid and filamentous hemagglutinin. One acellular pertussis vaccine also contains pertactin, and another contains pertactin and two types of fimbriae. Adult formulations of acellular pertussis vaccines have been shown to be safe, immunogenic, and efficacious in clinical trials in adolescents and adults and are now recommended for routine immunization of these groups in several countries.

Although whole-cell vaccines are still used extensively in developing regions of the world, acellular pertussis vaccines are used exclusively for childhood immunization in much of the developed world. In light of evidence of early waning of immunity among children who received acellular pertussis vaccine in infancy, the WHO Strategic Advisory Group of Experts (SAGE) recommends that countries using whole-cell pertussis vaccine for the primary infant immunization series continue to do so. In countries using acellular pertussis vaccines in infancy, additional booster immunizations in older children, adolescents, and adults are recommended to prevent pertussis in high-risk infants. Pertussis immunization is also recommended during pregnancy to increase passive transfer of maternal antibodies to the fetus. Studies in high-income countries demonstrate that immunization of women during pregnancy is 90–93% effective at preventing pertussis in infants <2 months of age and is safe. In North America, acellular pertussis vaccines for children are given as a three-dose primary series at 2, 4, and 6 months of age, with a reinforcing dose at 15–18 months of age and a booster dose at 4–6 years of age. Adolescents (11–18 years of age) and all unvaccinated adults should receive a dose of the adult-formulation diphtheria–tetanus–acellular pertussis vaccine. Immunization is specifically recommended for health care providers, individuals in close contact with infants, and women during the third trimester of every pregnancy. Pertussis vaccine coverage among U.S. adolescents was 86.4% in 2015, and coverage among pregnant women was 48.8% in 2015–2016. However, coverage among adults remains low (23.1% in 2015). Further improvements in adult vaccine coverage may permit better control of pertussis across the age spectrum, with collateral protection of infants too young to be immunized. However, more effective vaccines with longer-lasting protection will ultimately be needed to control this disease.

161 Diseases Caused by Gram-Negative Enteric Bacilli

Thomas A. Russo, James R. Johnson

GENERAL FEATURES AND PRINCIPLES

The post-antibiotic era has begun. For most people, this is the first time in their lives that an effective treatment for a bacterial infection may not exist. The Enterobacteriaceae are at the forefront of this evolving public health crisis. For example, the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have designated carbapenem-resistant Enterobacteriaceae (CRE) as representing a threat level of "urgent" and "priority one, critical."

Enterobacteriaceae are responsible for a significant proportion of the deaths attributed to antimicrobial-resistant bacteria, of which an estimated 23,000 and 25,000 occur annually in the United States and the European Union, respectively, and three to five times as many (per capita) in low- and middle-income countries (e.g., Thailand). These pathogens cause a wide variety of infections involving diverse anatomic sites in both healthy and compromised hosts. Therefore, a thorough knowledge of clinical presentations and appropriate therapeutic choices is necessary for optimal outcomes. *Escherichia coli*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, *Cronobacter*, and *Edwardsiella* are enteric gram-negative bacilli (GNB) within the family Enterobacteriaceae that commonly cause extraintestinal infections. *Salmonella*, *Shigella*, and *Yersinia*, which also are in the family Enterobacteriaceae but more commonly cause gastrointestinal infections, are discussed in **Chaps. 165, 166, and 171**, respectively.

EPIDEMIOLOGY

E. coli, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, *Cronobacter*, and *Edwardsiella* are components of the normal animal and human colonic microbiota and/or the microbiota in various environmental habitats, including long-term-care facilities (LTCFs) and hospitals. As a result, except for certain pathotypes of intestinal pathogenic *E. coli*, these genera are global pathogens. The incidence of infection due to these agents is increasing because of the combination of an aging population and increasing antimicrobial resistance. In healthy humans, *E. coli* is the predominant species of GNB in the colonic microbiota, followed by *Klebsiella* and *Proteus*. GNB (primarily *E. coli*, *Klebsiella*, and *Proteus*) can also colonize the oropharynx and intact skin but, in healthy individuals, tend to do so only transiently. By contrast, in LTCFs and hospital settings, a variety of GNB emerge as the dominant colonizers of both mucosal and skin epithelial surfaces, particularly in association with antimicrobial use, severe illness, and extended length of stay. LTCFs are emerging as an important reservoir for resistant GNB. Such colonization with GNB may lead to subsequent extraintestinal infection; for example, oropharyngeal colonization may lead to pneumonia, and colonic/perineal colonization may lead to urinary tract infection (UTI). The use of ampicillin or amoxicillin was associated with an increased risk of subsequent infection due to the hypervirulent pathotype of *Klebsiella pneumoniae* in Taiwan; this association suggests that changes in the quantity or prevalence of colonizing bacteria may significantly influence the risk of infection. *Serratia*, *Enterobacter*, and, less commonly, *Citrobacter* infection may be acquired directly through a variety of infusates (e.g., medications, blood products, non–U.S. Food and Drug Administration [FDA] approved stem cell products). *Edwardsiella* infections are acquired through freshwater and marine environment exposures and are most common in Southeast Asia.

STRUCTURE AND FUNCTION

Enteric GNB possess an extracytoplasmic outer membrane consisting of a lipid bilayer with associated proteins, lipoproteins, and polysaccharides (capsule, lipopolysaccharide). The outer membrane interfaces with the external environment, including the human host. A variety of components of the outer membrane are critical determinants in pathogenesis (e.g., capsule) and antimicrobial resistance (e.g., permeability barrier, efflux pumps). In addition, secreted products play an important role in both host infection (e.g., iron acquisition molecules) and environmental niche survival and colonization (e.g., type VI secretion systems).

PATHOGENESIS

Multiple bacterial virulence factors are required for the pathogenesis of infections caused by GNB. Possession of specialized virulence genes defines pathogens and enables them to infect the host efficiently. Hosts and their cognate pathogens have been co-adapting throughout evolutionary history. During the host–pathogen "chess match" over time, various and redundant strategies have emerged in both the pathogens and their hosts **(Table 161-1)**.

TABLE 161-1 Interactions of Extraintestinal Pathogenic *Escherichia coli* with the Human Host: A Paradigm for Extracellular, Extraintestinal Gram-Negative Bacterial Pathogens

BACTERIAL GOAL	HOST OBSTACLE	BACTERIAL SOLUTION
Extraintestinal attachment	Flow of urine, mucociliary escalator	Multiple adhesins (e.g., type 1, S, and F1C fimbriae; P pili)
Nutrient acquisition for growth	Nutrient sequestration (e.g., iron via intracellular storage and extracellular scavenging via lactoferrin and transferrin)	Cellular lysis (e.g., hemolysin), multiple mechanisms for competing for iron (e.g., siderophores) and other nutrients
Initial avoidance of host bactericidal activity	Complement, phagocytic cells, antimicrobial peptides	Capsular polysaccharide, lipopolysaccharide
Dissemination (within host and between hosts)	Intact tissue barriers	Irritant tissue damage resulting in increased excretion (e.g., toxins such as hemolysin), invasion of brain endothelium
Late avoidance of host bactericidal activity	Acquired immunity (e.g., specific antibodies), treatment with antibiotics	Cell entry, acquisition of antimicrobial resistance

Intestinal pathogenic (diarrheagenic) mechanisms are discussed below. The members of the Enterobacteriaceae family that cause extraintestinal infections are primarily extracellular pathogens and therefore share certain pathogenic features. The two principal components of host defense against Enterobacteriaceae, regardless of species, are innate immunity (including intact skin and mucosal barriers; the withholding of nutrients; and the activities of complement, antimicrobial peptides, and professional phagocytes) and humoral immunity. Both susceptibility to and severity of infection are increased with dysfunction or deficiencies of these host components. By contrast, the virulence traits of intestinal pathogenic *E. coli*—i.e., the distinctive strains that can cause diarrheal disease—are for the most part different from those of extraintestinal pathogenic *E. coli* (ExPEC) and other GNB that cause extraintestinal infections. This distinction reflects site-specific differences in host environments, defense mechanisms, and physiological derangements that lead to disease.

A given enterobacterial strain usually possesses multiple adhesins for binding to a variety of host cells (e.g., in *E. coli*: type 1, S, and F1C fimbriae; P pili). Nutrient acquisition (e.g., of iron via siderophores) requires many genes that are necessary but not sufficient for pathogenesis. The ability to resist the bactericidal activity of complement and phagocytes in the absence of antibody (e.g., as conferred by capsule or the O antigen component of lipopolysaccharide) is one of the defining traits of an extracellular pathogen. Tissue damage (e.g., as mediated by *E. coli* hemolysin) may facilitate nutrient acquisition and spread within the host. Without doubt, many important virulence genes await identification.

The ability to induce septic shock is another defining feature of these genera. GNB are the most common causes of this potentially lethal syndrome. Pathogen-associated molecular pattern molecules (PAMPs; e.g., the lipid A moiety of lipopolysaccharide) stimulate a proinflammatory host response via pattern recognition receptors (e.g., Toll-like or C-type lectin receptors) that activate host defense signaling pathways; if overly exuberant, this response results in shock **(Chap. 304)**. Direct bacterial damage of host tissue (e.g., by toxins) or collateral damage from the host response can result in the release of damage-associated molecular pattern molecules (DAMPs; e.g., HMGB1) that can propagate a detrimental proinflammatory host response.

Many antigenic variants (serotypes) exist in most genera of GNB. For example, *E. coli* has >150 O (somatic) antigens, 80 K (capsular) antigens, and 53 H (flagellar) antigens. This antigenic variability, which permits immune evasion and allows recurrent infection by different strains of the same species, has impeded vaccine development **(Chap. 123)**.

INFECTIOUS SYNDROMES

Depending on both the host and the pathogen, GNB can infect nearly every organ or body cavity. *E. coli* can cause either intestinal or extraintestinal infection, depending on the particular pathotype, and *Edwardsiella tarda* can cause both intestinal and extraintestinal infection. *Klebsiella* causes primarily extraintestinal infection, but a toxin-producing variant of *Klebsiella oxytoca* has been associated with hemorrhagic colitis, and *Providencia alcalifaciens* and *Escherichia albertii* have been associated with gastroenteritis.

E. coli and—to a lesser degree—*Klebsiella* account for most extraintestinal infections due to GNB. These species (for *K. pneumoniae*, primarily its hypervirulent pathotype) are the most virulent pathogens within this group, as demonstrated by their ability to cause severe infections in healthy, ambulatory hosts from the community. However, the other genera of GNB are also important extraintestinal pathogens, especially among LTCF residents and hospitalized patients, in large part because of the intrinsic or acquired antimicrobial resistance of these organisms and the increasing number of individuals with compromised host defenses. The mortality rate is substantial in many GNB infections and correlates with severity of illness, underlying host status, and in some cases the antimicrobial resistance of the infecting pathogen, which can result in suboptimal therapy. Especially problematic are pneumonia, sepsis, and septic shock (arising from any site of infection), for which the associated mortality rates are 20–60%.

DIAGNOSIS

Isolation of GNB from sterile sites almost always implies infection, whereas their isolation from nonsterile sites, particularly open wounds and the respiratory tract, requires clinical correlation to differentiate colonization from infection. Clinical microbiology laboratories are increasingly incorporating newer diagnostic methodologies (e.g., matrix-assisted laser desorption–ionization–time-of-flight mass spectrometry [MALDI-TOF-MS] and polymerase chain reaction [PCR]) and immunoassays to enhance the sensitivity, accuracy, and rapidity of reporting on pathogen identification and resistance genes. This information can be used to increase the timeliness of initiation and/or the accurate selection of empirical antimicrobial therapy, thereby improving outcomes.

TREATMENT

Principles Guiding Treatment in the Era of Increasing Antimicrobial Resistance

(See also Chap. 144) Initiation of appropriate empirical antimicrobial therapy early in the course of infections due to GNB (particularly the more serious ones) leads to improved outcomes. The ever-increasing prevalence of multidrug-resistant (MDR) and extensively drug-resistant (XDR) GNB; the lag between published and current resistance rates; and variations in antimicrobial susceptibility by species, geographic location, regional antimicrobial use, and hospital site (e.g., intensive care units [ICUs] vs wards) necessitate familiarity with evolving patterns of antimicrobial resistance for the selection of appropriate empirical therapy.

Patient factors predictive of resistance in a given isolate include recent antimicrobial use, a health care association (e.g., recent or ongoing hospitalization, dialysis, residence in an LTCF, transplant, hematologic malignancy), or international travel (e.g., to Asia, Latin America, Africa, Eastern Europe). Resistance rates will almost certainly increase over time and will likely be higher than shown here by the time this chapter is published. Of concern are an increasing number of reports on resistant Enterobacteriaceae causing infections in ambulatory patients without known risk factors.

In this era of increasing antimicrobial resistance, it is critical to culture the primary site of infection before initiating antimicrobial therapy and, for systemically ill patients, to obtain blood cultures. In vitro testing may not always detect antimicrobial resistance; therefore, it is important to assess the patient's clinical response to treatment. Moreover (see discussion of AmpC β-lactamases below), resistance may emerge during therapy. In addition, drainage of abscesses, resection of necrotic tissue, and removal of infected foreign bodies, sometimes referred to collectively as "source control," are often required for cure.

For appropriately selected patients, it may be prudent initially, pending antimicrobial susceptibility results, to use two potentially active agents as a way to increase the likelihood that at least one agent will be active against the patient's organism. If broad-spectrum treatment has been initiated, it is important to switch to the most appropriate narrower-spectrum agent once antimicrobial susceptibility results become available. Such responsible antimicrobial stewardship should help disrupt the ever-escalating cycle of selection for increasingly resistant bacteria, plus decrease the likelihood of *Clostridioides difficile* infection, decrease costs, and maximize the useful longevity of available antimicrobial agents. Likewise, it is important to avoid treatment of patients who are colonized but not infected (e.g., who have a positive sputum culture without evidence of pneumonia, or a positive urine culture without clinical manifestations of UTI).

At present, the most reliably and broadly active antimicrobial agents in vitro against Enterobacteriaceae are the carbapenems (excepting imipenem, to which the Proteeae [*Proteus*, *Morganella*, *Providencia*] are intrinsically resistant); the aminoglycosides amikacin and plazomicin (excepting the Proteeae); the fourth-generation cephalosporin cefepime; the β-lactamase inhibitor combination agents piperacillin-tazobactam, ceftolozane-tazobactam, ceftazidime-avibactam, meropenem-vaborbactam; and the novel cephalosporin-siderophore cefiderocol. A limitation of imipenem/cilastatin-relebactam; the tetracycline derivatives tigecycline, omadacycline, and eravacycline; and the polymyxins B and E (colistin) (which are otherwise very active) is their poor activity against the Proteeae and *Serratia*. Furthermore, the tetracycline derivatives achieve suboptimal concentrations at several anatomic sites (including urine and blood). Clinical data are limited for cefiderocol outside of UTIs; thus, caution is in order for serious infections.

The number of antimicrobial agents effective against certain Enterobacteriaceae is shrinking, and truly pan-resistant GNB exist. Accordingly, the currently available antimicrobial drugs must be used judiciously. Extensive resistance to available agents may leave the clinician with few or no ideal therapeutic options. However, use of a regimen that takes into account the site of infection, achievable drug levels at that site (e.g., higher concentrations of many agents in urine), and pharmacodynamically guided administration strategies (e.g., prolonged infusion of β-lactam agents to maintain drug levels above the minimal inhibitory concentration [MIC]) may increase the chance for a successful outcome. In the near future, point-of-care identification of resistance mechanisms in GNB will enable a strain-specific, patient-specific precision medicine–based treatment approach that would be predicted to improve outcome.

GNB are commonly involved in polymicrobial infections, in which the role of each individual pathogen is uncertain **(Chap. 177)**. Although some GNB are more pathogenic than others, it is usually prudent, if possible, to design an antimicrobial regimen active against all of the GNB identified, because each is typically capable of pathogenicity in its own right. For patients treated initially with a broad-spectrum empirical regimen, the regimen should be de-escalated as expeditiously as possible once susceptibility results are known and the patient has responded to therapy.

Treatment duration is best individualized based on underlying host status and site of infection. However, for selected non–critically ill patients with source control and a satisfactory clinical response to therapy, 7 days of treatment may suffice.

ANTIMICROBIAL TREATMENT AND RESISTANCE MECHANISMS

The most common resistance mechanisms possessed by Enterobacteriaceae are summarized in **Table 161-2**. However, enzymatic hydrolysis (e.g., β-lactamases, of which >3000 variants have been described) and modification of antimicrobials are the major

TABLE 161-2 Common Antimicrobial Resistance Mechanisms Possessed by the Enterobacteriaceae

MECHANISM	ANTIMICROBIALS MOST SIGNIFICANTLY AFFECTED	COMMON MEDIATORS OF RESISTANCE
Efflux	Tetracyclines, fluoroquinolones (FQ)	Efflux pumps
Decreased permeability	Fosfomycin	Alterations in uptake system
Target site alteration or over-production	FQ, trimethoprim-sulfamethoxazole (TMP-SMX), and polymyxins	DNA gyrase or topoisomerase IV for FQ; enzymes for folic acid synthesis for TMP-SMX Lipid A for polymyxins
Enzymatic hydrolysis of antimicrobials	Penicillins, cephalosporins, cephamycins, carbapenems	Broad-spectrum β-lactamases (e.g., TEM, SHV) ESBLs (e.g., CTX-M, modified TEM and SHV) AmpC β-lactamases Carbapenemases (e.g., serine based KPC, SME, OXA; and metallo-based NDM, VIM, IMP)
Enzymatic modification of antimicrobials	Aminoglycosides	AAC, ANT, APH

Abbreviations: AAC, *N*-acetyltransferases; ANT, O-adenyltranferases; APH, *O*-phosphotransferases; CTX, cefotaxime β-lactamase; ESBL, extended-spectrum β-lactamase; IMP, active on imipenem; KPC, *Klebsiella pneumoniae* carbapenemase; NDM, New Delhi metallo-β-lactamase; OXA, oxacillinase; SHV, sulfhydryl reagent variable β-lactamase; SME, *Serratia marcescens* enzyme; TEM, temoniera β-lactamase; VIM, Verona integron-mediated metallo-β-lactamase.

mediators of resistance in GNB and will be discussed in detail below. Importantly, it is becoming increasingly recognized that MDR and XDR GNB often possess multiple plasmids and genes that encode for multiple β-lactamases.

Broad-spectrum β-lactamases mediate resistance to many penicillins and first-generation cephalosporins and are frequently expressed in enteric GNB. These enzymes are inhibited by β-lactamase inhibitors (e.g., clavulanate, sulbactam, tazobactam, avibactam). In their wild-type form, they do not hydrolyze third- and fourth-generation cephalosporins or cephamycins (e.g., cefoxitin).

Extended spectrum β-lactamases (ESBLs) are modified broad-spectrum enzymes that hydrolyze third-generation cephalosporins, aztreonam, and (in some instances) fourth-generation cephalosporins, in addition to the drugs hydrolyzed by broad-spectrum β-lactamases. GNB that express ESBLs may also exhibit porin mutations that result in decreased uptake of relevant β-lactam agents (cephalosporins, β-lactam/β-lactamase inhibitor combinations, and carbapenems), further reducing susceptibility to these agents. The prevalence of acquired ESBL production, particularly of CTX-M-type enzymes, is increasing in GNB worldwide, largely due to the presence of the corresponding genes on transferable (conjugal) plasmids, which also variably confer or are associated with resistance to fluoroquinolones, trimethoprim-sulfamethoxazole (TMP-SMX), aminoglycosides, tetracyclines, and (more recently) fosfomycin. To date, ESBLs are most prevalent in *E. coli* (especially ST131), *K. pneumoniae*, and *K. oxytoca*, but these enzymes can occur in all Enterobacteriaceae. The approximate regional prevalence of ESBL-producing GNB currently follows a descending gradient as follows: China > Eastern Europe > other parts of Asia (e.g., India) > Latin America and Africa > Western Europe, the United States, Canada, and Australia. Travel to high-prevalence regions increases the likelihood of colonization with these strains. The incidence of community-acquired infections due to ESBL-producing *Enterobacteriaceae* has increased worldwide, including in the United States.

Carbapenems are the most reliably active β-lactam agents against ESBL-expressing strains. Piperacillin-tazobactam, when active in vitro, has been used as a carbapenem-sparing alternative, but recent data from the MERINO trial do not support its use for bloodstream infections. Ceftazidime-avibactam, ceftolozane-tazobactam (less active against *Klebsiella*, *Enterobacter*, and *Citrobacter*), meropenem-vaborbactam, imipenem/cilastatin-relebactam, and plazomicin are active against most ESBL-producing strains and have limited clinical data that support potential utility. The roles for tigecycline, eravacycline, and omadacycline are unclear despite these agents' excellent in vitro activity against most Enterobacteriaceae; however, they are inactive against *Proteus*, *Morganella*, *Providencia*, and *Serratia*.

Oral options for the treatment of ESBL-expressing strains are limited. Fosfomycin, nitrofurantoin (for *E. coli*, 75–90% susceptible), pivmecillinam (not available in the United States), and omadacycline are the most reliably active agents. Older tetracyclines (e.g., doxycycline and minocycline) are also often active, although urine levels may be insufficient and clinical experience with gram-negative infections is limited.

AmpC β-lactamases, when induced or stably derepressed to high levels of expression, confer resistance to the same substrates as do ESBLs, plus to the cephamycins (e.g., cefoxitin and cefotetan). The genes encoding these enzymes are primarily chromosomal and therefore may not exhibit the linked resistance to TMP-SMX, aminoglycosides, and tetracyclines that is common with ESBLs. These enzymes are problematic for the clinician: resistance may develop during therapy with third-generation cephalosporins and result in clinical failure, particularly in the setting of bacteremia. Although chromosomal AmpC β-lactamases are present in nearly all members of the Enterobacteriaceae family (with the notable exceptions of *K. pneumoniae*, *K. oxytoca*, and *Proteus mirabilis*), the risk of clinically significant induction of high-level expression or selection of stably derepressed mutants with cephalosporin treatment is not uniform across species, being greatest with *Enterobacter cloacae*, *Klebsiella* (formerly *Enterobacter*) *aerogenes*, *Citrobacter freundii*, and *Hafnia alvei*, and less with *Serratia marcescens*, *Providencia*, and *Morganella morganii*. In addition, rare strains of *E. coli*, *K. pneumoniae*, and other Enterobacteriaceae have acquired plasmids that contain AmpC β-lactamase genes.

For AmpC-expressing strains, carbapenems are an appropriate treatment option, especially for severely ill patients. Meta-analyses support piperacillin-tazobactam as a possible option. The fourth-generation cephalosporin cefepime may be an appropriate option if the concomitant presence of an ESBL can be excluded (a task that currently exceeds the capability of most clinical microbiology laboratories) and source control is achieved. Vaborbactam and avibactam are the most potent β-lactamase inhibitors. Ceftazidime-avibactam, imipenem/cilastatin-relebactam, and cefiderocol are active in vitro, but clinical data are limited. Other carbapenem-sparing alternatives to consider if isolates are susceptible in vitro include fluoroquinolones, TMP-SMX, and aminoglycosides. Tigecycline, eravacycline, and omadacycline are active in vitro (except against *Proteus*, *Morganella*, *Providencia*, and *Serratia*).

Carbapenemases of Ambler class A (serine-based hydrolytic mechanism; *K. pneumoniae* carbapenemase [KPC], *Serratia marcescens* enzyme [SME]) and class B (metallo [zinc]-based hydrolytic mechanism; New Delhi metallo-β-lactamase [NDM], Verona integron-mediated metallo-β-lactamase [VIM], active on imipenem [IMP]) confer resistance to the same drugs as do ESBLs, plus to cephamycins and carbapenems. By contrast, Ambler class D carbapenemases (serine-based hydrolytic mechanism, e.g., oxacillinase [OXA]) hydrolyze carbapenems and penicillins, but they have minimal activity against extended-spectrum cephalosporins. As with ESBLs, carbapenemase-encoding genes may be present on transferable plasmids, which often encode linked resistance to fluoroquinolones, TMP-SMX, tetracyclines, and aminoglycosides. Transposon-mediated spread (e.g., TN4401 for KPC) is also important. Although all major carbapenemases have been described around the globe, KPC is most common in the Americas, NDM in Asia, and OXA in Europe. Asymptomatic intestinal carriage may facilitate spread.

Carbapenemase production by Enterobacteriaceae (CPE) is most prevalent in *K. pneumoniae*, followed by *Enterobacter* spp. and *E. coli*, but has been described in nearly all members of the family. *M. morganii*, *Proteus*, and *Providencia* exhibit intrinsic low-level imipenem resistance. Although for carbapenem-resistant isolates the Clinical and Laboratory Standards Institute (CLSI) no longer recommends routine identification of CPE, such data conceivably could inform epidemiologic surveillance, infection control efforts, antimicrobial stewardship, and treatment decisions, especially if susceptibility data for selected agents are not available. Genotypic and phenotypic methods can detect carbapenemase genes or activity. Each of these methodologies has pros and cons. At the time of this writing, CLSI endorses the modified carbapenem inactivation method and the Carba NP test.

For the treatment of infections due to Enterobacteriaceae that produce class A or D carbapenemases (serine-based hydrolysis; KPC, OXA, SME), ceftazidime-avibactam is emerging as a first-line agent particularly for bacteremia, but suboptimal efficacy has been observed with pneumonia and in patients on renal replacement therapy, and resistance has developed in up to 10% of cases. Polymyxins are also active. Clinical success against KPC-producing CRE has also been reported for meropenem-vaborbactam and, to a lesser extent, imipenem/cilastatin-relebactam; importantly, however, neither of these agents is active against OXA-producing CRE. For SME, based on limited in vitro data, vaborbactam is most active, followed by avibactam, whereas relebactam is significantly less active; this suggests that meropenem-vaborbactam or ceftazidime-avibactam should be viable treatment options for SME-producing CRE. Ceftazidime, cefepime, and aztreonam are active against OXA-48-like–producing CRE.

Treatment of infections due to class B metallo-β-lactamase–producing CRE is more challenging. The polymyxins B and E currently constitute one of the last lines of defense against strains that produce metallo-carbapenemases (e.g., NDM-1). However, these agents' nephrotoxicity and neurotoxicity potential, their limited clinical efficacy, and the recent emergence of the polymyxin resistance gene *mcr-1* on a stable transferable plasmid and *mcr-1*–independent resistance threaten their utility.

Aztreonam is active against metallo-carbapenemases but is hydrolyzed by ESBLs and AmpC β-lactamases, which often coexist in XDR strains. Ongoing studies are assessing aztreonam plus avibactam, a promising combination with in vitro activity against class A, B, and D enzymes, for the treatment of CRE strains that produce both NDM plus KPC or OXA. A currently available workaround involving approved drugs is co-administration of ceftazidime-avibactam and aztreonam; avibactam protects aztreonam from hydrolysis from ESBLs and AmpC β-lactamases.

Although tigecycline, eravacycline, and omadacycline are active in vitro, pharmacokinetic-pharmacodynamic limitations exist, and along with the polymyxins, they exhibit poor activity against the Proteeae and *Serratia*. Cefiderocol is active in vitro against KPC, most NDM carbapenemases, and OXA (i.e., classes A, B, and D enzymes); clinical trials for the treatment of carbapenemase-resistant GNB are in progress. Aminoglycosides, of which plazomicin is most active, may have some utility for combination therapy. Fosfomycin is often active in vitro, but clinical data in the treatment of serious infections due to CPE are limited, resistance may develop with monotherapy, and a parenteral formulation is not yet available in the United States and certain other countries. Collectively, these considerations recommend fosfomycin as a second-line agent and for use in combination therapy, except perhaps for prostatitis due to superior penetration.

Carbapenem resistance in the absence of carbapenemases can occur in the presence of ESBLs or AmpC β-lactamases in combination with porin mutations (non-CP-CRE); however, most laboratories will not be able to differentiate CPE from non-CP-CRE. The non-CP-CRE phenotype is most commonly seen in *E. coli* and *Enterobacter* spp. In general, resistance to noncarbapenem antimicrobial classes is less, but data are limited on the optimal management approach for non-CP-CRE.

β-Lactamase inhibitor resistance is an uncommon (4% of *E. coli*/*K. pneumoniae* blood isolates) but increasingly recognized phenotype that is characterized by resistance to β-lactamase inhibitors, but not to third-generation cephalosporins. This mechanism of resistance is distinct from production of ESBLs, AmpC β-lactamases, and carbapenemases, and is still being delineated. Limited evidence suggests that ceftriaxone is an appropriate treatment option for such strains.

Fluoroquinolone resistance is usually due to alterations in or protection of the target sites in DNA gyrase and topoisomerase IV, with or without decreased permeability and active efflux. Fluoroquinolone resistance is increasingly prevalent among GNB and is associated with resistance to other antimicrobial classes; for example, 20–80% of ESBL-producing enteric GNB are also resistant to fluoroquinolones. At present, fluoroquinolones should be considered unreliable as empirical therapy for GNB infections in critically ill patients.

Aminoglycoside resistance in Enterobacteriaceae is conferred via enzymatic modification by *N*-acetyltransferases, *O*-adenyltransferases, or *O*-phosphotransferases, which in turn affects ribosomal binding. Amikacin is less affected by these transferases than gentamicin and tobramycin and therefore is generally more active. Plazomicin is unaffected by all of these enzymes that confer resistance to amikacin, gentamicin, and tobramycin, thereby making this an important alternative agent in the treatment of selected XDR strains (excepting the Proteeae, against which plazomicin is poorly active). An as yet uncommon resistance mechanism involves 16S ribosomal RNA methylases, which prevent all aminoglycosides (including plazomicin) from binding to their target ribosomes. To date, these methylases are most common in strains that possess metallo-carbapenemases (e.g., NDM).

PREVENTION

(See also Chap. 142) Certain measures are broadly applicable for decreasing infection risk. Antimicrobial stewardship programs should be instituted to facilitate appropriate antimicrobial use, which will minimize the development of resistance. Diligent adherence to hand-hygiene protocols by health care personnel and cleaning/disinfection or single-patient use of objects that come into contact with patients (e.g., stethoscopes and blood pressure cuffs) are essential. Indwelling devices (e.g., urinary and intravascular catheters) should be used only when necessary and inserted according to an appropriate protocol; protocols for daily-use evaluation and prompt removal should be implemented. Multi-use medication vials should be avoided if possible. Oral application of chlorhexidine decreases the incidence of pneumonia among patients on ventilators. Increasing data support the implementation of universal decolonization (e.g., chlorhexidine bathing) to prevent infection in ICU patients. The public health threat from CRE has resulted in additional recommendations, especially for carbapenemase-producing CRE, which are an even greater concern. These recommendations include contact precautions for patients colonized or infected with CRE, notification to the receiving facility from facilities transferring such a patient, and daily environmental cleaning. Screening of contacts and active surveillance for these bacteria may also be appropriate.

ESCHERICHIA COLI INFECTIONS

All *E. coli* strains share a core genome of ~2000 genes. In contrast, an *E. coli* strain's ability to cause infection and the nature of such infections are defined largely by accessory (i.e., noncore, nonessential) genes that encode various virulence factors. The composition of the *E. coli* accessory genome is continuously in flux, as demonstrated by the recent evolution of Shiga toxin–producing enteroaggregative *E. coli*.

COMMENSAL STRAINS

Commensal *E. coli* variants are an important constituent of the normal intestinal microbiota that confer benefits to the host (e.g., resistance to colonization with pathogenic organisms). Such strains generally lack the specialized virulence traits that enable extraintestinal and

intestinal pathogenic *E. coli* strains to cause disease outside and within the gastrointestinal tract, respectively. However, even commensal *E. coli* strains can be involved in extraintestinal infections in the presence of an aggravating factor, such as a foreign body (e.g., a urinary catheter), host compromise (e.g., local anatomic or functional abnormalities [including urinary or biliary tract obstruction] or systemic immunocompromise), or an inoculum that is large or contains a mixture of bacterial species (e.g., fecal contamination of the peritoneal cavity).

EXTRAINTESTINAL PATHOGENIC STRAINS

ExPEC strains are the most common enteric GNB to cause community-acquired and health care–associated bacterial infections. The emerging propensity of these strains to acquire new mechanisms of antimicrobial resistance (e.g., FQ resistance mutations, ESBLs, carbapenemases) poses novel challenges in managing ExPEC infection. Several ExPEC clonal groups (e.g., sequence types [STs] ST131, ST95, ST69, ST73) are recognized to have undergone global dissemination. The mechanisms underlying the epidemiologic success of such disseminated lineages remain an area of active investigation. In the case of ST131, efficient human-to-human transmission followed by colonization and long-term persistence within the intestinal microbiota appears to be a critical factor. Although acquisition of ESBL-producing *E. coli* from the food chain has been described, this appears to occur relatively uncommonly.

Like commensal *E. coli* (but unlike intestinal pathogenic *E. coli*), ExPEC strains are often found in the intestinal microbiota of healthy individuals and, except for rare chimeric ExPEC/intestinal pathogenic *E. coli* strains, do not cause gastroenteritis in humans. Entry from their site of colonization (e.g., the colon, vagina, or oropharynx) into a normally sterile extraintestinal site (e.g., the urinary tract, peritoneal cavity, or lungs) is the rate-limiting step for infection. ExPEC strains have acquired accessory genes encoding diverse virulence factors that enable the bacteria to cause infections outside the gastrointestinal tract in both normal and compromised hosts (Table 161-1). These virulence genes define ExPEC and, for the most part, are distinct from the virulence genes that enable intestinal pathogenic strains to cause diarrheal disease **(Table 161-3).** All age groups, all types of hosts, and nearly all organs and anatomic sites are susceptible to infection by ExPEC. Even previously healthy hosts can become severely ill or die when infected with ExPEC; however, adverse outcomes are more common among hosts with comorbid illnesses and host defense abnormalities. The diversity and the medical and economic impact of ExPEC infections are evident from consideration of the following specific syndromes.

Extraintestinal Infectious Syndromes

• URINARY TRACT INFECTION The urinary tract is the site most frequently infected by ExPEC. UTI is an exceedingly common infection among ambulatory patients, accounting for 1% of ambulatory care visits in the United States and second only to lower respiratory tract infection among infections responsible for hospitalization. UTIs are best considered by clinical syndrome (e.g., cystitis, pyelonephritis, catheter-associated UTI) and within the context of specific hosts (e.g., premenopausal women, compromised hosts; **Chap. 135**). *E. coli* is the single most common pathogen for all UTI syndrome/host group combinations. Each year in the United States, *E. coli* causes 80–90% of the estimated 6–8 million episodes of cystitis that occur in ambulatory, premenopausal women with an anatomically and functionally normal urinary tract (i.e., uncomplicated cystitis). Furthermore, 20% of women with an initial cystitis episode develop frequent recurrences.

Uncomplicated cystitis, the most common acute UTI syndrome, is characterized by dysuria, urinary frequency and urgency, and suprapubic pain. Progression to more severe infection is rare; the natural history is slow spontaneous symptom resolution, which antimicrobial therapy hastens. Fever and/or back pain suggest progression to pyelonephritis. Even when pyelonephritis is treated effectively, fever may take 5–7 days to resolve completely. Persistently elevated or increasing fever, flank pain, and neutrophil counts should prompt evaluation for intrarenal or perinephric abscess and/or obstruction. Pyelonephritis uncommonly causes renal parenchymal damage and loss of renal function, primarily in association with urinary obstruction, which can be preexisting or, rarely, occurs de novo in diabetic patients who develop renal papillary necrosis as a result of kidney infection. Pregnant women are at unusually high risk for developing pyelonephritis, which can adversely affect the outcome of pregnancy. As a result, prenatal screening for and treatment of asymptomatic bacteriuria during pregnancy are standard. Prostatic infection (prostatitis), a potential complication of UTI in men, can present either acutely (severe), which is rare, or in a chronic manner (recurrent cystitis), which is much more common. Acute pyelonephritis, acute prostatitis, and other systemic illnesses due to UTI can be designated collectively as *urosepsis*, *febrile UTI*, or *systemic UTI*, and may or may not be accompanied by bacteremia. The diagnosis and treatment of UTI, as detailed in **Chap. 135**, should be tailored to the individual host, the nature and site of infection, and local patterns of antimicrobial susceptibility.

ABDOMINAL AND PELVIC INFECTION The abdomen/pelvis is the second most common site of extraintestinal infection due to *E. coli*. A wide variety of clinical syndromes occur in this location, including acute peritonitis secondary to fecal contamination, spontaneous bacterial peritonitis, dialysis-associated peritonitis, diverticulitis, appendicitis, intraperitoneal or visceral abscesses (hepatic, pancreatic, splenic), infected pancreatic pseudocysts, and septic cholangitis and/or cholecystitis. In intraabdominal infections, *E. coli* can be isolated either alone or, as occurs more often, in combination with other facultative and/or anaerobic members of the intestinal microbiota **(Chap. 132)**.

PNEUMONIA *E. coli* is not usually considered an important cause of pneumonia **(Chap. 126)**. Indeed, enteric GNB account for only 1–3%

TABLE 161-3 Intestinal Pathogenic *Escherichia coli*

PATHOTYPE	EPIDEMIOLOGY	CLINICAL SYNDROME[a]	DEFINING MOLECULAR TRAIT	RESPONSIBLE GENETIC ELEMENT[b]
STEC/EHEC/ ST-EAEC	Food, water, person-to-person; all ages, industrialized countries	Hemorrhagic colitis, hemolytic-uremic syndrome	Shiga toxin	Lambda-like Stx1- or Stx2-encoding bacteriophage
ETEC	Food, water; young children in and travelers to developing countries	Traveler's diarrhea	Heat-stable and labile enterotoxins, colonization factors	Virulence plasmid(s)
EPEC	Person-to-person; young children and neonates in developing countries	Watery diarrhea, persistent diarrhea	Localized adherence, attaching and effacing lesion on intestinal epithelium	EPEC adherence factor plasmid pathogenicity island (locus for enterocyte effacement [LEE])
EIEC	Food, water; children in and travelers to developing countries	Watery diarrhea, occasionally dysentery	Invasion of colonic epithelial cells, intracellular multiplication, cell-to-cell spread	Multiple genes contained primarily in a large virulence plasmid
EAEC	?Food, water; children in and travelers to developing countries; all ages, industrialized countries	Traveler's diarrhea, acute diarrhea, persistent diarrhea	Aggregative/diffuse adherence, virulence factors regulated by AggR	Chromosomal or plasmid-associated adherence and toxin genes

[a]Classic syndromes; see text for details on disease spectrum. [b]Pathogenesis involves multiple genes, including genes in addition to those listed.

Abbreviations: EAEC, enteroaggregative *E. coli;* EHEC, enterohemorrhagic *E. coli*; EIEC, enteroinvasive *E. coli*; EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*; ST-EAEC, Shiga toxin–producing enteroaggregative *E. coli*; STEC, Shiga toxin–producing *E. coli.*

of cases of community-acquired pneumonia, in part because these organisms colonize the oropharynx only transiently in a minority of healthy individuals. However, rates of oral colonization with *E. coli* and other GNB increase with severity of illness and antibiotic use. Consequently, GNB are a more common cause of pneumonia among residents of LTCFs and are the most common cause (60–70% of cases) of hospital-acquired pneumonia **(Chap. 142)**, particularly among postoperative and ICU patients (e.g., ventilator-associated pneumonia).

Pulmonary infection is usually acquired by small-volume aspiration but occasionally occurs via hematogenous spread, in which case multifocal nodular infiltrates can be seen. Tissue necrosis, probably due in part to bacterial cytotoxins, is common. Despite significant institutional variation, *E. coli* is generally the third or fourth most commonly isolated type of GNB in hospital-acquired pneumonia, accounting for 5–8% of episodes in both U.S.-based and Europe-based studies. Regardless of the host, pneumonia due to ExPEC is a serious disease, with high crude and attributable mortality rates (20–60% and 10–20%, respectively).

MENINGITIS **(See also Chap. 138)** *E. coli* is one of the leading causes of neonatal meningitis, together with group B *Streptococcus*. Most *E. coli* strains that cause neonatal meningitis possess the K1 capsular antigen and derive from a limited number of meningitis-associated clonal groups. Ventriculomegaly occurs commonly. After the first month of life, *E. coli* meningitis is uncommon, and usually accompanies surgical or traumatic disruption of the meninges or hepatic cirrhosis. In patients with cirrhosis who develop meningitis, the meninges are presumably seeded due to poor hepatic clearance of portal vein bacteremia.

CELLULITIS/MUSCULOSKELETAL INFECTION *E. coli* contributes frequently to infections of decubitus ulcers and occasionally to infections of lower-extremity ulcers and wounds in diabetic patients and other hosts with neurovascular compromise. Osteomyelitis secondary to contiguous spread can occur in these settings. *E. coli* also causes cellulitis or infections of burn sites and surgical wounds (accounting for ~10% of surgical site infections), particularly when the infection originates close to the perineum. *E. coli* causes hematogenously acquired osteomyelitis, especially of vertebral discs and bodies, accounting for up to 10% of cases in some series **(Chap. 131)**. *E. coli* occasionally causes orthopedic device–associated infection or septic arthritis and rarely causes hematogenous myositis. Myositis or fasciitis of the thigh due to *E. coli* should prompt an evaluation for an abdominal source with contiguous spread.

ENDOVASCULAR INFECTION Despite being one of the most common causes of bacteremia, *E. coli* rarely seeds native heart valves. When the organism does infect native valves, it usually does so in the setting of prior valvular disease. *E. coli* infections of aneurysms, the portal vein (*pylephlebitis*), and vascular grafts are quite uncommon.

MISCELLANEOUS INFECTIONS *E. coli* can cause infection in nearly every organ and anatomic site. It occasionally causes postoperative mediastinitis or complicated sinusitis and uncommonly causes endophthalmitis, ecthyma gangrenosum, or brain abscess.

BACTEREMIA *E. coli* bacteremia can arise from infection at any extraintestinal site. In addition, *E. coli* bacteremia can arise from percutaneous intravascular devices, transrectal prostate biopsy, and the increased intestinal mucosal permeability seen in neonates and patients with advanced cirrhosis, neutropenia, chemotherapy-induced mucositis, trauma, and extensive burns. *E. coli* bacteremia due to an ESBL-producing strain also has been reported after fecal microbiota transplant in patients with increased mucosal permeability. Roughly equal proportions of *E. coli* bacteremia cases originate in the community and in health care settings. Isolation of *E. coli* from the blood is almost always clinically significant and may be accompanied by the sepsis syndrome (dysfunction of at least one organ or system) or septic shock **(Chap. 304)**.

The urinary tract is the most common source for *E. coli* bacteremia, accounting for one-half to two-thirds of episodes. Bacteremia from a urinary tract source is particularly common among patients with pyelonephritis, urinary tract obstruction, or urinary instrumentation in the presence of infected urine. The abdomen is the second most common source, accounting for ~25% of episodes. Although many of these episodes result from biliary obstruction (stones, tumor) and overt bowel disruption, which typically are readily apparent, some abdominal sources (e.g., abscesses) are remarkably silent clinically and require identification via imaging studies (e.g., computed tomography). Therefore, especially given the high prevalence of asymptomatic bacteriuria among elderly and functionally compromised individuals, the physician should be cautious in attributing *E. coli* bacteremia to a urinary source in the absence of characteristic signs and symptoms of UTI. Soft tissue, bone, pulmonary infections, and intravascular catheter infections are other sources of *E. coli* bacteremia.

Diagnosis Strains of *E. coli* that cause extraintestinal infections usually grow both aerobically and anaerobically within 24 h on standard diagnostic media and are identified readily by the clinical microbiology laboratory according to routine biochemical criteria. More than 90% of ExPEC strains are rapid lactose fermenters and are indole-positive.

TREATMENT

Extraintestinal *E. coli* Infections

E. coli does not possess clinically significant intrinsic resistance to antimicrobials; however, increasing acquired resistance is making treatment problematic. Although geographic differences exist, in general, the prevalence of resistance is >20% for ampicillin, amoxicillin-clavulanate, ampicillin-sulbactam, cefazolin, TMP-SMX, and fluoroquinolones, even in community-acquired infections. This resistance precludes empirical use of these agents for serious infections. Travel outside of the United States, prior exposure to an antimicrobial agent, or exposure to a health care setting further increases the likelihood of resistance. Fortunately, >90% of isolates that cause uncomplicated cystitis remain susceptible to nitrofurantoin and fosfomycin.

From 2015 to 2017, the U.S. National Healthcare Safety Network (USNHSN) identified 24% of *E. coli* clinical isolates as ESBL-producers. Higher prevalences are reported from Asia, Eastern Europe, South America, and Africa; prevalence is also greater in isolates from health care settings, especially LTCFs. However, community-acquired UTIs caused by *E. coli* strains that produce CTX-M ESBLs are increasingly common. Oral treatment options for such strains are limited; however, in vitro and limited clinical data indicate that fosfomycin, pivmecillinam, and nitrofurantoin are highly active and can be used for cystitis, and omadacycline is predicted to be active based on in vitro data. For parenteral therapy of carbapenem-sensitive strains, the most predictably active agents (>90%) include carbapenems, amikacin, plazomicin, ceftazidime-avibactam, ceftolozane-tazobactam, meropenem-vaborbactam, imipenem/cilastatin-relebactam, piperacillin-tazobactam, polymyxins, cefiderocol, tigecycline, eravacycline, and omadacycline. Treatment of carbapenemase-producing strains is dependent of the class of enzyme produced (see "Carbapenemase" above). Uncertainty exists on the optimal treatment for non-CP-CR *E. coli*.

Empirical treatment decisions for critically ill patients should be dictated by local susceptibility patterns and patient-specific risk factors (1.2% prevalence from the USNHSN 2015–2017 data). Equally important as prompt institution of effective empirical therapy for seriously ill patients is use of appropriate narrower-spectrum agents for definitive therapy whenever possible and avoidance of treatment for patients who are colonized but not infected.

INTESTINAL PATHOGENIC STRAINS

Pathotypes Certain strains of *E. coli* are capable of causing diarrheal disease. **(Other important intestinal pathogens are discussed in Chaps. 133, 134, and 165–168.)** At least in the industrialized world, intestinal pathogenic *E. coli* strains are rarely encountered in the fecal flora of healthy persons, and instead appear to be essentially obligate

pathogens. These strains have evolved a special ability to cause enteritis, enterocolitis, and colitis when ingested in sufficient quantities by a naive host. At least five distinct pathotypes of intestinal pathogenic *E. coli* exist: (1) Shiga toxin–producing *E. coli* (STEC), which includes the subsets enterohemorrhagic *E. coli* (EHEC) and the recently evolved Shiga toxin–producing enteroaggregative *E. coli* (ST-EAEC); (2) enterotoxigenic *E. coli* (ETEC); (3) enteropathogenic *E. coli* (EPEC); (4) enteroinvasive *E. coli* (EIEC); and (5) enteroaggregative *E. coli* (EAEC). Diffusely adherent *E. coli* (DAEC) and cytodetaching *E. coli* are additional putative pathotypes. Lastly, a variant termed adherent invasive *E. coli* (AIEC) has been associated with Crohn's disease (although a causal role remains unproven) but does not cause acute diarrheal disease.

Contaminated food and water are the primary transmission vehicles for ETEC, STEC/EHEC/ST-EAEC, EIEC, and EAEC, whereas person-to-person spread (direct or indirect) is the primary transmission route for EPEC and a secondary transmission route for STEC/EHEC/ST-EAEC. Gastric acidity confers some protection against infection; therefore, persons with decreased stomach acid levels are especially susceptible. Humans are the major reservoir for such strains (except for STEC/EHEC, for which bovines are the main carriers); host range appears to be dictated by species-specific attachment factors. Although some overlap exists, each pathotype possesses a distinctive combination of virulence traits that results in a pathotype-specific pathogenic mechanism (Table 161-3). With rare exceptions, these strains are largely incapable of causing disease outside the intestinal tract. Whereas disease due to STEC/EHEC/ST-EAEC occurs primarily in high-income countries, disease due to ETEC, EPEC, and EIEC occurs primarily in low- and middle-income countries in Asia, Africa, and Latin America, and disease due to EAEC occurs globally.

SHIGA TOXIN–PRODUCING *E. COLI* STEC/EHEC/ST-EAEC strains are pathogens that can cause hemorrhagic colitis and the hemolytic-uremic syndrome (HUS). In contrast to other intestinal pathotypes, STEC/EHEC/ST-EAEC causes infections more frequently in industrialized countries than in developing regions. Several large outbreaks resulting from the consumption of fresh produce (e.g., lettuce, spinach, sprouts) and of undercooked ground beef have received significant media attention. In addition, a dramatic 2011 outbreak—mainly in Germany—involved an EAEC strain that acquired a Shiga toxin–encoding phage, resulting in a novel genotype, ST-EAEC (O104:H4). This strain was transmitted to the primary cases by sprouted fenugreek seeds, with subsequent human-to-human transmission, and resulted in >4000 cases and 54 deaths.

STEC strains are the fourth most commonly reported cause of bacterial diarrhea in the United States (after *Campylobacter*, *Salmonella*, and *Shigella*). O157:H7 is the most prominent serotype among STEC strains, but many other serogroups have been described, including O6, O26, O45, O55, O91, O103, O111, O113, O121, and O145. Domesticated ruminant animals, particularly cattle and young calves, serve as the major reservoir for STEC/EHEC. Ground or mechanically tenderized beef—the most common food source of STEC/EHEC strains—is often contaminated with intestinal bacteria from the source animals during processing. Furthermore, manure from cattle or other animals (including in the form of fertilizer) can contaminate produce (potatoes, lettuce, spinach, sprouts, fallen fruits, nuts, strawberries), and fecal runoff from manure can contaminate water systems. Dairy products and petting zoos are additional sources of infection.

It is estimated that $<10^2$ colony-forming units (CFU) of STEC/EHEC/ST-EAEC can cause disease. Therefore, not only can low levels of food or environmental contamination (e.g., in water swallowed while swimming) result in disease, but person-to-person transmission (e.g., at day-care centers and in institutions) is an important route for secondary spread. Laboratory-associated infections also occur. Illness due to this group of pathogens peaks in the summer months and occurs both as outbreaks and as sporadic cases.

For STEC/EHEC/ST-EAEC, production of Shiga toxin (Stx2a-g and/or Stx1a,c,d) is a critical factor for occurrence of clinical disease, as demonstrated by the 2011 ST-EAEC outbreak. The *stx* gene is present on chromosomally integrated prophages, and various combinations of *stx* types and subtypes can occur in a given strain. *Shigella dysenteriae* strains that produce the closely related Shiga toxin Stx also can cause hemorrhagic colitis and HUS. Stx2 (especially Stx2a,c,d) appears to be more important than Stx1 in the development of HUS. All Shiga toxins studied to date are multimers; they comprise one A subunit that is enzymatically active and five identical B subunits that mediate binding to globosyl ceramides, which are membrane-associated glycolipids expressed on certain host cells. As in ricin, the Stx A subunit cleaves an adenine from the host cell's 28S rRNA, thereby irreversibly inhibiting ribosomal function (i.e., protein synthesis) and potentially leading to apoptosis.

For full pathogenicity, STEC strains require additional properties such as acid tolerance and epithelial cell adherence. Most disease-causing isolates possess the chromosomal locus for enterocyte effacement (LEE). This pathogenicity island was first described in EPEC strains; it contains genes that mediate adherence to intestinal epithelial cells and a system that subverts host cells by the translocation of bacterial proteins (type III secretion system). EHEC strains make up the subgroup of STEC strains that possess stx_1 and/or stx_2, as well as LEE. In contrast, the 2011 ST-EAEC outbreak strain lacked LEE, yet was associated with a higher proportion of patients developing HUS (22%) than the historical average for STEC/EHEC outbreaks (2–8%). Data support the essential role of the 2011 outbreak strain's EAEC-associated virulence factors (e.g., AAF/I fimbriae, serine proteases SigA, SepA) in adherence, increased inflammation, and disruption of the intestinal epithelial barrier, which in turn increased the systemic translocation of Stx2a.

After exposure to STEC/EHEC/ST-EAEC and a 3- to 4-day incubation period, colonization of the colon and perhaps the ileum results in symptoms. Colonic edema and an initial nonbloody secretory diarrhea may progress to the hallmark syndrome of grossly bloody diarrhea (identified by history or examination). Significant abdominal pain and fecal leukocytes are common (70% of cases), whereas fever is not; absence of fever can incorrectly lead to consideration of noninfectious conditions (e.g., intussusception and inflammatory or ischemic bowel disease). Occasionally, infections caused by *C. difficile*, *K. oxytoca* (see "*Klebsiella* Infections," below), *Campylobacter*, and *Salmonella* present in a similar fashion. STEC/EHEC disease is usually self-limited, lasting 5–10 days.

A feared complication of infection with STEC/EHEC strains is HUS, which occurs 2–14 days after diarrhea, most often in young children (estimated to occur in 15% of infected children <10 years of age) or elderly patients. It is estimated that in the United States >50% of all HUS cases—and 90% of HUS cases in children, which is a leading cause of acute renal failure in this latter population—are caused by STEC/EHEC. In contrast, with ST-EAEC infection, HUS occurs more commonly among nonelderly adults, especially young women. HUS is mediated by the systemic translocation of Shiga toxins. Erythrocytes may serve as carriers of Stx to endothelial cells located in the small vessels of the kidney and brain. The subsequent development of thrombotic microangiopathy (perhaps with direct toxin-mediated effects on various nonendothelial cells) commonly produces some combination of fever, hemolytic anemia, thrombocytopenia, renal failure, and encephalopathy. Stx-mediated complement activation may also play a role in the development of HUS. Although with dialysis support the mortality rate of HUS is <10%, survivors often have persisting renal and neurologic dysfunction.

ENTEROTOXIGENIC *E. COLI* ETEC is a major cause of endemic diarrhea in low- and middle-income countries and is responsible for an estimated 800 million cases annually. After weaning, children in these locales commonly experience several episodes of ETEC infection during the first 3 years of life. The incidence of disease diminishes with age, a pattern that correlates with the development of mucosal immunity to colonization factors (i.e., adhesins).

In industrialized countries, ETEC is the most common agent of traveler's diarrhea, causing 25–75% of cases. The incidence of infection may be decreased by prudent avoidance of potentially contaminated fluids and foods, particularly items that are raw, insufficiently cooked, peeled, or unrefrigerated **(Chap. 124)**. ETEC infection is uncommon

in the United States, but outbreaks secondary to consumption of food products imported from endemic areas have occurred. A large inoculum (10^6–10^8 CFU) is needed to produce disease, which usually develops after an incubation period of 12–72 h.

After adherence of ETEC to enterocytes via colonization factors (e.g., CFA/I, CS), disease is mediated, primarily by a heat-labile toxin (LT) and/or a heat-stable toxin (STa), leading to diarrheal disease. Disease is less severe with strains that produce only LT. Both LT and STa cause net fluid secretion via activation of adenylate cyclase and/or guanylate cyclase C (STa) in the jejunum and ileum. The result is watery diarrhea accompanied by cramps.

LT consists of an A and a pentameric B subunit and is structurally and functionally similar to cholera toxin. Strong binding of the B subunit to the GM_1 ganglioside on intestinal epithelial cells leads to the intracellular translocation of the A subunit, which functions as an ADP-ribosyltransferase. Mature STa is an 18- or 19-amino-acid secreted peptide that leads to increased intracellular concentrations of cGMP. Characteristically absent in ETEC-mediated disease are histopathologic changes within the small bowel; mucus, blood, and inflammatory cells in stool; and fever.

The disease spectrum of ETEC infection ranges from mild illness to a life-threatening, cholera-like syndrome. Although symptoms are usually self-limited (typically lasting for 3–5 days), infection may result in significant morbidity and mortality (>250,000 deaths annually, mostly from profound volume depletion) when access to health care or suitable rehydration fluids is limited and when small and/or undernourished children are affected.

ENTEROPATHOGENIC *E. COLI* EPEC causes disease primarily in young children, including neonates. The first *E. coli* pathotype recognized as an agent of diarrheal disease, EPEC was responsible for outbreaks of infantile diarrhea (including in hospital nurseries) in industrialized countries in the 1940s and 1950s. At present, EPEC infection is uncommon in high-income countries, but among infants in low- and middle-income countries, it is an important cause of diarrhea (both sporadic and epidemic), often accompanied by vomiting and fever. Breast-feeding diminishes the incidence of EPEC infection. Rapid person-to-person spread may occur.

Symptoms develop after colonization of the small bowel and a brief incubation period (1 or 2 days). Initial localized adherence to enterocytes via type IV bundle-forming pili leads to a characteristic effacement of microvilli, with the formation of cuplike, actin-rich pedestals mediated by factors in the LEE. Diarrhea production is a complex and regulated process in which host cell modulation by a type III secretion system plays an important role. Strains lacking bundle-forming pili have been categorized as atypical EPEC (aEPEC); increasing data support a role for these strains as intestinal pathogens in all age groups and among HIV-infected individuals. Diarrheal stool often contain mucus but not blood. Although EPEC diarrhea is usually self-limited (lasting 5–15 days), it may persist for weeks.

ENTEROINVASIVE *E. COLI* EIEC, a relatively uncommon (or perhaps underrecognized) cause of diarrhea, is rarely identified in the United States, although a few food-related outbreaks have been described. In low- and middle-income countries, sporadic disease is recognized infrequently in children and travelers.

EIEC shares many genetic and clinical features, as well as a common ancestor, with *Shigella*. Both are intracellular pathogens for which virulence is mediated by the presence of specific factors and by the loss or inactivation of other factors (antivirulence genes), which presumably occurred during these organisms' transition from an extracellular to an intracellular lifestyle.

Colonization and invasion of the colonic mucosa, followed by replication therein and cell-to-cell spread (in part via a type III secretion system), result in the development of inflammatory colitis. However, unlike *Shigella*, EIEC produces disease only with a large inoculum (10^8–10^{10} CFU) and is less virulent, typically causing only mild, self-limited (7–10 days), watery diarrhea. Onset generally follows an incubation period of 1–3 days. Occasionally, EIEC can cause a shigellosis-like (dysentery) syndrome characterized by fever, abdominal pain, tenesmus, and scant stool containing mucus, blood, and inflammatory cells.

ENTEROAGGREGATIVE AND DIFFUSELY ADHERENT *E. COLI* EAEC has been described primarily in low- and middle-income countries and in young children. However, recent studies indicate that it also may be a relatively common cause of diarrhea in all age groups in industrialized countries. EAEC has been recognized increasingly as an important cause of traveler's diarrhea. It is highly adapted to humans—the probable reservoir. A large inoculum is required for infection, which usually manifests as watery and sometimes persistent diarrhea in healthy but also malnourished or HIV-infected hosts.

In vitro, EAEC cells exhibit a diffuse or "stacked-brick" pattern of adherence to small-intestine epithelial cells. Virulence factors that probably are necessary for disease are regulated in large part by the transcriptional activator AggR. The pathogenesis of EAEC disease begins with intestinal adherence, which results from stimulation of epithelial mucus production and bacterial biofilm formation, the latter mediated by fimbriae and possibly the mucinase Pic and dispersin. Inflammation ensues, resulting in epithelial cell exfoliation and intestinal secretion, which is mediated by the enterotoxins Pet, EAST-1, ShET1, and HlyE.

An additional enteric pathotype, DAEC, is associated with diarrheal disease, primarily in children 2–6 years of age in some developing countries, and may cause traveler's diarrhea. The Afa/Dr adhesins may contribute to the pathogenesis of such infections.

Diagnosis Acute infectious diarrhea can be classified as noninflammatory (most commonly viral) or inflammatory (usually bacterial); the latter is suggested by grossly bloody or mucoid stools or a positive test for fecal leukocytes, lactoferrin, or calprotectin **(Chap. 133)**. ETEC, EPEC, DAEC, and EAEC cause noninflammatory diarrhea. Identification of these agents can be achieved with a commercial platform (e.g., BioFire® Film Array® Gastrointestinal Panel can detect STEC, ETEC, EPEC, EAEC, and EIEC). However, organism identification is rarely needed because the associated diseases are self-limited. ETEC causes the majority and EAEC a minority of cases of noninflammatory traveler's diarrhea; here again, however, definitive diagnosis generally is not necessary for management (as discussed below). If diarrhea persists for >10 days despite treatment, *Giardia* or *Cryptosporidium* (or, in immunocompromised hosts, certain opportunistic pathogens) should be sought.

Because of the considerable public-health importance of STEC/EHEC/ST-EAEC infections, including the threat of HUS, the CDC now recommends that all patients with community-acquired diarrhea, whether inflammatory or not, be evaluated for these pathogens by simultaneous culture (to provide an isolate for strain typing and for outbreak detection and control) and detection of Shiga toxin or the corresponding genes. The rationale for testing all cases of community-acquired diarrhea, regardless of clinical features, is that bloody stool and fecal white blood cells (or lactoferrin) are not reliably present with STEC/EHEC/ST-EAEC infection. In addition, the use of both tests increases diagnostic sensitivity over that with either test alone.

O157 STEC/EHEC may be identified via culture by screening for *E. coli* strains that do not ferment sorbitol, with subsequent serotyping and testing for Shiga toxin. Selective or screening media are not available for culture-based detection of non-O157 STEC/EHEC/ST-EAEC strains. Detection of Shiga toxins or toxin genes via DNA-based, enzyme-linked immunosorbent, and cytotoxicity assays offers the advantages of rapidity and detection of non-O157 STEC/EHEC/ST-EAEC strains. Specimens positive for toxin but culture-negative for O157 should be forwarded to the local or state public-health laboratory for specialized testing.

TREATMENT

Intestinal *E. coli* Infections

The mainstay of treatment for all diarrheal syndromes is replacement of water and electrolytes. This measure is especially important for STEC/EHEC/ST-EAEC infection because appropriate volume expansion may protect against renal injury and improve outcome.

The use of prophylactic antibiotics to prevent traveler's diarrhea generally should be discouraged, especially in light of high rates of antimicrobial resistance. However, in selected patients (e.g., those who cannot afford a brief illness or are predisposed to infection), the use of rifaximin, which is nonabsorbable and is well tolerated, is reasonable.

When stools are free of mucus and blood, early patient-initiated treatment of traveler's diarrhea with a fluoroquinolone or azithromycin decreases the duration of illness, and the use of loperamide may halt symptoms within a few hours. Although dysentery caused by EIEC is self-limited, antimicrobial therapy hastens the resolution of symptoms, particularly in severe cases. In contrast, antimicrobial therapy for STEC/EHEC/ST-EAEC infection (the presence of which is suggested by grossly bloody diarrhea without fever) should be avoided because antibiotics may increase the incidence of HUS (possibly via increased production/release of Stx). In the treatment of HUS, plasmapheresis has no benefit and the value of inhibition of C5 (via eculizumab) is unresolved.

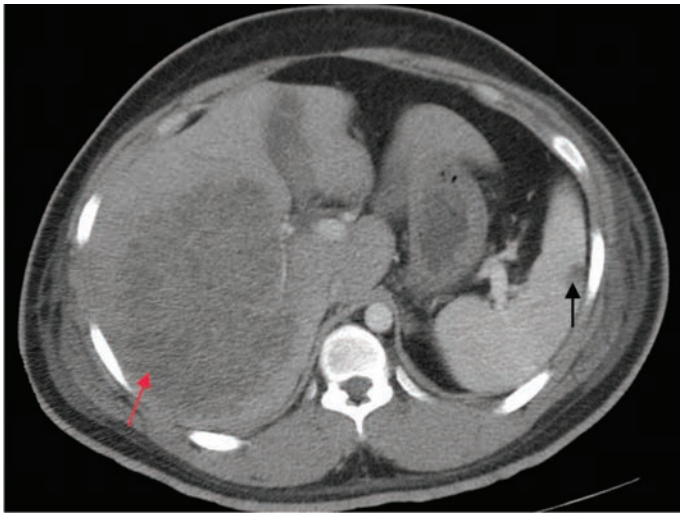
KLEBSIELLA INFECTIONS

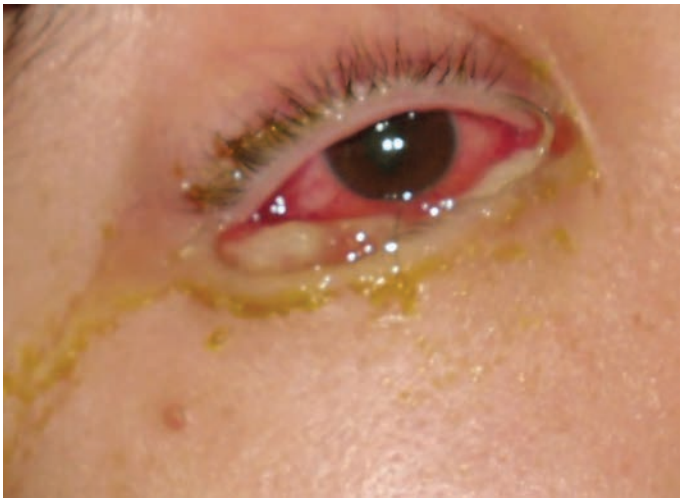
K. pneumoniae is the most important *Klebsiella* species from a medical standpoint, causing community-acquired, LTCF-acquired, and nosocomial infections. *K. oxytoca* and *K.* (formerly *Enterobacter*) *aerogenes* are primarily pathogens in LTCFs and hospitals. *Klebsiella* species are broadly prevalent in the environment and colonize the mucosal surfaces of mammals. In healthy humans, the prevalence of *K. pneumoniae* colonization is 5–35% in the colon and 1–5% in the oropharynx; skin is usually colonized only transiently.

Most *Klebsiella* infections in Western countries are caused by "classical" *K. pneumoniae* (cKp) and occur in hospitals and LTCFs. The most common clinical syndromes due to cKp are pneumonia, UTI, abdominal infection, intravascular device infection, surgical site infection, soft tissue infection, and secondary bacteremia. cKp strains have gained notoriety because of their propensity for acquiring treatment-confounding antimicrobial resistance determinants and causing both localized and widespread outbreaks, such as with the global spread of NDM-1-producing cKp strains from India associated with medical tourism. Clonal groups STs 11, 15, 101, 307, and 258/512, many members of which produce carbapenemases, are undergoing international dissemination. Transmission within or between institutions is common. *K. pneumoniae* is nearly four-fold more transmissible than *E. coli*, and, disconcertingly, carbapenemase-producing strains are associated with increased spread compared to carbapenem-susceptible strains.

In addition, hypervirulent *K. pneumoniae* (hvKp) strains that are phenotypically and clinically distinct from cKp have emerged recently, after their initial recognition in Taiwan in 1986. Although hvKp infections have occurred globally in all ethnic groups, most cases have been reported in individuals of Asian ethnicity residing in countries from the Asian Pacific Rim, but also in Asians living in other countries. Affected individuals often have diabetes mellitus. These demographics raise the possibility of a locale-specific distribution of the organism or an increased susceptibility of Asian hosts, especially those who are diabetic. In contrast to the usual health care–associated context for cKp infections in the West, hvKp is capable of causing serious life- and organ-threatening infections in younger, healthy individuals from the community and can spread metastatically from the primary site of infection or present with multiple sites of infection. Of concern, recent reports from Asian countries have demonstrated that hvKp is responsible for an increasing number of health care–associated or hospital-acquired infections.

hvKp infection initially was characterized and distinguished from traditional infections caused by cKp strains by its (1) presentation as community-acquired monomicrobial pyogenic liver abscess **(Fig. 161-1, *top*)**, (2) occurrence in patients lacking a history of hepatobiliary disease, and (3) propensity for metastatic spread to distant sites. Subsequently, the hvKp pathotype has been recognized as the cause of extrahepatic abscesses and infections with or without liver involvement, including pneumonia; meningitis (in the absence of trauma or





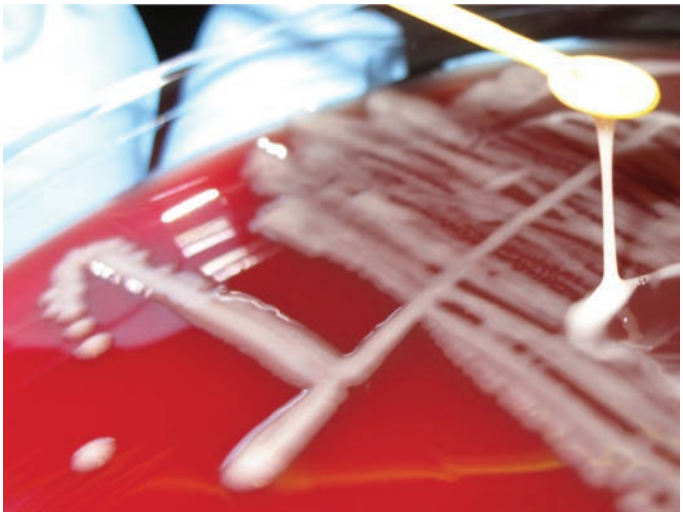


FIGURE 161-1 Hypervirulent pathotype of *K. pneumoniae* (hvKp). ***Top:*** Abdominal CT scan of a previously healthy 24-year-old Vietnamese man shows a primary liver abscess (*red arrow*) with metastatic spread to the spleen (*black arrow*). *(Courtesy of Drs. Chiu-Bin Hsaio and Diana Pomakova.)* ***Middle:*** A previously healthy 33-year-old Chinese man presented with endophthalmitis. *(AS Shon, RP Bajwa, TA Russo: Hypervirulent (hypermucoviscous) Klebsiella pneumoniae: A new and dangerous breed. Virulence 4:107, 2013.)* ***Bottom:*** A hypermucoviscous phenotype (which does not necessarily equate with a mucoid phenotype) has been associated with hvKp strains. A positive string test is shown. However, this test is not optimally sensitive or specific. Identification of the combination of the biomarkers *iucA*, *iroB*, *peg-344*, *rmpA*, and *rmpA2* is presently the most accurate means to identify hvKp.

neurosurgery); endophthalmitis (Fig. 161-1, *middle*); splenic, psoas, prostatic, epidural, and brain abscesses; and necrotizing fasciitis. Survivors often suffer catastrophic morbidity, such as vision loss and major neurologic sequelae. Most recently, clinicians are faced with an even greater challenge—the confluence of antimicrobial resistance determinants possessed by cKp and the virulence factors possessed by hvKp on the same or coexisting plasmids. The result is the evolution of MDR and XDR hvKp.

K. pneumoniae subspecies *rhinoscleromatis* is the causative agent of rhinoscleroma, a granulomatous mucosal upper-respiratory infection that progresses slowly (over months or years) and causes necrosis and occasionally obstruction of the nasal passages. *K. pneumoniae* subspecies *ozaenae* has been implicated as a cause of chronic atrophic rhinitis and rarely of invasive disease in compromised hosts. *K.* (*Calymmatobacterium*) *granulomatis*, a sexually transmitted pathogen, is the causative agent of granuloma inguinale (donovanosis) that results in chronic genital ulcers (Chap. 173). These *Klebsiella* pathotypes are usually isolated from patients in tropical climates and are genomically distinct from both cKp and hvKp.

INFECTIOUS SYNDROMES

Pneumonia Although cKp accounts for only a small proportion of cases of community-acquired pneumonia in Western countries (Chap. 126), cKP and *K. oxytoca* are common causes of pneumonia among LTCF residents and hospitalized patients because of increased rates of oropharyngeal colonization with these organisms in such individuals. Mechanical ventilation is an important risk factor. In Asia and South Africa, community-acquired pneumonia due to hvKp is becoming increasingly common, rivaling *Streptococcus pneumoniae*, and may occur in younger patients with no underlying disease. *Klebsiella* is also a common cause of pneumonia in severely malnourished children in developing countries.

As in all pneumonias due to enteric GNB, typical manifestations include production of purulent sputum and evidence of airspace disease. Presentation with earlier, less extensive infection is now more common than is the classically described lobar infiltrate, bulging fissure, and currant-jelly sputum. Pulmonary infection due to hvKp that has spread metastatically (e.g., from a hepatic abscess) usually includes nodular bilateral densities, more commonly in the lower lobes. Pulmonary necrosis, pleural effusion, and empyema can occur with disease progression.

UTI cKP accounts for only 1–2% of UTI episodes among otherwise healthy adults but for 5–17% of episodes of UTI in patients with anatomic and functional abnormalities of the urinary tract, including indwelling urinary catheter use (complicated UTI). UTI due to hvKp presents more commonly as renal or prostatic abscess due to bacteremic spread than as ascending infection from the urethra and bladder.

Abdominal Infection cKp causes a spectrum of abdominal infections similar to that caused by *E. coli* but is less frequently isolated from such infections than is *E. coli*. hvKp is a common cause of monomicrobial community-acquired pyogenic liver abscess; in the Asian Pacific Rim, it has been recovered with steadily increasing frequency over the past two decades, replacing *E. coli* as the most common pathogen causing this syndrome. hvKp also is increasingly described as a cause of spontaneous bacterial peritonitis and splenic abscess.

Other Infections When cKp and *K. oxytoca* cause cellulitis or soft tissue infection, the process most frequently involves devitalized tissue (e.g., decubitus and diabetic ulcers, burn wounds) and immunocompromised hosts. cKp and *K. oxytoca* cause some cases of surgical site infection and nosocomial sinusitis as well as occasional cases of osteomyelitis contiguous to soft tissue infection, nontropical myositis, and meningitis (during the neonatal period and after neurosurgery). By contrast, hvKp has become an important cause of community-acquired monomicrobial necrotizing fasciitis, meningitis, endophthalmitis (Fig. 161-1, *middle*), and abscesses within the brain, subdural space, and epidural space, particularly in the Asian Pacific Rim but also globally. Cytotoxin-producing strains of *K. oxytoca* have been implicated as a cause of non–*C. difficile* antibiotic-associated hemorrhagic colitis.

Bacteremia *Klebsiella* infection at any site can produce bacteremia. Infections of the urinary tract, respiratory tract, and abdomen (especially hepatic abscess) each account for 15–30% of episodes of *Klebsiella* bacteremia. Intravascular device–related infections account for another 5–15% of episodes, and surgical site and miscellaneous infections account for the rest. *Klebsiella* is an occasional cause of sepsis in neonates and of bacteremia in neutropenic patients. However, like enteric GNB in general, *Klebsiella* rarely causes endocarditis or other endovascular infections, although the endocarditis can involve extensive valvular destruction.

DIAGNOSIS

Klebsiellae are readily isolated and identified in the laboratory. These organisms usually ferment lactose, although the subspecies *rhinoscleromatis* and *ozaenae* are nonfermenters and are indole-negative. hvKp usually possesses a hypermucoviscous phenotype (Fig. 161-1, *bottom*), although the sensitivity and specificity of the string test are less than optimal. Identification of the combination of the biomarkers *iucA*, *iroB*, *peg-344*, *rmpA*, and *rmpA2* is presently the most accurate means to identify hvKp, although currently, this test is not routinely available.

TREATMENT

Klebsiella Infections

K. (formerly *Enterobacter*) *aerogenes* has a similar resistance profile to *E. cloacae*, the treatment of which is discussed below. *K. pneumoniae* and *K. oxytoca* have similar antibiotic resistance profiles; both are intrinsically resistant to ampicillin. The prevalence of acquired resistance in *K. pneumoniae* and *K. oxytoca* is generally >30% for amoxicillin-clavulanate, ampicillin-sulbactam, nitrofurantoin, and TMP-SMX and ~10–20% for fluoroquinolones, piperacillin-tazobactam, fosfomycin, and omadacycline.

USNHSN data from 2015–2017 identified 25% of *K. pneumoniae* as ESBL-producing strains; higher rates are reported from Asia, South America, and Africa. Although prevalent ESBL-producing strains are greatest in LTCF, isolates of cKp that produce CTX-M ESBLs are increasingly described from the community. Oral treatment for infection due to ESBL-producing strains is more challenging with *Klebsiella* than with *E. coli* because of the comparatively poor activity of nitrofurantoin, the lesser activity of fosfomycin (~80%), and limited available data regarding pivmecillinam (>80%) and omadacycline (75–100% susceptible for ESBL-producing isolates, but 60% if resistant to tetracycline).

Predictably, the ESBL-driven use of carbapenems has selected for strains of cKp and *K. oxytoca* that express carbapenemases (8–18% based on the study and locale, 8.6% prevalence from 2015–2017 USNHSN data). Treatment can be problematic for such organisms, especially those with a metallo-β-lactamase (e.g., NDM), for which the highest prevalences are in cKp and *K. oxytoca* isolates from Eastern Europe and Asia and among health care–associated isolates. Likewise, hvKp strains from Asia are also increasingly reported to produce ESBLs and carbapenemases.

Treatment options for carbapenem-resistant *Klebsiella* are similar to those described for *E. coli* and depend on the class of carbapenemase produced (see "Carbapenemase" above); consultation with relevant experts is advised. For carbapenem-sensitive strains, the most predictably active agents include carbapenems, amikacin, plazomicin, ceftazidime-avibactam, ceftolozane-tazobactam, meropenem-vaborbactam, imipenem/cilastatin-relebactam, polymyxins, cefiderocol, tigecycline, eravacycline, and omadacycline. Empirical treatment decisions for the critically ill patient should be dictated by local susceptibility patterns and patient-specific risk factors.

PROTEUS INFECTIONS

Proteus species are part of the colonic flora of a wide variety of mammals, birds, fish, and reptiles. The ability of these GNB to generate histamine from contaminated fish has implicated them in the pathogenesis of scombroid (fish) poisoning (Chap. 460).

P. mirabilis causes 90% of *Proteus* infections, which occur in the community, LTCFs, and hospitals. By contrast, *Proteus vulgaris* and *Proteus penneri* are associated primarily with infections acquired in LTCFs or hospitals. Correspondingly, *P. mirabilis* colonizes healthy humans (prevalence, 50%), whereas *P. vulgaris* and *P. penneri* are isolated primarily from individuals with underlying disease. By far the most common site of *Proteus* infection is the urinary tract, where the principal known urovirulence factors of *Proteus* include adhesins, flagella, IgA-IgG protease, iron acquisition systems, and urease. *Proteus* less commonly causes infection at a variety of other extraintestinal sites.

INFECTIOUS SYNDROMES

UTI *P. mirabilis* causes only 1–2% of UTIs in healthy women, and *Proteus* species collectively cause only 5% of hospital-acquired UTIs. However, *Proteus* is responsible for 10–15% of cases of complicated UTI, primarily those associated with catheterization; indeed, *Proteus* accounts for 20–45% of urine isolates from chronically catheterized patients. This high prevalence is due in part to bacterial production of urease, which hydrolyzes urea to ammonia and results in alkalization of the urine. In alkaline urine, organic and inorganic compounds precipitate, contributing to the formation of struvite and carbonate–apatite crystals, biofilms on catheters, and/or frank calculi. *Proteus* becomes associated with the stones and biofilms; thereafter, it usually cannot be eradicated without removal of the stones or catheter. Over time, staghorn calculi may form within the renal pelvis and lead to obstruction and renal failure. Although biologically plausible, clinical support is lacking for the concept that urine samples exhibiting unexplained alkalinity should be cultured, and that isolation of a *Proteus* species (or other urea-splitting organism) should prompt consideration of an evaluation for urolithiasis.

Other Infections *Proteus* occasionally causes pneumonia (primarily in LTCF residents or hospitalized patients), nosocomial sinusitis, intraabdominal abscesses, biliary tract infection, surgical site infection, soft tissue infection (especially decubitus and diabetic ulcers), and osteomyelitis (primarily contiguous); in rare cases, it causes nontropical myositis. In addition, *Proteus* uncommonly causes neonatal meningitis, with the umbilicus frequently implicated as the source; this disease is often complicated by development of a cerebral abscess. Otogenic brain abscess also occurs.

Bacteremia Most episodes of *Proteus* bacteremia originate from the urinary tract, although intravascular devices and any of the less common sites of *Proteus* infection are also potential sources. Endovascular infection is rare. *Proteus* species are occasional agents of sepsis in neonates and of bacteremia in neutropenic patients.

DIAGNOSIS

Proteus is readily isolated and identified in the laboratory. Most strains are lactose-negative, produce H_2S, and demonstrate characteristic swarming motility on agar plates. *P. mirabilis* and *P. penneri* are indole-negative, whereas *P. vulgaris* is indole-positive. The inability to produce ornithine decarboxylase differentiates *P. penneri* from *P. mirabilis*.

TREATMENT

Proteus Infections

Intrinsic resistance occurs in all *Proteus* spp. to nitrofurantoin, polymyxins, imipenem, and the tetracycline derivatives (e.g., tigecycline, eravacycline, omadacycline) and, in *P. vulgaris* and *P. penneri*, also to ampicillin and the first- and second-generation cephalosporins. Acquired resistance (% of isolates) occurs in *P. mirabilis* to ampicillin (15–65%), and in *Proteus* spp. to fluoroquinolones (10–55%), fosfomycin (7–22%), and TMP-SMX (20–50%). In *P. mirabilis*, ampicillin-sulbactam is more active than ampicillin, with resistance prevalences of 6–18%, but the prevalence of ESBL production (which confers ampicillin-sulbactam resistance) is increasing in the United States (5–10%) and Asia (up to 60%). Isolates of *P. mirabilis* that produce CTX-M ESBLs have been recovered from ambulatory patients with no recent health care contact (see the section on the treatment of extraintestinal *E. coli* infections for treatment considerations). The use of third-generation cephalosporins can induce or select for stable de-repression of AmpC β-lactamase in *P. vulgaris*. Acquired carbapenem resistance remains relatively infrequent (<10%). However, production of a class B metallo-β-lactamase (e.g., NDM) limits treatment options due to the inherent resistance of *Proteus* spp. to polymyxins and tetracycline derivatives (see "Carbapenemase" above). For critically ill patients, agents with excellent activity overall against *Proteus* spp. (90–100% of isolates susceptible) include carbapenems (excepting imipenem), amikacin, piperacillin-tazobactam, aztreonam, cefepime, ceftazidime-avibactam, ceftolozane-tazobactam, and meropenem-vaborbactam.

ENTEROBACTER AND *CRONOBACTER* INFECTIONS

The *E. cloacae* complex is responsible for most *Enterobacter* infections, whereas *Cronobacter sakazakii* (formerly *Enterobacter sakazakii*), *Cronobacter malonaticus*, *Enterobacter cancergenus*, and *Enterobacter gergoviae* are less commonly isolated (<1% for each). *Enterobacter bugandensis* has been recently described as an agent of sepsis in neonates and was isolated from the International Space Station. *Enterobacter* spp. cause primarily health care–related infections. The organisms are widely prevalent in foods, environmental sources (including equipment at health care facilities), and a variety of animals.

Colonization with these organisms is uncommon among healthy humans, but increases significantly with LTCF residence or hospitalization. Although colonization is an important prelude to infection, direct introduction via IV lines (e.g., contaminated IV fluids or pressure monitors) or contaminated non-FDA-approved stem cell products also occurs. Extensive antibiotic resistance has developed in *Enterobacter* spp. and probably has contributed to these organisms' emergence as prominent nosocomial pathogens. Risk factors for *Enterobacter* infection include prior antibiotic treatment, comorbid disease, and ICU residency. *Enterobacter* spp. causes a spectrum of extraintestinal infections similar to those described for other GNB.

INFECTIOUS SYNDROMES

The most commonly encountered syndromes include pneumonia, UTI (particularly catheter-associated), intravascular device–related infection, surgical site infection, and abdominal infection (primarily postoperative or related to devices such as biliary stents). Nosocomial sinusitis, meningitis related to neurosurgical procedures (including use of intracranial pressure monitors), osteomyelitis, and endophthalmitis after eye surgery are less frequent. Neonates (particularly if low-birth-weight) are at risk for *C. sakazakii* infection, including neonatal bacteremia, necrotizing enterocolitis, and meningitis (which is often complicated by brain abscess or ventriculitis). Contaminated powdered infant formula has been implicated as a source for such neonatal infections. The WHO recommends that, to reduce the initial number of bacteria, powdered infant formula should be reconstituted with hot water (>70°C) and, to limit replication of residual bacteria, the reconstituted formula should be stored at <5°C or its storage time minimized.

Enterobacter bacteremia can result from primary infection at any anatomic site. In bacteremia of unclear origin, particularly in an outbreak setting, sources for consideration should include contaminated IV fluids or medications, blood components or plasma derivatives, catheter-flushing fluids, pressure monitors, and dialysis equipment. *Enterobacter* can also cause bacteremia in neutropenic patients. *Enterobacter* endocarditis is rare, occurring primarily in association with illicit IV drug use or prosthetic valves.

DIAGNOSIS

Enterobacter is readily isolated and identified in the laboratory. Most strains are lactose-positive and indole-negative.

TREATMENT

Enterobacter Infections

E. cloacae is intrinsically resistant to ampicillin, ampicillin-sulbactam, ampicillin-clavulanate, the first-generation cephalosporins, and the cephamycins. The prevalence of acquired resistance has ranged from 15 to 40% for piperacillin-tazobactam, 5 to 23% for polymyxin E, 15 to 17% for fosfomycin, 15 to 30% for TMP-SMX, and 5 to 20% for fluoroquinolones and is ~10% for omadacycline (53% if tetracycline resistant). USNHSN data from 2015–2017 identified 8.9% of *E. cloacae* isolates as presumptively ESBL-producing, based on cefepime resistance. The prevalence of ESBLs in *E. cloacae* outside of the United States is 20–50%. The use of third-generation cephalosporins can induce or select for stable de-repression of AmpC β-lactamase. Because resistance may emerge during therapy (in one study, this phenomenon was documented in 20% of clinical isolates), these agents should be avoided in the treatment of serious *Enterobacter* infection.

Cefepime is stable in the presence of AmpC β-lactamases; thus, it is a suitable option for treatment of *Enterobacter* infections so long as no coexistent ESBL is present. Overall, resistance prevalence generally ranges from 10 to 25% for cefepime and 25 to 50% for aztreonam and the third-generation cephalosporins. Carbapenem resistance remains relatively uncommon (USNHSN data from 2015–2017 identified a 5% prevalence) and is more commonly associated with increased AmpC expression and decreased permeability due to porin mutations rather than carbapenemase production, although acquisition of carbapenemase genes is increasing (see "Carbapenemase" above). Uncertainty exists on the optimal treatment for non-CP-CR-*Enterobacter* spp. Fortunately, overall, the percentage of susceptibility is high (90–99%) for carbapenems, amikacin, plazomicin, ceftazidime-avibactam, meropenem-vaborbactam, imipenem/cilastatin-relebactam, cefiderocol, tigecycline, eravacycline, and omadacycline (the latter three for tetracycline-susceptible isolates). Once susceptibility data for a patient's isolate become available, de-escalation of the antimicrobial regimen is advisable whenever possible.

SERRATIA INFECTIONS

S. marcescens causes >90%, and *Serratia liquefaciens* complex <10%, of *Serratia* infections. Serratiae are found primarily in the environment (including in health care institutions), particularly in moist settings. Serratiae have been isolated from a variety of animals, insects, and plants, but only infrequently from healthy humans. In LTCFs and hospitals, reservoirs for the organisms include the hands and fingernails of health care personnel, food, milk (on neonatal units), sinks, medical equipment or devices, IV solutions or parenteral medications (particularly those generated by compounding pharmacies), prefilled syringes and multiple-access medication vials (e.g., for heparin, propofol, saline), blood products (e.g., platelets), hand soaps and lotions, irrigation solutions, and even disinfectants such as chlorhexidine.

Infection results from either direct inoculation (e.g., via contaminated injected substances [IV fluids, medications, or recreational drugs] or snake bite) or colonization (primarily of the respiratory tract). Sporadic infection is most common, but outbreaks (often involving MDR strains in adult and neonatal ICUs) also occur. Hygiene, medication-compounding standards, sterile technique, and infection control programs are critical measures to prevent infection.

The spectrum of extraintestinal infections caused by *Serratia* is similar to that for other GNB. *Serratia* species are usually considered to cause mainly health care–associated infections; they account for 1–3% of hospital-acquired infections. However, population-based laboratory surveillance studies in Canada and Australia have demonstrated that community-acquired *Serratia* infections occur more commonly than was previously appreciated, and case reports have documented serious infection in otherwise healthy hosts. *Serratia* also is one of the pathogens associated with chronic granulomatous disease.

INFECTIOUS SYNDROMES

The most common primary sites of *Serratia* infection are the respiratory and genitourinary tracts, intravascular devices, the eye (contact lens–associated keratitis and other ocular infections), surgical wounds, and the bloodstream (from contaminated infusions), although most episodes of *Serratia* bacteremia arise from one of the listed focal infections rather than contaminated infusate. Less common syndromes are soft tissue infections (including myositis, fasciitis, mastitis), osteomyelitis, abdominal and biliary tract infections (usually postprocedural), and septic arthritis (primarily from intraarticular injections). Serratiae are uncommon causes of neonatal meningitis; postsurgical meningitis, endophthalmitis, or breast implant infection; and bacteremia in neutropenic patients. Endocarditis is rare, occurring most commonly in IV drug users.

DIAGNOSIS

Serratiae are readily cultured and identified by the laboratory and are usually lactose- and indole-negative. The red pigmentation of some *S. marcescens* strains and *Serratia rubidaea* can produce distinctive clinical findings (e.g., pink breast milk or hypopyon; pseudohemoptysis).

TREATMENT

Serratia Infections

Most *Serratia* strains (>80%) are intrinsically resistant to ampicillin, amoxicillin-clavulanate, ampicillin-sulbactam, first- and second-generation cephalosporins, cephamycins, nitrofurantoin, and polymyxins; likewise, tetracycline derivatives are poorly active. By contrast, fluoroquinolones, TMP-SMX, piperacillin-tazobactam, fosfomycin, and omadacycline are active against 85–95% of U.S. and European isolates, including those resistant to tetracycline. Both in the United States and globally, the prevalence of ESBL-producing isolates is generally low (<10%), but rates of 20–30% have been reported in Asia and Latin America. The use of third-generation cephalosporins may result in the induction or selection of variants with stable de-repression of chromosomal AmpC β-lactamases during therapy but is uncommon. Resistance prevalence generally ranges from 10 to 20% for aztreonam and the third-generation cephalosporins. Acquisition of carbapenemase-encoding genes is uncommon but increasing. Production of a class B metallo-β-lactamase (e.g., NDM) limits treatment options due to *Serratia*'s predictable resistance to polymyxins and tetracycline derivatives (see "Carbapenemase" above). For critically ill patients, the most active agents overall (>90% susceptible) are carbapenems, piperacillin-tazobactam, cefepime, amikacin, plazomicin, ceftazidime-avibactam, ceftolozane-tazobactam, and meropenem-vaborbactam.

CITROBACTER INFECTIONS

C. freundii and *Citrobacter koseri* cause most human *Citrobacter* infections, which are epidemiologically and clinically similar to *Enterobacter* infections. *Citrobacter* species are commonly present in water, food, soil, and certain animals. Colonization with these organisms is uncommon among healthy humans, but increases significantly with LTCF residence or hospitalization. *Citrobacter* species account for 1–2% of nosocomial infections. The affected hosts are usually immunocompromised and/or have comorbid disease or disruption of skin or mucosal barriers. Infection from treatment with contaminated, non-FDA-approved stem cell products has been described. *Citrobacter* causes extraintestinal infections similar to those described for other GNB.

INFECTIOUS SYNDROMES

The urinary tract accounts for 40–50% of *Citrobacter* infections. Less commonly involved sites include the biliary tree (particularly with stones or obstruction), the respiratory tract, surgical sites, soft tissue (e.g., decubitus ulcers), the peritoneum, and intravascular devices. Osteomyelitis (usually from a contiguous focus), central nervous system infection in adults (from neurosurgical or other types of meningeal

disruption), and myositis occur rarely. *Citrobacter* (primarily *C. koseri*) also causes 1–2% of neonatal meningitis cases, of which 50–80% are complicated by brain abscess. Further, case reports in adults suggest that *C. koseri* infection has a predilection for abscess formation. *Citrobacter* bacteremia is most often due to UTI, biliary/abdominal infection, or intravascular device infection, and occurs in some neutropenic patients. Endocarditis and other endovascular infections are rare.

DIAGNOSIS

Citrobacter species are readily isolated and identified; 35–50% of isolates are lactose-positive, and 100% are oxidase-negative. *C. freundii* is indole-negative, whereas *C. koseri* is indole-positive.

TREATMENT

Citrobacter Infections

C. freundii is more extensively antibiotic-resistant than is *C. koseri*. Most *C. freundii* isolates are intrinsically resistant to ampicillin, ampicillin-sulbactam, amoxicillin-clavulanate, first-generation cephalosporins, and cephamycins. *C. koseri* exhibits intrinsic resistance to ampicillin and ampicillin-sulbactam. Overall, the prevalence of acquired resistance generally ranges from 15 to 35% for third-generation cephalosporins, piperacillin-tazobactam, fluoroquinolones, and TMP-SMX and is ~10% for nitrofurantoin and omadacycline (but 39% for omadacycline if tetracycline-resistant). The prevalence of ESBL production ranges from 5 to 30%. The use of third-generation cephalosporins may result in the induction or selection of variants with stable de-repression of chromosomal AmpC β-lactamases during therapy. Presently, <10% of isolates have acquired carbapenemases (see "Carbapenemase" above). Carbapenems, amikacin, plazomicin, fosfomycin, polymyxins, cefepime, ceftazidime-avibactam, cefiderocol, tigecycline, eravacycline, and omadacycline (the latter three if tetracycline-susceptible) are the most active agents against *Citrobacter* isolates (>90% susceptible).

MORGANELLA AND *PROVIDENCIA* INFECTIONS

M. morganii, Providencia stuartii, and (less frequently) *Providencia rettgeri* are the members of their respective genera that cause systemic human infections. *P. alcalifaciens* has been implicated as a cause of food-borne gastroenteritis. These organisms' epidemiologic associations, pathogenic properties, and clinical manifestations resemble those of *Proteus* species. *Morganella* and *Providencia* occur more commonly among LTCF residents than among hospitalized patients, largely resulting from chronic urinary catheter use. Because of these organisms' intrinsic resistance to polymyxins and tigecycline, they may become increasingly common in settings with extensive use of these agents.

INFECTIOUS SYNDROMES

These species are primarily urinary tract pathogens, causing UTIs that are most often associated with long-term (>30-day) catheterization. Such infections commonly lead to biofilm formation and catheter encrustation (sometimes causing catheter obstruction) or the development of struvite bladder or renal stones (sometimes causing renal obstruction, abscess, and extrarenal extension, and serving as foci for relapse). They can cause purple urine ("purple bag syndrome"), as can *P. mirabilis*, *K. pneumoniae*, *E. coli*, and *P. aeruginosa*. *Morganella* is also commonly isolated from snakebite infection.

Other, less common infectious syndromes due to *Morganella* and *Providencia* include surgical site infection, soft tissue infection (primarily involving decubitus and diabetic ulcers), burn site infection, pneumonia (particularly ventilator-associated), intravascular device infection, and intraabdominal infection. Rarely, the other extraintestinal infections described for GNB also occur. Bacteremia is uncommon; when it does occur, any infected site can serve as the source, but the urinary tract accounts for most cases, followed by surgical site, soft tissue, and hepatobiliary infections.

DIAGNOSIS

M. morganii and *Providencia* are readily isolated and identified. Nearly all isolates are lactose-negative and indole-positive.

TREATMENT

Morganella and *Providencia* Infections

Morganella and *Providencia* are intrinsically resistant to ampicillin, ampicillin-clavulanate, ampicillin-sulbactam, first-generation cephalosporins, nitrofurantoin, tetracyclines and derivatives (e.g., tigecycline), imipenem (but not the other carbapenems), and the polymyxins. *P. stuartii* additionally exhibits intrinsic resistance to gentamicin and tobramycin, as does *M. morganii* to second-generation cephalosporins. Fosfomycin is poorly active (>50% resistance). The prevalence of resistance generally ranges from 10 to 30% for the third-generation cephalosporins, from 10 to 40% for fluoroquinolones, and from 20 to 40% for TMP-SMX; the prevalence is more widely variable for piperacillin-tazobactam. The prevalence of ESBL production is generally <10%. The use of third-generation cephalosporins can induce or select for stable de-repression of AmpC β-lactamase for both *Morganella* and *Providencia*. The prevalence of acquired carbapenemase production is <10%. Production of a class B metallo-β-lactamase (e.g., NDM) limits treatment options due to the inherent resistance of the *Proteeae* to polymyxins and tetracycline derivatives (see "Carbapenemase" above). Overall, the most active agents (>90% of isolates susceptible) are carbapenems (excepting imipenem), amikacin, cefepime, ceftazidime-avibactam, ceftolozane-tazobactam, meropenem-vaborbactam, and cefiderocol. Removal of a colonized urinary catheter or stone is critical for eradication of UTI.

EDWARDSIELLA INFECTIONS

E. tarda is the only member of the genus *Edwardsiella* that is associated with human disease. This organism is found predominantly in freshwater and marine environments and in the associated aquatic animal species. Human acquisition occurs primarily from interaction with these reservoirs or ingestion of raw or inadequately cooked aquatic animals. *E. tarda* infection is rare in the United States, where acquisition occurs mainly along the Gulf of Mexico; recently reported cases are mostly from Asia. This pathogen shares clinical features with *Salmonella* species (as an intestinal pathogen; **Chap. 165**), *Vibrio vulnificus* (as an extraintestinal pathogen; **Chap. 168**), and *Aeromonas hydrophila* (as both an intestinal and an extraintestinal pathogen; **Chap. 158**).

INFECTIOUS SYNDROMES

Gastroenteritis is the predominant *Edwardsiella*-associated infectious syndrome (50–80% of reported cases). Self-limiting watery diarrhea is most common, but severe colitis also occurs. The most common extraintestinal infection is wound infection due to direct inoculation, which is often associated with brackish or freshwater injuries, snakebites, or fish-related trauma. A case of pneumonia occurred after a near-drowning incident. Cholecystitis, cholangitis, and hepatic abscess may be due to ascending infection via the biliary tree. Other infectious syndromes result from invasion of the gastrointestinal tract and subsequent bacteremia. A primary bacteremic syndrome, sometimes complicated by meningitis, has a 40% case–fatality rate; hematogenous seeding may result in hepatic and intra- and extraperitoneal abscesses, endocarditis, mycotic aneurysm, septic arthritis, osteomyelitis, necrotizing fasciitis, and empyema. Most hosts who develop systemic *Edwardsiella* infection have significant comorbidities (e.g., hepatobiliary disease, iron overload, cancer, or diabetes mellitus).

DIAGNOSIS

Although *E. tarda* can readily be isolated and identified, most laboratories do not routinely screen for or identify it in stool samples. Production of hydrogen sulfide is a characteristic biochemical property.

TREATMENT

Edwardsiella Infections

E. tarda is susceptible to most antimicrobial agents appropriate for use against GNB. Gastroenteritis is generally self-limiting, but treatment with a fluoroquinolone may hasten resolution. In the setting of severe sepsis, fluoroquinolones, third- and fourth-generation cephalosporins, carbapenems, and amikacin—either alone or in combination—are the safest choices pending susceptibility data.

INFECTIONS CAUSED BY MISCELLANEOUS GENERA

Other gram-negative organisms such as *Hafnia*, *Kluyvera*, *Cedecea*, *Pantoea*, *Ewingella*, *Leclercia*, *Raoultella*, and *Photorhabdus* spp. are occasionally isolated from diverse clinical specimens, including blood, sputum, urine, cerebrospinal fluid, joint fluid, bile, and wounds. Such organisms cause infection predominantly in compromised hosts or in association with an invasive procedure or foreign body. Cephalosporinases from *Kluyvera* have been implicated as the progenitors of CTX-M ESBLs. *Kluyvera* and *Raoultella* may produce carbapenemases.

162 *Acinetobacter* Infections

Rossana Rosa, L. Silvia Munoz-Price

DEFINITION

Acinetobacter species were first described in 1911 and named *Micrococcus calcoaceticus*. Thereafter, the genus was renamed multiple times; since 1950, it has been known as *Acinetobacter*. *Acinetobacter* species are gram-negative, oxidase-negative, nonmotile, nonfermenting coccobacilli that are easily recovered on standard culture media. Differentiation among *Acinetobacter* species on the basis of phenotypic characteristics alone is very difficult. Molecular-based methods such as matrix-assisted laser desorption–ionization–time-of-flight mass spectrometry (MALDI-TOF-MS) and quantitative real-time polymerase chain reaction (PCR) are usually necessary to identify *Acinetobacter baumannii*, the most clinically relevant species of the genus.

ETIOLOGY AND EPIDEMIOLOGY

Acinetobacter species are naturally encountered in water and soil and have also been recovered from fruits and vegetables. In humans, *Acinetobacter* can be found on the skin and in the respiratory and gastrointestinal tracts. *A. baumannii* is capable of surviving environmental desiccation for weeks; this characteristic is important from an infection-control perspective as it allows this organism to persist in the hospital environment and on equipment.

Acinetobacter was historically considered a pathogen of hot and humid climates. In recent years, however, hospital outbreaks caused by *A. baumannii* have been reported worldwide, even in temperate climates. In the United States, the Centers for Disease Control and Prevention (CDC) estimates that 12,000 *Acinetobacter* infections occur every year, 7300 of which are caused by multidrug-resistant strains, with 500 attributable deaths. The increase in the number of infections with *A. baumannii* is suspected to be due to the rapid spread of certain genetically distinct lineages; of the three international clonal lineages (ICLs), ICL I and ICL II are multidrug resistant. The predominance of these lineages remains unexplained, although it has been proposed that this population structure is the result of two waves of expansion. The first wave followed a bottleneck (possibly linked to a restricted ecologic niche) that occurred in the distant past. The second wave is ongoing and is being driven by the rapid expansion of a limited number of multidrug-resistant clones.

Analysis of the *A. baumannii* pangenome (the sum of the core and dispensable genomes) has shown that its organization is characterized by a small core genome and a large accessory or disposable genome. This organization reflects *A. baumannii's* high plasticity, which enables it to acquire exogenous genetic material. With few exceptions, gene functions associated with virulence are found in the core genome; this observation suggests a limited role for the acquisition of new virulence traits in the recent nosocomial expansion of *A. baumannii* clones. Genes associated with resistance to antimicrobial agents are found in both the species core genome and the accessory genome. In the accessory genome, these genes have been found in alien islands, often flanked by integrases, transposases, or insertion sequences. This pattern suggests possible acquisition by horizontal gene transfer from other *Acinetobacter* strains or even from different bacterial species present in the immediate environment. Acquisition of these antimicrobial resistance genes is hypothesized to have led to the recent rapid expansion of highly homogeneous clonal lineages, whose main difference from nonclonal *A. baumannii* appears to be their antimicrobial resistance.

Health Care–Associated Infections Infections caused by *A. baumannii* occur frequently among patients admitted to intensive care units (ICUs). Risk factors for colonization and infection with this pathogen include nursing home residence, prolonged ICU stay, central venous catheterization, tracheostomy, mechanical ventilation, enteral feedings, and treatment with third-generation cephalosporins,

fluoroquinolones, and carbapenems. Acquisition of carbapenem-resistant *A. baumannii* is most common among patients exposed to carbapenems. Spread of *A. baumannii* across different regions is facilitated by the movement of patients between health care systems and throughout the continuum of health care. Within the hospital, environmental spread of *A. baumannii* occurs as a result of inappropriate hand hygiene among workers providing health care for infected or colonized patients and the contamination of hospital equipment, such as respiratory therapy and ventilation equipment. The air surrounding the patient may also play a role in environmental colonization with *A. baumannii*, especially in inpatient areas without physical barriers between patients and with an inadequate number of air exchanges.

A. baumannii strains identified during hospital outbreaks are typically resistant to more antibiotic classes than strains from the community. The prevalence of colonization with *A. baumannii* at the time of admission or during a stay in a long-term acute-care hospital (LTACH) or nursing home is variable and depends on regional flora. Outbreaks of *A. baumannii* in acute-care hospitals and LTACHs that "share" patients have been described in Ohio, Michigan, Illinois, and Indiana.

Community-Acquired Infections Community-acquired infections caused by *Acinetobacter* have been described in Australia and Asia. Few cases have been reported in regions with a temperate climate, and even those few cases have taken place during warm and humid months. Risk factors for community-acquired pneumonia due to this organism include a history of alcohol abuse, diabetes mellitus, smoking, and chronic lung disease.

War Zone–Associated Infections Infections caused by *Acinetobacter* in war zones include skin and soft tissue infections associated with traumatic injuries and bloodstream infections. Outbreak investigations of *A. baumannii* infections among military personnel returning from Iraq and Afghanistan suggested the acquisition of *A. baumannii* in field hospitals rather than colonization of the skin before an injury. This view is supported by the recovery of *A. baumannii* isolates with similar genetic characteristics from inanimate surfaces in field hospitals and from patients.

Disaster Medicine *A. baumannii* is linked to infections among victims of trauma during tsunamis, earthquakes, and terrorist attacks. The types of infections most frequently observed in these settings are soft tissue injuries, but bloodstream infections and pneumonia have also been reported. In addition, outbreaks of *A. baumannii* infection in ICUs caring for disaster victims have been described.

PATHOGENESIS

Mechanisms of pathogenesis and virulence in *Acinetobacter* species have not been fully elucidated. However, *A. baumannii* seems to have greater virulence potential than other *Acinetobacter* species, as evidenced by its ability to grow at 37°C and to resist uptake by macrophages.

Initial *A. baumannii* colonization of the host and the environment is facilitated by the organism's ability to adhere to surfaces and human cells and to create biofilms. The ability to form a biofilm is phenotypically associated with exopolysaccharide production and pilus formation. A quorum-sensing molecule encoded by the *abaI* autoinducer synthase gene has been implicated in *A. baumannii* biofilm formation on abiotic surfaces. Outer-membrane porins appear to mediate cell apoptosis. *A. baumannii* can survive in harsh environments within the host and on inanimate surfaces by modifying the structure of its lipid A, with a consequent decrease in susceptibility to antibiotics and antimicrobial peptides and an increase in survival upon desiccation.

Acinetobacter species produce an extracellular capsule that protects the bacteria from external threats, including complement-mediated killing. Studies of mouse models showed that *Acinetobacter* species can increase capsule production in the presence of subinhibitory levels of antibiotic—an ability that leads to increased resistance to complement-mediated killing and a hypervirulent phenotype.

Phospholipase C and phospholipase D have been identified as virulence factors in *A. baumannii*. These enzymes exert cytotoxic effects on epithelial cells and facilitate their invasion.

Iron-acquisition systems are also important virulence mechanisms in *A. baumannii*. Through secretion of siderophores (low-molecular-mass ferric-binding compounds), *A. baumannii* is able to grow despite iron deficiencies in the surrounding environment (e.g., in the human host).

Several protein-secretion systems have been identified in *A. baumannii*. The most recently described is a type II secretion system. The substrate for this system, the LipA lipase, is required for growth on medium containing lipids as a sole carbon source. Mutants lacking the genes for the type II secretion system or its substrate exhibit defective in vivo growth in a neutropenic murine model of bacteremia. *A. baumannii* also has a type VI secretion system whose primary function seems to be to secrete antibacterial toxins that kill competing bacteria, including other strains in the same species.

The type V autotransporter system has been characterized in *A. baumannii*. In a murine systemic model of *Acinetobacter* infection, the *Acinetobacter* trimeric autotransporter mediates biofilm formation and maintenance; adherence to extracellular matrix components such as collagen I, II, and IV; and virulence.

Outer-membrane vesicles (OMVs) play a special role in protein secretion. Many *A. baumannii* strains secrete OMVs containing various virulence factors, including outer-membrane protein A (OmpA), proteases, and phospholipases. The membrane proteins in OMVs are responsible for eliciting a potent innate immune response. Several studies have shown that *A. baumannii* OMVs could be used as an acellular vaccine to effectively control *A. baumannii* infections.

Nosocomial strains of *Acinetobacter* can deploy multiple mechanisms of resistance, including alterations in porins and efflux pumps and expression of β-lactamases. More specifically, *Acinetobacter* species can reduce the expression of porins, thus hindering the passage of β-lactam antibiotics into the periplasmic space. These species can overexpress bacterial efflux pumps and decrease the concentration of β-lactam antibiotics in the periplasmic space. Efflux pumps can also actively remove quinolones, tetracyclines, chloramphenicol, disinfectants, and tigecycline. *Acinetobacter* species possess chromosomally encoded cephalosporinases and are capable of acquiring β-lactamases, including serine and metallo-β-lactamases. AmpC β-lactamases are class C β-lactamases intrinsic to all *A. baumannii* strains. Although these enzymes are expressed at low levels and are not inducible, the addition of the insertion sequence *ISAba1* next to the AmpC gene increases β-lactamase production, with resulting resistance to cephalosporins.

Carbapenem resistance in *Acinetobacter* species is mostly tied to the emergence of Ambler class D oxacillinases of group 2d, some of which are intrinsic and chromosomal (e.g., OXA-51-like) while others are acquired and are found in plasmids or are chromosomally encoded (e.g., OXA-23-like, 24 [33-like, 40-like], 58-like, 143-like, and 235-like).

CLINICAL MANIFESTATIONS

Pneumonia *A. baumannii* is a notorious cause of nosocomial pneumonia, most frequently among patients requiring prolonged mechanical ventilation. The onset of disease tends to be later than that caused by other gram-negative bacilli; however, clinical symptoms of hospital-acquired or ventilator-associated pneumonia due to *A. baumannii* are similar to those of nosocomial or ventilator-associated pneumonia due to other nosocomial pathogens. Thus, the most common indicators of infection include fever and increased sputum production. The positivity of respiratory cultures in most cases may present a challenge for the clinician, since airway colonization with *A. baumannii* is a risk factor for infection itself. Radiologic findings are nonspecific and can include lobar consolidations and pleural effusions, but cavitations are rarely seen. The crude mortality rates associated with nosocomial pneumonia due to *A. baumannii* are reported to be as high as 65%. However, since these infections occur in debilitated patients, their attributable mortality has been difficult to establish.

Community-acquired pneumonia due to *A. baumannii* is a relatively rare entity. Its clinical presentation is characterized by fever, severe respiratory symptoms, and multiple-organ dysfunction. Patients frequently have a cough productive of purulent sputum, shortness of

breath, and chest pain. Imaging studies usually show lobar consolidation. Mortality rates associated with this process are >50%.

Bloodstream Infections Bloodstream infections due to *A. baumannii* are most frequent among ICU patients and usually occur in the presence of a central venous catheter or as a secondary complication of hospital-acquired or ventilator-associated pneumonia. Polymicrobial growth has been reported in 20–36% of bacteremia episodes. Fever is the most common sign of infection (developing in >95% of cases), and presentation with septic shock and disseminated intravascular coagulopathy has been described in as many as 25 to 30% of patients, respectively. *A. baumannii* bloodstream infections often result in higher hospitalization costs and longer ICU stays. Crude mortality rates from this infection are as high as 40%; however, rates can be as high as 70% from infections caused by carbapenem-resistant isolates. In patients with infections caused by extremely drug-resistant strains, poor outcomes are thought to be driven by delays in the initiation of adequate antimicrobial therapy.

Skin and Soft Tissue Infections *Acinetobacter* species have been described as part of the skin flora, yet the majority of the organisms from this genus that colonize the skin are not those associated with nosocomial infections. Discerning infection from wound colonization is challenging. Gunshot wounds and the presence of orthopedic external-fixation devices are common among patients with combat trauma–associated *A. baumannii* skin and soft tissue infections. The report on a case series of eight U.S. military patients described the clinical presentation of their infections as evolving from an edematous *peau d'orange* appearance to a sandpaper appearance with overlying vesicles and then to a necrotizing process with hemorrhagic bullae. Other case series have also included necrotizing fasciitis. *A. baumannii* is an important pathogen in burn units worldwide. Large burns provide ideal conditions for *A. baumannii* and facilitate patient-to-patient transmission. The presence of *A. baumannii* in wounds contributes to healing delays and graft loss. In addition, wound colonization is a risk factor for bloodstream infections among patients with extensive burn injuries.

A. baumannii infections resulting from trauma to soft tissues in the setting of natural disasters, such as tsunamis and earthquakes, have been reported. The implication is that *A. baumannii* should be considered in the differential diagnosis of soft tissue infections following exposure to tropical and subtropical environments.

Urinary Tract Infections *A. baumannii* is an infrequent cause of urinary tract infections. The majority of cases reported are catheter-associated infections, reflecting the ability of *A. baumannii* to form biofilms on these devices. A few reports have described community-acquired infections occurring in the setting of nephrolithiasis and after renal transplantation.

Meningitis Central nervous system infections with *A. baumannii* have been reported in the context of outbreaks, traumatic injuries, neurosurgical procedures, and external ventricular drains. One case series described a petechial rash in up to 30% of patients. *Acinetobacter* species may look similar to *Neisseria meningitidis* on a Gram's stain of cerebrospinal fluid; both appear as gram-negative paired cocci.

Other Miscellaneous Infections A few cases of *A. baumannii* keratitis associated with the use of contact lenses have been reported. Cases of native- and prosthetic-valve endocarditis have also been described.

TREATMENT

Acinetobacter Infections

Treatment of *Acinetobacter* infections is challenging because *Acinetobacter* can develop resistance to most available antibiotics. Therefore, the choice of empirical therapy should be based on local epidemiology and the patient's colonization status. Definitive therapy should be determined by antimicrobial susceptibility testing.

TABLE 162-1 Therapeutic Options for the Management of Multidrug-Resistant *Acinetobacter baumannii* Infections

ANTIBIOTIC	DOSING[a]	COMMENTS
Sulbactam	3–9 g/d (9–27 g/d if given in combination with ampicillin)	Unavailable as single drug in many countries (including the United States)
Meropenem	2 g q8h	Prolonged infusion (3–4 h) has been used; limited data
Imipenem	500 mg q6h	Prolonged infusion (3–4 h) has been used; limited data
Cefiderocol	2g q8h	Prolonged infusion (3 h) used in pharmacokinetic models
Colistin	Loading dose of 5 mg/kg followed by 2.5–5.0 mg/kg per day of colistin base given in 2–4 divided doses	Optimal dosing regimen unknown Inhaled formulation has been used as adjunct treatment in lung infections.
Polymyxin B	1.5–3 mg/kg q12h	
Tigecycline	100-mg loading dose followed by 50 mg q12h	Low serum concentrations and bacteriostatic activity limit use in bacteremia.
Minocycline	100 mg q12h	Loading dose of 200 mg IV has been used.
Eravacycline	1 mg/kg q12h	
Amikacin	15 mg/kg qd	Inhaled formulation of tobramycin has been used as adjunct treatment in lung infections.
Rifampin	600 mg qd or 600 mg q12h	Use in combination therapy
Fosfomycin	4 g q12h PO	Use in combination therapy IV formulation not available in the United States

[a]All drugs are given by the IV route unless otherwise stated.

Antimicrobial options for the management of infections caused by *A. baumannii* are displayed in Table 162-1.

Acinetobacter species possess intrinsic β-lactamases that inactivate first- and second-generation cephalosporins. Through acquisition of extended-spectrum β-lactamases, the organisms can also become resistant to third- and fourth-generation cephalosporins. Nevertheless, when the isolate is susceptible, β-lactam agents are the drugs of choice for the treatment of *A. baumannii*. Among β-lactamase inhibitors, sulbactam is active against *A. baumannii* and is as effective as carbapenems and polymyxins. Cefiderocol is a novel cephalosporine and is stable against many β-lactamase classes, including extended-spectrum β-lactamases, AmpC, and carbapenemases. Cefiderocol has shown in vitro activity against *A. baumannii* isolates producing OXA-23, OXA-40, OXA-58, NDM, and IMP. However, published clinical trials have not included patients with infections caused by carbapenem-resistant strains.

Carbapenems have been the preferred drugs for treatment of invasive or hospital-acquired infections. Unfortunately, surveillance data from U.S. hospitals show that up to 50% of *A. baumannii* isolates recovered from ICUs are carbapenem resistant, and rates of carbapenem resistance are even higher around the world.

Aminoglycosides are of limited utility against *A. baumannii* because of toxicity and lack of lung penetration. Inhaled formulations of tobramycin have been used with variable success.

Polymyxins are cationic detergents that fell out of use as a result of nephrotoxicity and neurotoxicity. In vitro, they are the most active agents against carbapenem-resistant *A. baumannii*. Colistin has been used in both intravenous and inhaled formulations, although the optimal dosage has not yet been determined. Combination therapy using colistin as a base has long been preferred but randomized controlled trials have failed to show improved survival compared to colistin monotherapy.

Tigecycline is a glycylcycline with clinical activity against *A. baumannii*. It reaches only low serum concentrations and therefore cannot be used for bloodstream infections. The susceptibility of

isolates is variable, especially in outbreak settings, and the emergence of resistance during treatment has been reported.

Minocycline is a tetracycline that has a bacteriostatic effect on *A. baumannii*. Synergistic and bactericidal activity has been noted when minocycline is used in combination with colistin or a carbapenem.

Eravacycline is a novel tetracycline with in vitro activity against multidrug-resistant and extensively drug-resistant strains of *A. baumannii.* However, only a small number of carbapenem-resistant isolates have been included in clinical studies. Furthermore, eravacycline has been approved for the treatment of complicated intraabdominal infections but was shown to be inferior to levofloxacin and ertapenem for the management of complicated urinary tract infections.

Fosfomycin is an inhibitor of peptidoglycan synthesis that has no direct activity against *A. baumannii* but has been observed to be synergistic in vitro in combination with colistin or sulbactam. Clinical data have shown higher rates of microbiologic cure, but no differences in clinical response, with combinations of fosfomycin and colistin.

In vitro data favor combination therapy with colistin in many different regimens containing a carbapenem (imipenem, meropenem), rifampin, minocycline, ceftazidime, azithromycin, doxycycline, trimethoprim-sulfamethoxazole, or ampicillin-sulbactam. However, clinical data have not shown such combination therapy to be superior to colistin alone.

Bacteriophage therapy against multidrug-resistant *A. baumannii* has been reported with varied success rates. Furthermore, dosing and duration of therapy vary by syndrome and resistance can also arise during treatment.

COMPLICATIONS AND PROGNOSIS

Infections caused by *A. baumannii* can be associated with high mortality rates. Factors contributing to higher mortality are thought to include severity of the patient's underlying illness and drug resistance in the infecting strain.

INFECTION CONTROL AND PREVENTION

Acinetobacter species are capable of surviving on hospital surfaces for prolonged periods. In the hospital environment, *A. baumannii* has been associated with establishment of a *fecal patina*; this term refers to a coating of enteric organisms that can cover the skin of colonized patients and extend to their surrounding environment. Concentrations of enteric organisms are highest in the colonized patient's rectum, with spread in a target-like concentric pattern covering the patient's body and the surrounding environment. High-frequency touch areas in rooms occupied by patients colonized with *A. baumannii* are more likely to be contaminated. The hands, gloves, and gowns of health care workers can be contaminated after entry into the room of a patient colonized with *A. baumannii* **(Fig. 162-1)**.

Outbreaks caused by *A. baumannii* are frequently mono- or oligoclonal. A common source of infection has been identified in ~50% of outbreaks. These sources include respiratory therapy equipment, the hands of health care workers, bedside humidifiers, warm bathwater, hospital-prepared distilled water, bedpans, urine jugs, heparinized saline solution, mattresses, reusable pressure transducers in arterial lines, and fluids used for pressure lavage of wounds.

Control of multidrug-resistant *Acinetobacter* outbreaks starts with early recognition, with subsequent halting of the spread of infection throughout a facility and prevention of the establishment of an endemic strain. It is important to identify the outbreak strain and differentiate it from nonoutbreak strains so that infection control activities can be better targeted. Traditionally, the strain was identified with phenotypic typing systems (biotyping) or by determination of antimicrobial susceptibility patterns. Molecular typing systems have ushered in an era of molecular epidemiology that allows more precise identification of outbreak strains through use of techniques such as ribotyping, pulse-field gel electrophoresis, repetitive sequence-based PCR, and multilocus sequence testing.

During outbreaks, the simultaneous introduction of multiple ("bundled") measures makes it difficult to assess the impact of each individual measure. These interventions include aggressive cleaning of the general environment, active surveillance, contact isolation of colonized or infected patients, cohorting of medical staff, reinforcement of compliance with hand hygiene by health care workers, and use of aseptic care devices.

Colonization with *A. baumannii* is a strong predictor of subsequent clinical infection by this organism. Exposure to carbapenems is a risk factor for initial acquisition of this pathogen; therefore, efforts to curtail unnecessary use of antibiotics are fundamental to the prevention of

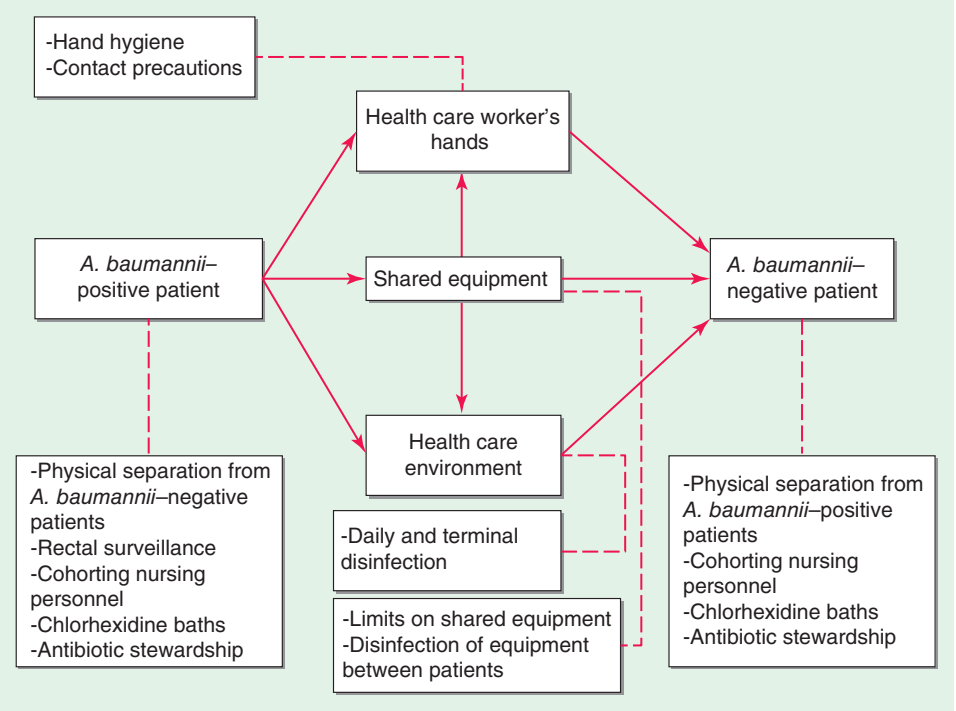

FIGURE 162-1 Strategies for the prevention of dissemination of *Acinetobacter baumannii* in health care facilities.

A. baumannii colonization of patients and the organism's establishment in health care facilities.

163 *Helicobacter pylori* Infections

John C. Atherton, Martin J. Blaser

Helicobacter pylori colonizes the stomach in ~50% of the world's human population, essentially for life unless eradicated by antibiotic treatment. Colonization with this organism is the main risk factor for peptic ulceration **(Chap. 324)** as well as for gastric adenocarcinoma and gastric mucosa-associated lymphoid tissue (MALT) lymphoma **(Chap. 80)**. Treatment for *H. pylori* has revolutionized the management of peptic ulcer disease, providing a permanent cure in most cases. Such treatment also represents first-line therapy for patients with low-grade gastric MALT lymphoma. Treatment of *H. pylori* is of no benefit in the treatment of gastric adenocarcinoma, but prevention of *H. pylori* colonization or eradicative treatment could potentially prevent gastric malignancy and peptic ulceration. In contrast, increasing evidence indicates that lifelong *H. pylori* colonization may offer some protection against complications of gastroesophageal reflux disease (GERD), including esophageal adenocarcinoma. Recent research has focused on whether *H. pylori* colonization is also a risk factor for some extragastric diseases and whether it is protective against some recently emergent medical problems, such as childhood-onset asthma and other allergic and metabolic conditions.

ETIOLOGIC AGENT

Helicobacter pylori *H. pylori* is a gram-negative bacillus that has naturally colonized humans for at least 100,000 years, and probably throughout human evolution. It lives in gastric mucus, with a proportion of the bacteria adherent to the mucosa and possibly a very small number of the organisms entering cells or penetrating the mucosa; the organism's distribution is mucosal rather than systemic. Its spiral shape and flagella render *H. pylori* motile in the mucus environment. The organism has several acid-resistance mechanisms, most notably a highly expressed urease that catalyzes urea hydrolysis to produce buffering ammonia. *H. pylori* is microaerophilic (i.e., grows in low levels of oxygen), is slow-growing, and requires complex growth media in vitro.

Other *Helicobacter* Species A small proportion of gastric *Helicobacter* infections are due to species other than *H. pylori*, possibly acquired as zoonoses. These non-*pylori* gastric helicobacters are associated with low-level inflammation and occasionally with disease. In immunocompromised hosts, several nongastric (intestinal) *Helicobacter* species can cause disease with clinical features resembling those of *Campylobacter* infections; these species are covered in **Chap. 167**.

EPIDEMIOLOGY

Prevalence and Risk Factors The prevalence of *H. pylori* among adults is <30% in most parts of the United States, Europe, and Oceania as opposed to >60% in many parts of Africa, South America, and West Asia. In the United States, prevalence varies with age: up to 50% of 60-year-old persons, ~20% of 30-year-old persons, and <10% of children are colonized. *H. pylori* is usually acquired in childhood. The age association is due mostly to a birth-cohort effect whereby current 60-year-olds were more commonly colonized as children than are current children. Spontaneous acquisition or loss of *H. pylori* in adulthood is uncommon. Childhood acquisition explains why the main risk factors for infection are markers of crowding and social deprivation in childhood. Longitudinal studies have shown declining prevalences over the past half-century, concomitant with socioeconomic development and widespread antibacterial treatments.

Transmission Humans are the only important reservoir of *H. pylori*. Children may acquire the organism from their parents (most often the primary caregiver) or from other children. The former is more common in developed countries and the latter in less developed countries. Whether transmission takes place more often by the fecal–oral or the oral–oral route is unknown, but *H. pylori* is easily cultured from vomitus and gastroesophageal refluxate and is much less easily cultured from stool. Most acquisition of *H. pylori* is during the early years of childhood.

PATHOLOGY AND PATHOGENESIS

Long-term *H. pylori* colonization induces *chronic superficial gastritis*, a tissue response in the stomach that includes infiltration of the mucosa by both mononuclear and polymorphonuclear cells. (The term *gastritis* should be used specifically to describe histologic features; it has also been used to describe endoscopic appearances and even symptoms, but only magnification endoscopy correlates with microscopic findings or even with the presence of *H. pylori*, and even this is insufficient for diagnosis.) Although *H. pylori* is capable of numerous adaptations that prevent excessive stimulation of the immune system, colonization is accompanied by a considerable persistent local and systemic immune response, including the production of antibodies and cell-mediated responses. However, these responses are ineffective in clearing the bacterium. This inefficient clearing appears to be due in part to *H. pylori*'s downregulation of the immune system, which fosters its own persistence.

Most *H. pylori*–colonized persons do not develop clinical sequelae. That some persons develop overt disease whereas others do not is related to a combination of factors: bacterial strain differences, host susceptibility to disease, and environmental factors.

Bacterial Virulence Factors Several *H. pylori* virulence factors are more common among strains that are associated with disease than among those that are not. The *cag* island is a group of genes that encodes a bacterial type IV secretion system. Through this system, an effector protein, CagA, is translocated into epithelial cells, where it may be activated by phosphorylation and induces host cell signal transduction; proliferative, cytoskeletal, and inflammatory changes in the cell result. The protein at the tip of the secretory apparatus, CagL, binds to integrins on the cell surface, transducing further signaling. Finally, soluble components of the peptidoglycan cell wall enter the cell, mediated by the same secretory system. These components are recognized by the intracellular bacterial receptor Nod1, which stimulates a proinflammatory cytokine response resulting in an enhanced tissue response. Carriage of *cag*-positive strains increases the risk of both peptic ulcer and gastric adenocarcinoma. A second major host-interaction factor is the vacuolating cytotoxin VacA, which forms pores in cell membranes. VacA is polymorphic, and carriage of more active forms also increases the risk of ulcer disease and gastric cancer. Other bacterial factors that are associated with increased disease risk include adhesins, such as BabA (which binds to blood group antigens on epithelial cells).

Host Genetic and Environmental Factors The best-characterized host determinants of disease are genetic polymorphisms leading to enhanced activation of the innate immune response, including polymorphisms in cytokine genes and in genes encoding bacterial recognition proteins such as Toll-like receptors. For example, colonized people with polymorphisms in the interleukin 1 gene that increase the production of this cytokine in response to *H. pylori* infection are at increased risk of gastric adenocarcinoma. In addition, environmental cofactors are important in pathogenesis. Smoking increases the risks of duodenal ulcers and gastric cancer in *H. pylori*–positive individuals. Diets high in salt and preserved foods increase cancer risk, whereas diets high in antioxidants and vitamin C are modestly protective.

Distribution of Gastritis and Differential Disease Risk The pattern of gastric tissue response is associated with disease risk: antral-predominant gastritis is most closely linked with duodenal ulceration, whereas pan-gastritis and corpus-predominant gastritis are linked with gastric ulceration and adenocarcinoma. This difference probably explains why patients with duodenal ulceration are not at high risk of developing gastric adenocarcinoma later in life, despite being colonized by *H. pylori*.

PATHOGENESIS OF DUODENAL ULCERATION How gastric colonization causes duodenal ulceration is now becoming clearer. *H. pylori*–induced tissue responses in the gastric antrum diminish the number of somatostatin-producing D cells. Because somatostatin inhibits gastrin release, gastrin levels are higher than in *H. pylori*–negative persons, and these higher levels lead to increased meal-stimulated acid secretion from the relatively spared gastric corpus. How this situation increases duodenal ulcer risk remains controversial, but the increased acid secretion may contribute to the formation of potentially acid-protective gastric metaplasia in the duodenum. Gastric metaplasia in the duodenum may become colonized by *H. pylori* and subsequently inflamed and ulcerated.

PATHOGENESIS OF GASTRIC ULCERATION AND GASTRIC ADENOCARCINOMA The pathogenesis of these conditions is less well understood, although both arise in association with pan- or corpus-predominant gastritis. The hormonal changes described above still occur, but the tissue responses in the gastric corpus mean that it produces less acid (hypochlorhydria) despite hypergastrinemia. Gastric ulcers commonly occur at the junction of antral and corpus-type mucosa, an area that is often particularly inflamed. Gastric cancer usually arises in stomachs with extensive atrophic gastritis and hypochlorhydria, and probably stems from progressive DNA damage and the survival of abnormal epithelial cell clones. The DNA damage is thought to be due principally to reactive oxygen and nitrogen species arising from inflammatory cells, perhaps in relation to other bacteria that survive in a hypochlorhydric stomach. Longitudinal analyses of gastric biopsy specimens taken years apart from the same patient show that the common *intestinal* type of gastric adenocarcinoma follows stepwise changes from simple gastritis to gastric atrophy, metaplasia, and dysplasia. A second, *diffuse* type of gastric adenocarcinoma found more commonly in younger adults may arise directly from chronic gastritis without atrophic changes. In recent years, there has been a progressive rise in gastric cancers centered on the gastric corpus and occurring in younger adults (<50 years old) and disproportionately in females; this appears to be in the absence of *H. pylori*.

PATHOGENESIS OF GASTRIC MALT LYMPHOMA Low-grade B-cell MALT lymphomas are rare malignancies, reported at a rate of ~1 per million population per year prior to the discovery of *H. pylori*. Since then, reported rates have increased substantially, possibly reflecting overdiagnosis. These tumors arise from the substrate of chronic stimulation of lymphocyte populations by the persistent *H. pylori* colonization. Importantly, there have been numerous reports of these low-grade tumors responding dramatically to *H. pylori* eradication therapies. However, the boundary between true malignancy and benign lymphoid hypertrophy is uncertain. Among responders to *H. pylori* eradication, most do not have the characteristic t(11;18)(q21;q21) translocation of the malignancy and may not have true malignancies but rather benign polyclonal lymphoid proliferation. CagA-positive *H. pylori* strains have been significantly associated with the t(11;18)(q21;q21)–positive gastric MALT lymphoma compared with translocation-negative cases.

CLINICAL MANIFESTATIONS

Essentially all *H. pylori*–colonized persons have histologic gastritis, but only ~10–15% develop associated illnesses such as peptic ulceration, gastric adenocarcinoma, or gastric lymphoma **(Fig. 163-1)**. Despite similar rates of *H. pylori* colonization, rates of these diseases among women are less than half of those among men.

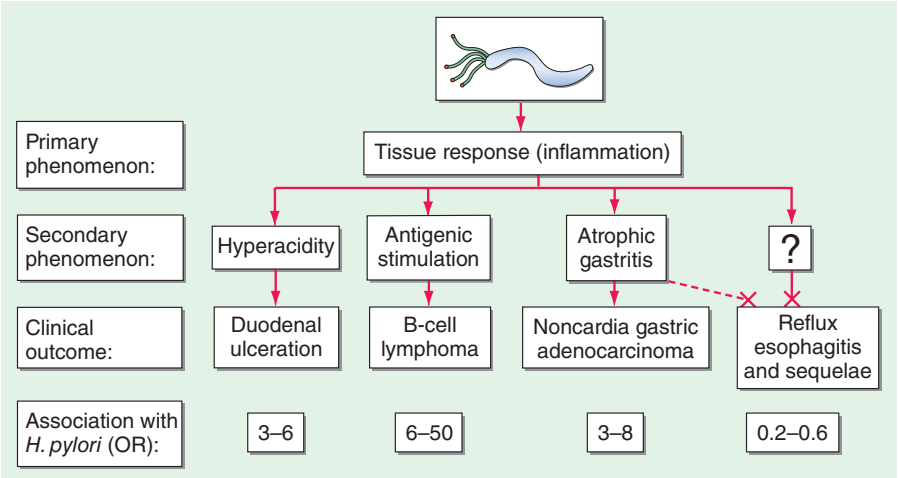

FIGURE 163-1 Schematic of the relationships between colonization with *Helicobacter pylori* and diseases of the upper gastrointestinal tract. Essentially all persons colonized with *H. pylori* develop a host response, which is generally termed *chronic gastritis*. The nature of the host's interaction with the particular bacterial population determines the clinical outcome. *H. pylori* colonization increases the lifetime risk of peptic ulcer disease, noncardia gastric cancer, and B-cell non-Hodgkin's gastric lymphoma (odds ratios [ORs] for all, >3). In contrast, a growing body of evidence indicates that *H. pylori* colonization (especially with *cagA*$^+$ strains) protects against adenocarcinoma of the esophagus (and the sometimes related gastric cardia) and premalignant lesions such as Barrett's esophagus (ORs, <1). Although the incidences of peptic ulcer disease (cases not due to nonsteroidal anti-inflammatory drugs) and noncardia gastric cancer are declining in developed countries, the incidence of adenocarcinoma of the esophagus is increasing. *(Reproduced with permission from MJ Blaser: Hypothesis: The changing relationships of Helicobacter pylori and humans: Implications for health and disease. J Inf Dis 179:1523, 1999.)*

PEPTIC ULCER DISEASE

Worldwide, ~70% of duodenal ulcers and ~50% of gastric ulcers are related to *H. pylori* colonization (Chap. 324). However, in particular, the proportion of gastric ulcers caused by aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) is increasing, and in many developed countries, these drugs have overtaken *H. pylori* as a cause of gastric ulceration. The main lines of evidence supporting an ulcer-promoting role for *H. pylori* are that (1) the presence of the organism is a risk factor for the development of ulcers, (2) non-NSAID-induced ulcers rarely develop in the absence of *H. pylori*, (3) eradication of *H. pylori* virtually abolishes long-term ulcer relapse, and (4) experimental *H. pylori* infection of gerbils can cause gastric ulceration. Thus, *H. pylori* is neither necessary nor sufficient for the development of peptic ulcer disease, but it is a very strong risk factor for its occurrence, and removal of *H. pylori* changes the natural history of ulcer disease.

Gastric Adenocarcinoma and Lymphoma Prospective nested case–control studies have shown that *H. pylori* colonization is a risk factor for adenocarcinomas of the distal (noncardia) stomach (Chap. 80). Long-term experimental infection of gerbils also may result in gastric adenocarcinoma. Moreover, *H. pylori* may induce primary gastric lymphoma, although this condition is much less common, and the approaches to histopathologic and cytogenetic evaluations are not standardized. Many of the diagnosed low-grade gastric B-cell lymphomas are dependent on *H. pylori* for continuing growth and proliferation, and these tumors may regress either fully or partially after *H. pylori* eradication. However, they require careful short- and long-term monitoring; any that are not confined to the superficial mucosa (and, indeed, some that are) require additional treatment with chemotherapeutic agents or radiotherapy.

Functional Dyspepsia Many patients have upper gastrointestinal symptoms but have normal results on upper gastrointestinal endoscopy (so-called functional or nonulcer dyspepsia; Chap. 324). Because *H. pylori* is common, some of these patients will be colonized with the organism. *H. pylori* eradication leads to symptom resolution up to 15% more commonly than does placebo treatment. Whether such patients have peptic ulcers in remission at the time of endoscopy or whether a small subgroup of patients with "true" functional dyspepsia respond to *H. pylori* treatment is unclear. Either way, because functional dyspepsia is often persistent and difficult to treat, most consensus conference guidelines recommend *H. pylori* eradication in these patients. If this advice is followed, it is important to realize that only a small subgroup of patients who are treated will benefit.

Protection Against Peptic Esophageal Disease, Including Esophageal Adenocarcinoma Much interest has focused on a protective role for *H. pylori* against GERD (Chap. 323), Barrett's esophagus (Chap. 323), and adenocarcinoma of the esophagus and gastric cardia (Chap. 80). The main lines of evidence for this role are (1) that there is a temporal relationship between a falling prevalence of gastric *H. pylori* colonization and a rising incidence of these conditions; (2) that, in most studies, the prevalence of *H. pylori* colonization (especially with proinflammatory *cagA*$^+$ strains) is significantly lower among patients with these esophageal diseases than among control participants; and (3) that, in prospective nested studies (see above), the presence of *H. pylori* is inversely related to these cancers. The mechanism underlying this protective effect is likely *H. pylori*–induced hypochlorhydria. Because, at the individual level, GERD severity may decrease, worsen, or remain unchanged after *H. pylori* treatment, concerns about GERD should not affect decisions about whether to treat *H. pylori* in an individual patient if a clear-cut indication exists; if there is no clear indication, clinicians should carefully balance considerations of benefit and harm.

Other Pathologies *H. pylori* has an increasingly recognized role in other gastric pathologies. It may predispose some patients to iron deficiency through occult blood loss and/or hypochlorhydria and reduced iron absorption. In addition, several extragastrointestinal pathologies have been linked with *H. pylori* colonization, although evidence of causality is less strong. Studies of *H. pylori* treatment in idiopathic thrombocytopenic purpura have consistently described improvement in or even normalization of platelet counts. Potentially important but even more controversial (protective) associations are with ischemic heart disease and cerebrovascular disease. However, the strength of the latter associations is reduced if confounding factors are taken into account, and our present knowledge is incomplete. Most authorities consider the associations to be noncausal. An increasing number of studies have shown an inverse association of *cagA*$^+$ *H. pylori* with childhood-onset asthma, hay fever, and atopic disorders. These associations have been shown to be causal in animal models, but the effect size in humans has not been established.

DIAGNOSIS

Tests for *H. pylori* fall into two groups: tests that require upper gastrointestinal endoscopy and simpler tests that can be performed in the clinic (Table 163-1).

Endoscopy-Based Tests Endoscopy is usually unnecessary in the initial management of young patients with simple dyspepsia but is commonly used to exclude malignancy and make a positive diagnosis in older patients or those with "alarm" symptoms. If endoscopy is performed, the most convenient biopsy-based test is the biopsy urease test, in which one large or two small gastric biopsy specimens are placed into a gel containing urea and an indicator. The presence of *H. pylori* urease leads to a rise in pH and therefore to a color change, which often occurs within minutes but can require up to 24 h. Histologic examination of biopsy specimens for *H. pylori* also is accurate, provided that a special stain (e.g., a modified Giemsa, silver, or immuno-stain) permitting optimal visualization of the organism is used. If biopsy specimens are obtained from both antrum and corpus, histologic study yields additional information, including the degree and pattern of inflammation and the presence of any atrophy, metaplasia, or dysplasia. Microbiologic culture is most specific but may be insensitive because of difficulty with *H. pylori* isolation. Once the organism is cultured, its identity as *H. pylori* can be confirmed by its typical appearance on Gram's stain and its positive reactions in oxidase, catalase, and urease tests. Moreover, the organism's susceptibility to antibiotics can be determined, and this information can be clinically useful in difficult cases. The occasional biopsy specimens containing the less common non-*pylori* gastric helicobacters give weakly positive results in the

TABLE 163-1 Tests Commonly Used to Detect *Helicobacter pylori*

TEST	ADVANTAGES	DISADVANTAGES
Tests Based on Endoscopic Biopsy		
Biopsy urease test	Quick, simple	Some commercial tests not fully sensitive before 24 h
Histology	May give additional histologic information	Sensitivity dependent on experience and use of special stains
Culture	Permits determination of antibiotic susceptibility	Sensitivity dependent on experience
Noninvasive Tests		
Serology	Inexpensive and convenient; not affected by recent antibiotics or proton pump inhibitors to the same extent as breath and stool tests	Cannot be used to monitor treatment success; some commercial kits inaccurate, and most less accurate than urea breath test
^{13}C urea breath test	Inexpensive and simpler than endoscopy; useful for follow-up after treatment	Requires fasting; not as convenient as blood or stool tests
Stool antigen test	Inexpensive and convenient; useful for follow-up after treatment; may be particularly useful in children	Stool-based tests disliked by people from some cultures

biopsy urease test. Positive identification of these bacteria requires visualization of the characteristic long, tight spirals in histologic sections; they cannot easily be cultured.

Noninvasive Tests Noninvasive *H. pylori* testing is the norm if gastric cancer does not need to be excluded by endoscopy. The longest-established test (and a very accurate one) is the *urea breath test*. In this simple test, the patient drinks a solution of urea labeled with the nonradioactive isotope ^{13}C and then blows into a tube. If *H. pylori* urease is present, the urea is hydrolyzed, and labeled carbon dioxide is detected in breath samples. The *stool antigen test*, a simple and accurate test using monoclonal antibodies specific for *H. pylori* antigens, is more convenient and less expensive than the urea breath test, but some patients dislike sampling stool. The simplest tests for ascertaining *H. pylori* status are *serologic assays* measuring specific IgG levels in serum by enzyme-linked immunosorbent assay or immunoblot. The best of these tests are nearly as accurate as other diagnostic methods, but many commercial tests—especially rapid office tests—do not perform well.

Use of Tests to Assess Treatment Success The urea breath test, the stool antigen test, and biopsy-based tests can all be used to assess the success of treatment **(Fig. 163-2)**. However, because these tests are dependent on *H. pylori* load, their use <4 weeks after treatment may yield false-negative results. Early suppression of bacterial numbers may lead to false-negative results since regrowth of the organism can result in its detection weeks later. For the same reason, these tests are unreliable if performed within 4 weeks of intercurrent treatment with antibiotics or bismuth compounds or within 2 weeks of the discontinuation of proton pump inhibitor (PPI) treatment. In the assessment of treatment success, noninvasive tests are normally preferred. However, after gastric ulceration, endoscopy should be repeated to ensure healing and exclude gastric carcinoma by further histologic sampling; if PPIs have been stopped for at least 2 weeks and no antibiotics or bismuth compounds have been given for at least 6 weeks, there is an opportunity to assess treatment success with biopsy-based tests. Serologic tests are not used to monitor treatment success, as the gradual drop in titer of *H. pylori*–specific antibodies is too slow (requiring >14 weeks) to be of practical use.

TREATMENT

Helicobacter pylori Infection

INDICATIONS

The most clear-cut indications for treatment are *H. pylori*–related duodenal or gastric ulceration or low-grade gastric B-cell MALT lymphoma. Whether or not the ulcers are currently active, *H. pylori* should be eradicated in patients with documented ulcer disease to prevent relapse (Fig. 163-2). Guidelines have recommended *H. pylori* treatment for colonized patients with functional dyspepsia in case they are among the small percentage who will benefit from such therapy (beyond placebo effects). *H. pylori* eradication in the treatment of conditions not definitively known to respond has also been recommended but is not universally supported; such conditions include idiopathic thrombocytopenic purpura, vitamin B_{12} deficiency, and iron-deficiency anemia where other causes have been carefully excluded. For individuals with a strong family history of gastric cancer, treatment to eradicate *H. pylori* in the hope of reducing cancer risk is reasonable but of unproven value: it slightly reduces future cancer incidence, but there is no evidence it reduces all-cause mortality. For older dyspeptic patients in the community or those who have "alarm" symptoms (e.g., weight loss) associated with their dyspepsia, upper gastrointestinal endoscopy is indicated to seek a diagnosis and test for *H. pylori*; the decision regarding whether to eradicate the organism can then be based on indication. Endoscopy is usually considered unnecessary for young dyspeptic patients in the community who have no alarm symptoms (with the precise age cutoff dependent on local guidelines). If the community prevalence of *H. pylori* is below ~20%, such patients are treated with a short course of acid suppression using a PPI. If these patients do not respond or relapse when treatment is stopped, or if the

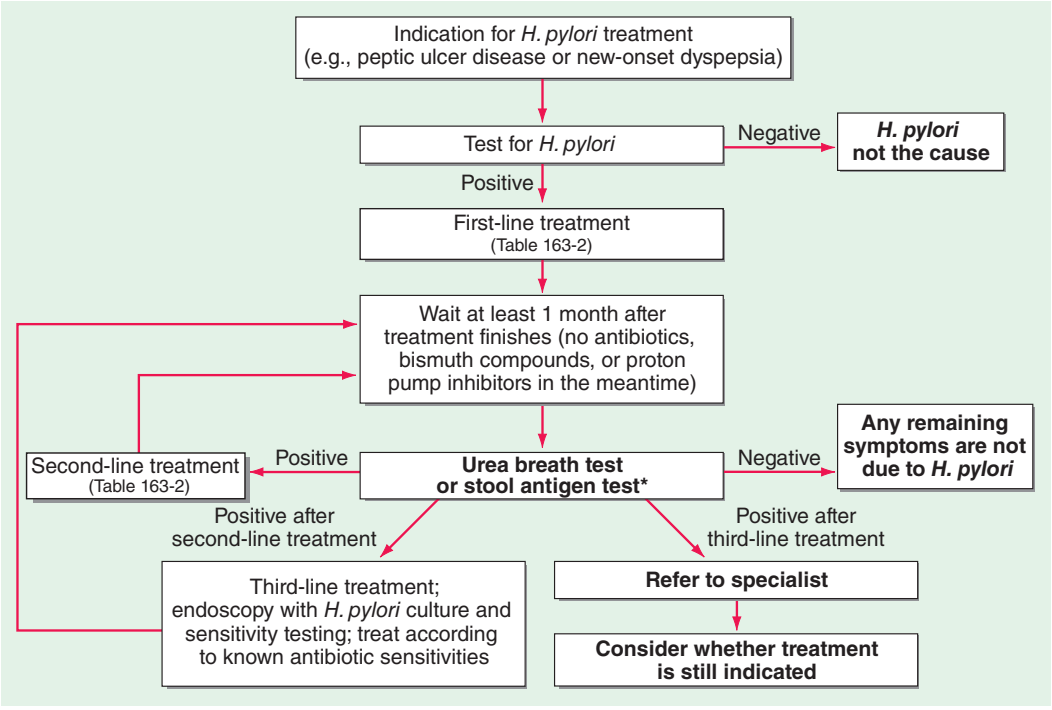

FIGURE 163-2 Algorithm for the management of *Helicobacter pylori* infection. *Note that either the urea breath test or the stool antigen test can be used in this algorithm. Occasionally, endoscopy and a biopsy-based test are used instead of either of these tests in follow-up after treatment. The main indication for these invasive tests is in follow-up after gastric ulceration; in this condition, as opposed to duodenal ulceration, it is important to check healing and exclude underlying gastric adenocarcinoma. However, even in this situation, patients undergoing endoscopy may still be receiving proton pump inhibitor therapy, which precludes *H. pylori* testing. Thus, a urea breath test or a stool antigen test is still required at a suitable interval after the end of therapy to determine whether treatment has been successful (see text). Some authorities use empirical third-line regimens, of which several have been described.

H. pylori community prevalence is >20%, many national guidelines recommend a strategy of testing for *H. pylori* noninvasively and eradicating it if it is found. This strategy will benefit patients who have peptic ulcers and the ~5–10% of patients who have functional dyspepsia responsive to *H. pylori* eradication, but most patients will be treated unnecessarily. Currently, widespread community screening for and treatment of *H. pylori* as primary prophylaxis for gastric cancer and peptic ulcers are not recommended in most countries, mainly because the extent of the consequent reduction in cancer risk is not known. Several studies have found a modestly reduced cancer risk after treatment, but the period of follow-up is still fairly short, and the magnitude of the effect in different populations remains unclear. Other reasons not to treat *H. pylori* in asymptomatic populations at present include (1) the adverse side effects (which are common and can be severe in rare cases) of the multiple-antibiotic regimens used; (2) antibiotic resistance, which may emerge in *H. pylori* or other incidentally carried bacteria; (3) the anxiety that may arise in otherwise healthy people, especially if treatment is unsuccessful; and (4) the existence of a subset of people who will develop GERD symptoms after treatment. Despite the absence of screening strategies, many doctors treat *H. pylori* if it is known to be present (particularly in children and younger adults), even when the patient is asymptomatic. The rationale is that it reduces patient concern and may reduce future gastric cancer risk and that any reduction in risk is likely to be greater in younger patients. However, such practices do not factor in any potential benefits of *H. pylori* colonization. Overall, despite widespread clinical activity in this area, most treatment of persons with asymptomatic *H. pylori* carriage is given with no firm evidence base. Because a proportion of patients (up to 70%) of those diagnosed with gastric low-grade B-cell MALT lymphomas respond to *H. pylori* eradication, it should be used in all cases, regardless of whether *H. pylori* can be detected by the diagnostic modalities used since there may be falsely negative results. However, not all of these cases represent true malignancies, so the reported success rate may reflect the eradication of benign processes. Examination of tissues for the characteristic chromosomal translocations should be done to help distinguish benign and malignant processes and to guide further therapeutic approaches. These generally are slowly progressive tumors, so the time needed for *H. pylori* eradication and subsequent evaluation will not interfere with the use of subsequent chemotherapy and/or radiotherapy, if needed.

REGIMENS

Although *H. pylori* is susceptible to a wide range of antibiotics in vitro, monotherapy is not usually successful, probably because of inadequate active antibiotic delivery to the colonization niche. Clinical failure of monotherapy prompted the development of multidrug regimens. Current regimens consist of a PPI and two or three antimicrobial agents given for 10–14 days **(Table 163-2)**. The optimal regimens vary in different parts of the world, depending on the known rates of primary antibiotic resistance in most *H. pylori* strains in a particular locale. For this reason, guidelines on optimal regimens for *H. pylori* eradication in individual countries are evolving, and physicians should refer to the most up-to-date local guideline.

The two most important factors in successful *H. pylori* treatment are the patient's close compliance with the regimen and the use of drugs to which the patient's strain of *H. pylori* has not acquired resistance. Treatment failure following minor lapses in compliance is common and often leads to acquired resistance. To stress the importance of compliance, written instructions should be given to the patient, and minor side effects of the regimen should be explained. Increasing levels of primary *H. pylori* resistance to clarithromycin, levofloxacin, and—to a lesser extent—metronidazole are of growing concern. In most parts of the world (the main exception being northwestern Europe), the rate of primary clarithromycin resistance is sufficiently high that regimens containing clarithromycin plus one other antibiotic often fail; regimens with clarithromycin and two other antibiotics remain an option as the other two antibiotics are likely to eradicate *H. pylori* even if the strain is clarithromycin-resistant. When a patient is known to have been exposed—even remotely in time—to clarithromycin or a fluoroquinolone, these antibiotics usually should be avoided. Resistance to amoxicillin or tetracycline is unusual, even if these antibiotics have been given previously, and resistance to metronidazole is only partial; thus, there is no need to avoid using these antibiotics whether or not they have been previously prescribed. Whichever antibiotic regimen is used, meta-analyses show that using high rather than moderate doses of acid-suppressive PPIs with the antibiotics increases the effectiveness of the regimen. Similarly, use of vonoprazan, a highly effective potassium-competitive acid blocker, currently licensed in Japan, was associated with higher eradication rates in conjunction with amoxicillin and clarithromycin, than when a PPI was used for acid suppression.

Assessment of antibiotic susceptibilities before treatment would be optimal but is not usually undertaken because endoscopy and mucosal biopsy are necessary to obtain *H. pylori* for culture and because most microbiology laboratories are inexperienced in *H. pylori* culture. If initial *H. pylori* treatment fails, the usual approach is empirical re-treatment with another drug regimen (Table 163-2). The third-line approach ideally should be endoscopy, biopsy, and culture plus treatment based on documented antibiotic sensitivities. However, empirical third-line therapies are often used.

TABLE 163-2 Commonly Recommended Treatment Regimens for *Helicobacter pylori*

REGIMEN[a] (DURATION)	DRUG 1	DRUG 2	DRUG 3	DRUG 4
Regimen 1: OCM (14 days)[b]	Omeprazole (20 mg bid[c])	Clarithromycin (500 mg bid)	Metronidazole (500 mg bid)	—
Regimen 2: OCA (14 days)[b]	Omeprazole (20 mg bid[c])	Clarithromycin (500 mg bid)	Amoxicillin (1 g bid)	—
Regimen 3: OBTM (14 days)[d]	Omeprazole (20 mg bid[c])	Bismuth subsalicylate (2 tabs qid)	Tetracycline HCl (500 mg qid)	Metronidazole (500 mg tid)
Regimen 4: concomitant (14 days)[e]	Omeprazole (20 mg bid[c])	Amoxicillin (1 g bid)	Clarithromycin (500 mg bid)	Tinidazole (500 mg bid[f])
Regimen 5: OAL (10 days)[g]	Omeprazole (20 mg bid[c])	Amoxicillin (1 g bid)	Levofloxacin (500 mg bid)	—

[a]The recommended first-line regimens for most of the world are shown in **bold** type. [b]This regimen should be used only for populations in which the prevalence of clarithromycin-resistant strains is known to be <20%. In practice, this restriction limits the regimens' appropriate range mainly to northern Europe. [c]Many authorities and some guidelines recommend doubling this dose of omeprazole as trials show resultant increased efficacy with some antibiotic combinations. Omeprazole may be replaced with any proton pump inhibitor (PPI) at an equivalent dosage. Because extensive metabolizers of PPIs are prevalent among Caucasian populations, many authorities recommend esomeprazole (40 mg bid) or rabeprazole (20 mg bid), particularly for regimens 4 and 5. [d]Data supporting this regimen come mainly from Europe and are based on the use of bismuth subcitrate (1 tablet qid) and metronidazole (400 mg tid). This is a recommended first-line regimen in most countries and is the recommended second-line regimen in northern Europe. [e]This regimen may be used as an alternative to regimen 3. [f]Metronidazole (500 mg bid) may be used as an alternative. [g]This regimen is used as second-line treatment in many countries (particularly where quadruple or concomitant therapy is used as the first-line regimen) and as third-line treatment in others. It may be less effective where rates of fluoroquinolone use are high and is more likely to be ineffective if there is a personal history of fluoroquinolone use for previous treatment of other infections.

Non-*pylori* gastric helicobacters are treated in the same way as *H. pylori*. However, in the absence of trials, it is unclear whether a positive outcome always represents successful treatment or whether it is sometimes due to natural clearance of the bacteria.

PREVENTION

Carriage of *H. pylori* has considerable public health significance in economically richer countries, where it is associated with peptic ulcer disease and gastric adenocarcinoma, and in some, but not all, economically poorer countries, where gastric adenocarcinoma may be an even more common cause of cancer death late in life. If mass prevention were contemplated, vaccination would be the most obvious method: experimental immunization of animals has given promising results, and the first reported trial in humans has shown some efficacy. Further trials are ongoing. However, given that *H. pylori* has co-evolved with its human host over millennia, preventing colonization on a population basis may have biological and clinical costs. For example, lifelong absence of *H. pylori* is a risk factor for GERD complications, including esophageal adenocarcinoma. We have speculated that the disappearance of *H. pylori* may also be associated with an increased risk of other emergent diseases reflecting aspects of the current Western lifestyle, such as childhood-onset asthma and allergy, as supported by both epidemiologic and animal model studies.

164 Infections Due to *Pseudomonas*, *Burkholderia*, and *Stenotrophomonas* Species

Reuben Ramphal

The pseudomonads are a heterogeneous group of gram-negative bacteria that have in common an inability to ferment lactose. Formerly classified in the genus *Pseudomonas*, the members of this group have been assigned to three medically important genera—*Pseudomonas, Burkholderia*, and *Stenotrophomonas*—whose biologic behaviors encompass both similarities and marked differences and whose genetic repertoires differ in many respects. The pathogenicity of most pseudomonads is based on opportunism; the exceptions are *Burkholderia pseudomallei* and *Burkholderia mallei*, which are primary pathogens.

The genus *Pseudomonas* now contains >140 species. *Pseudomonas aeruginosa*, the major pathogen of the group, is a significant cause of infections in hospitalized patients and in patients with cystic fibrosis (CF; **Chap. 291**). Cytotoxic chemotherapy, mechanical ventilation, and broad-spectrum antibiotic therapy set up conditions that predispose to colonization and infection of increasing numbers of hospitalized patients by this pathogen. Other significant members of the genus—*Pseudomonas putida, Pseudomonas fluorescens*, *Pseudomonas oryzihabitans*, and *Pseudomonas stutzeri*—infect humans infrequently and are generally opportunists always present in the environment.

The genus *Burkholderia* comprises >20 species, of which *Burkholderia cepacia* is most frequently encountered in Western countries. Similar to *P. aeruginosa, B. cepacia* (now referred to as the *B. cepacia* complex species) is both an opportunistic nosocomial pathogen and a cause of infection in CF. The other medically important members of this genus are *B. pseudomallei* and *B. mallei*, the etiologic agents of melioidosis and glanders, respectively.

The genus *Stenotrophomonas* contains one species of medical significance, *Stenotrophomonas maltophilia*. This organism is strictly an opportunist that "overgrows" in the setting of broad-spectrum antibiotic use.

PSEUDOMONAS AERUGINOSA

EPIDEMIOLOGY

P. aeruginosa is found in most moist environments. Soil, plants, vegetables, tap water, and countertops are all potential reservoirs for this microbe, as it has simple nutritional needs. Given the ubiquity of *P. aeruginosa*, it is clear that simple contact with the organism is not sufficient for colonization or infection. Clinical and experimental observations suggest that infection by *P. aeruginosa* occurs concomitantly with compromised host defenses, mucosal trauma, physiologic derangement, and antibiotic-mediated suppression of normal flora. Thus, it comes as no surprise that the majority of *P. aeruginosa* infections occur in intensive care units (ICUs), where these factors frequently converge. The organism is initially acquired from environmental sources, but patient-to-patient spread also occurs in CF clinics.

In the past, burned patients appeared to be unusually susceptible to *P. aeruginosa*. For example, in 1959–1963, *Pseudomonas* burn-wound sepsis was the principal cause of death in 60% of burned patients dying at the U.S. Army Institute of Surgical Research. For reasons that are unclear, *P. aeruginosa* infection in burns is no longer the major problem that it was during the 1950s and 1960s. Similarly, in the 1960s, *P. aeruginosa* appeared as a common pathogen in patients receiving cytotoxic chemotherapy at many institutions in the United States, but it has subsequently diminished in importance. Despite this subsidence, *P. aeruginosa* remains one of the most feared pathogens in this population because of its high attributable mortality.

In some parts of Asia and Latin America, *P. aeruginosa* continues to be the most common cause of gram-negative bacteremia in neutropenic patients.

In contrast to the trends for burned patients and neutropenic patients in the United States, the incidence of *P. aeruginosa* infections among patients with CF has not changed. *P. aeruginosa* remains the most common contributing factor to respiratory failure in CF and is responsible for the majority of deaths among CF patients.

LABORATORY FEATURES

P. aeruginosa is a nonfastidious, motile, gram-negative rod that grows on most common laboratory media, including blood and MacConkey agars. It is easily identified in the laboratory on primary-isolation agar plates by pigment production that confers a yellow to dark green or even bluish appearance. Colonies have a shiny "gun-metal" appearance and a characteristic fruity odor. Two of the identifying biochemical characteristics of *P. aeruginosa* are an inability to ferment lactose on MacConkey agar and a positive reaction in the oxidase test. Most strains are identified on the basis of these readily detectable laboratory features even before extensive biochemical testing is done. Some isolates from CF patients are easily identified by their mucoid appearance, which is due to the production of large amounts of the mucoid exopolysaccharide or alginate.

PATHOGENESIS

Unraveling the mechanisms that underlie disease caused by *P. aeruginosa* has proved challenging. Of the common gram-negative bacteria, no other species produces such a large number of putative virulence factors **(Table 164-1)**. Yet *P. aeruginosa* rarely initiates an infectious process in the absence of host injury or compromise, and few of its putative virulence factors have been shown definitively to be involved in disease in humans. Despite its metabolic versatility and possession of multiple colonizing factors, *P. aeruginosa* exhibits no competitive advantage over enteric bacteria in the human gut; it is not a normal inhabitant of the healthy human gastrointestinal tract, despite the host's continuous environmental exposure to the organism.

Virulence Attributes Involved in Acute *P. aeruginosa* Infections

• **MOTILITY AND COLONIZATION** A general tenet of bacterial pathogenesis is that most bacteria must adhere to surfaces or colonize a host niche in order to initiate disease. Most gram-negative bacteria examined thus far possess adherence factors called *adhesins. P. aeruginosa* is no exception. Among its many adhesins are its pili, which demonstrate adhesive properties for a variety of cells and adhere best to injured cell surfaces. In the organism's flagellum, the flagellin molecule binds to cells, and the flagellar cap attaches to mucins through the recognition of glycan chains. Other *P. aeruginosa* adhesins include the outer core of the lipopolysaccharide (LPS) molecule, which binds to the cystic fibrosis transmembrane conductance regulator (CFTR) and aids in internalization of the organism, and the alginate coat of mucoid strains, which enhances adhesion to cells and mucins. In addition, membrane proteins and lectins have been proposed as colonization factors. The deletion of any given adhesin is not sufficient to abrogate the ability of *P. aeruginosa* to colonize surfaces. Motility is important in host invasion via mucosal surfaces in some animal models of infection; however, nonmotile strains are not uniformly avirulent. It has been well demonstrated that nonmotile strains of *P. aeruginosa* are poorly phagocytosed, possibly leading to enhancement of the virulence of this organism.

TABLE 164-1 Main Putative Virulence Factors of *Pseudomonas aeruginosa*

SUBSTANCE/ ORGANELLE	FUNCTION	VIRULENCE IN ANIMAL DISEASE
Pili	Adhesion to cells	?
Flagella	Adhesion, motility, inflammation	Yes
Lipopolysaccharide	Antiphagocytic activity, inflammation	Yes
Type III secretion system	Toxic activity (ExoU, ExoS)	Yes
Type II secretion system	Toxic activity	Yes
Proteases	Proteolytic activity	?
Phospholipases	Cytotoxicity	?
Exotoxin A	Cytotoxicity	?
Pyocyanin	Cytotoxicity	Yes

EVASION OF HOST DEFENSES The transition from bacterial colonization to disease requires the evasion of host defenses followed by invasion by the microorganism. *P. aeruginosa* appears to be well equipped for evasion. Attached bacteria inject four known toxins (ExoS or ExoU, ExoT, and ExoY) via a type III secretion system that allows the bacteria to evade phagocytic cells either by direct cytotoxicity or by inhibition of phagocytosis. Clinical studies suggest that the mortality rate is higher among patients infected by strains that secrete the ExoU toxin. Another secretion system—the type II system—secretes toxins that can kill animals, and some of its secreted toxins, such as exotoxin A, have the potential to kill phagocytic cells. Multiple proteases secreted by this system may degrade host effector molecules, such as cytokines and chemokines, that are released in response to infection.

TISSUE INJURY Among gram-negative bacteria, *P. aeruginosa* probably produces the largest number of substances that are toxic to cells and thus have the potential to injure tissues. The toxins secreted by the organism's type III secretion system are capable of injuring tissue. However, their delivery requires the adherence of the organism to cells. Thus, the effects of these toxins are likely to be local or to depend on the presence of large numbers of bacteria at the site of an infection or in the bloodstream. On the other hand, diffusible toxins, secreted by the organism's type II secretion system, can act freely wherever they come into contact with cells. Possible effectors of this system include exotoxin A, at least four different proteases, and at least two phospholipases. In addition to these secreted toxins, rhamnolipids, pyocyanins—the pigments that confer the characteristic color and odor of *P. aeruginosa* colonies—and hydrocyanic acid, are produced by *P. aeruginosa* and are all capable of causing host tissue injury and even neutrophil death.

INFLAMMATORY COMPONENTS The inflammatory responses to the lipid A component of *Pseudomonas* LPS and to its flagellin, mediated through the Toll-like receptor (TLR) system (principally TLR4 and TLR5, respectively), are thought to represent important factors in disease causation. Although these inflammatory responses are required for successful defense against *P. aeruginosa* (i.e., in their absence, animals are defenseless against *P. aeruginosa* infection), florid responses are likely to result in disease. Thus, when the sepsis syndrome and septic shock develop in *P. aeruginosa* infection, they are probably the result of the host response to one or both of these substances, but injury to the lung by *Pseudomonas* toxins may also result in sepsis syndromes, possibly by causing cell death and the release of cellular components (e.g., heat-shock proteins) that may activate the TLR or another proinflammatory system. Thus, the virulence of this bacterium in acute infections is likely to be multifactorial with a great redundancy of effector molecules being produced.

Chronic *P. aeruginosa* Infections

Chronic infection due to *P. aeruginosa* occurs mainly in the lungs in the setting of structural pulmonary diseases. The classic example is CF; others include bronchiectasis and chronic relapsing panbronchiolitis, a disease seen in Japan and some Pacific Islands. A hallmark of these illnesses is severely defective mucociliary clearance leading to mucus stasis and mucus accumulation in the lungs. There is probably a common factor that selects for *P. aeruginosa* colonization in these lung diseases—perhaps the adhesiveness of *P. aeruginosa* for mucus, a phenomenon that is not noted for most other common gram-negative bacteria, and/or the ability of *P. aeruginosa* to evade host defenses in mucus. Furthermore, *P. aeruginosa* undergoes evolutionary adaptations and diversification in ways that allow its prolonged survival in the lung without an early fatal outcome for the host. The strains found in CF patients exhibit minimal production of virulence factors. Many strains lose the ability to produce pili and flagella, and most become complement-sensitive because

of the loss of the O side chain of their LPS molecules. In addition, most strains found in CF patients overproduce a mucoid exopolysaccharide. These changes probably dampen the host response, allowing the organism to survive in CF mucus. *P. aeruginosa* is also believed to lose its ability to secrete many of its injectable toxins during growth in mucus. Although the alginate coat is thought to play a role in the organism's survival, alginate is not essential as nonmucoid strains may predominate for long periods. In short, virulence in chronic infections may be mediated by the chronic but attenuated host inflammatory response, which injures the lungs over decades.

CLINICAL MANIFESTATIONS

P. aeruginosa causes infections at almost all sites in the body but shows a rather marked predilection for the lungs. The infections encountered most commonly in hospitalized patients are described below.

Bacteremia Crude mortality rates exceeding 50% have been reported among patients with *P. aeruginosa* bacteremia. Consequently, this clinical entity has been much feared, and its management has been attempted with the use of multiple antibiotics. Recent publications report attributable mortality rates of 28–44%, with the precise figure depending on the adequacy and timing of treatment and the seriousness of the underlying disease. In the past, the patient with *P. aeruginosa* bacteremia classically was neutropenic or had a burn injury. Today, however, a minority of such patients have bacteremic *P. aeruginosa* infections. Rather, *P. aeruginosa* bacteremia is seen most often in patients in ICUs with the lungs, the urinary tract, central venous lines, or wounds being the most important portals for systemic invasion.

The clinical presentation of *P. aeruginosa* bacteremia rarely differs from that of sepsis in general **(Chap. 304)**. Patients are usually febrile, but those who are most severely ill may be in shock or even hypothermic. The only point differentiating this entity from gram-negative sepsis of other causes may be the distinctive skin lesions (ecthyma gangrenosum) of *Pseudomonas* infection, which occur almost exclusively in markedly neutropenic patients and patients with AIDS. These small or large, painful, reddish, maculopapular lesions have a geographic margin; they are initially pink, then darken to purple, and finally become black and necrotic **(Fig. 164-1)**. Histopathologic studies indicate that the lesions are due to vascular invasion and are teeming with bacteria. Although similar lesions may occur in aspergillosis, mucormycosis, and occasionally *Staphylococcus aureus* bacteremia, their presence in a neutropenic patient generally suggests *P. aeruginosa* bacteremia as the most likely cause.

TREATMENT

P. aeruginosa Bacteremia

(Table 164-2) Antimicrobial treatment of *P. aeruginosa* bacteremia has been controversial. Combination therapy with an antipseudomonal β-lactam and an aminoglycoside became the standard of care because of the dismal outcome of single-drug therapy, mainly with aminoglycosides and polymixins, prior to 1971—first for *P. aeruginosa* bacteremia in febrile neutropenic patients and then extrapolated to all *P. aeruginosa* bacteremic infections in both neutropenic and nonneutropenic patients.

FIGURE 164-1 Ecthyma gangrenosum in a neutropenic patient 3 days after onset.

Following the introduction of new antipseudomonal drugs, a number of studies have revisited the choice between combination treatment and monotherapy for *Pseudomonas* bacteremia. Although some clinicians still favor combination therapy, most recent observational studies indicate that a single modern antipseudomonal β-lactam agent to which the isolate is sensitive is as efficacious as a combination. Even in patients at greatest risk of early death from *P. aeruginosa* bacteremia (i.e., those with fever and neutropenia), empirical antipseudomonal monotherapy is deemed to be as efficacious as empirical combination therapy by the practice guidelines of the Infectious Diseases Society of America (IDSA). One firm conclusion is that monotherapy with an aminoglycoside is not optimal.

There are, of course, institutions and countries where rates of susceptibility of *P. aeruginosa* to first-line antibiotics are <80%. Thus, when a septic patient with a high probability of *P. aeruginosa* infection is encountered in such settings, empirical combination therapy should be administered until the pathogen is identified and susceptibility data become available. Thereafter, whether one or two agents should be continued remains a matter of individual preference. Recent studies suggest that extended infusions of β-lactams such as cefepime, piperacillin/tazobactam, or meropenem may result in better outcomes of *Pseudomonas* bacteremia and possibly of *Pseudomonas* pneumonia. The duration of antibiotic therapy has now become an important consideration due to the increasing isolation of multiple drug-resistant (MDR) and extensively drug-resistant (XDR) *P. aeruginosa* strains. Recently published studies now strongly support the use of shorter courses of therapy (7 days) rather than the longer duration (10–14 days) that is commonly recommended for many cases of *Pseudomonas* bacteremia.

Acute Pneumonia Respiratory infections are the most common of all infections caused by *P. aeruginosa*. *P. aeruginosa* is common in both hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP). This organism appears first or second among the causes of VAP. However, much debate centers on the actual role of *P. aeruginosa* in VAP. Many of the relevant data are based on cultures of sputum or endotracheal tube aspirates and may represent nonpathogenic colonization of the tracheobronchial tree, biofilms on the endotracheal tube, or simple tracheobronchitis.

Older reports of *P. aeruginosa* pneumonia described patients with an acute clinical syndrome of fever, chills, cough, and necrotizing pneumonia indistinguishable from other gram-negative bacterial pneumonias. The traditional accounts described a fulminant infection. Chest radiographs demonstrated bilateral pneumonia, often with nodular densities with or without cavities. This picture is now remarkably rare. Today, the typical patient is on a ventilator, has a slowly progressive infiltrate, and has been colonized with *P. aeruginosa* for days. While some cases may progress rapidly over 48–72 h, they are the exceptions. Nodular densities are not commonly seen. However, infiltrates may go on to necrosis. Necrotizing pneumonia has also been seen in the community (e.g., after inhalation of hot-tub water contaminated with *P. aeruginosa*). The typical patient has fever, leukocytosis, and purulent sputum, and the chest radiograph shows a new infiltrate or the expansion of a preexisting infiltrate. A sputum Gram's stain showing mainly polymorphonuclear leukocytes (PMNs) in conjunction with a culture positive for *P. aeruginosa* in this setting suggests a diagnosis of acute *P. aeruginosa* pneumonia.

There have been increasing reports of the occurrence of community-acquired *P. aeruginosa* pneumonia among patients with underlying lung diseases. While this undoubtedly occurs, it is difficult to make this diagnosis with a great degree of certainty with the use of sputum cultures in a population prone to airway colonization by multiple strains of bacteria. The patient population in whom the possibility of a community-acquired *P. aeruginosa* pneumonia should be considered is the neutropenic patient, given the pivotal role that neutrophils play in defense against this bacterium. Such a patient, whether hospitalized or admitted from the community with a pneumonia, should be treated empirically for *P. aeruginosa*.

TABLE 164-2 Antibiotic Treatment of Infections Due to *Pseudomonas aeruginosa* and Related Species

INFECTION	ANTIBIOTICS AND DOSAGES	OTHER CONSIDERATIONS
Bacteremia		
Nonneutropenic host	Ceftazidime (2 g q8h IV) *or* cefepime (2 g q8h IV) *or* piperacillin/tazobactam (3.375 g q4h IV) *or* imipenem (500 mg q6h IV) *or* meropenem (1 g q8h IV) *or* doripenem (500 mg q8h IV) ***Optional:*** Amikacin (7.5 mg/kg q12h or 15 mg/kg q24h IV)	Add an aminoglycoside for patients in shock and in regions or hospitals where rates of resistance to the primary β -lactam agents are high. Tobramycin may be used instead of amikacin (susceptibility permitting). The duration of therapy is 7 days for nonneutropenic patients. Neutropenic patients should be treated until no longer neutropenic.
Neutropenic host	Cefepime (2 g q8h IV) *or* all the other agents above (except doripenem) in the above dosages	
Endocarditis	Antibiotic regimens as for bacteremia for 6–8 weeks	Resistance during therapy is common. Surgery is required for relapse.
Pneumonia	Drugs and dosages as for bacteremia, except that the available carbapenems should not be the sole primary drugs because of high rates of resistance during therapy.	IDSA guidelines recommend the addition of an aminoglycoside or ciprofloxacin. The duration of therapy is 7 days.
Bone infection, malignant otitis externa	Cefepime or ceftazidime at the same dosages as for bacteremia; aminoglycosides not a necessary component of therapy; ciprofloxacin (500–750 mg q12h PO) may be used	Duration of therapy varies with the drug used (e.g., 6 weeks for a β -lactam agent; at least 3 months for oral therapy except in puncture-wound osteomyelitis, for which the duration should be 2–4 weeks).
Central nervous system infection	Ceftazidime or cefepime (2 g q8h IV) *or* meropenem (1 g q8h IV)	Abscesses or other closed-space infections may require drainage. The duration of therapy is ≥2 weeks.
Eye infection		
Keratitis/ulcer	Topical therapy with tobramycin/ciprofloxacin/levofloxacin eyedrops	Use maximal strengths available or compounded by pharmacy. Therapy should be administered for 2 weeks or until the resolution of eye lesions, whichever is shorter.
Endophthalmitis	Ceftazidime or cefepime as for central nervous system infection ***plus*** Topical therapy	
Urinary tract infection (UTI)	Ciprofloxacin (500 mg q12h PO) *or* levofloxacin (750 mg q24h) *or* any aminoglycoside (total daily dose given once daily). Cefepime or ceftazidime (1g q8h) *or* piperacillin/tazobactam (4.5 g q8h)	Uncomplicated cystitis may be treated for 3 days with oral agents. Relapse may occur if an obstruction or a foreign body is present. The duration of therapy for complicated UTI is 7–10 days (up to 2 weeks for pyelonephritis).
Multidrug- and extreme drug-resistant *P. aeruginosa* infection	Ceftazidime/avibactam (2.5 g q8h, infused over 2 h) *or* ceftolozane/tazobactam (1.5 g q8h) *or* meropenem/vaborbactam (2 g q8h) or imipenem/relebactam (500 mg q6h) *or* cefiderocol (2 g q8h) *or* colistin (100 mg q12h IV for the shortest possible period to obtain a clinical response)	Higher doses of ceftolozane/tazobactam may be required for pneumonias. The colistin doses used have varied. Dosage adjustment for colistin is required in renal failure. Inhaled colistin may be added for pneumonia (100 mg q12h).
Burkholderia cepacia complex infection	Meropenem (1 g q8h IV) *or* TMP-SMX (1600/320 mg q12h IV) for 14 days	Resistance to both agents is increasing. Do not use them in combination because of possible antagonism.
Melioidosis (*B. pseudomallei*), Glanders (*B. mallei*)	Ceftazidime (2 g q6h) *or* meropenem (1 g q8h) *or* imipenem (500 mg q6h) for 2 weeks ***followed by*** TMP-SMX (1600/320 mg q12h PO) for 3 months	
Stenotrophomonas maltophilia infection	TMP-SMX (1600/320 mg q12h IV) *plus* ticarcillin/clavulanate (3.1 g q4h IV) for 14 days	Resistance to all agents is increasing. Levofloxacin or tigecycline may be alternatives, but there is little published clinical experience with these agents.

Abbreviations: IDSA, Infectious Diseases Society of America; TMP-SMX, trimethoprim-sulfamethoxazole.

TREATMENT

Acute Pneumonia

(Table 164-2) Therapy for *P. aeruginosa* pneumonia remains unsatisfactory. Reports suggest mortality rates of 40–80%, but how many of these deaths are attributable to underlying disease remains unknown. The drugs of choice for *P. aeruginosa* pneumonia are similar to those given for bacteremia. A potent antipseudomonal β-lactam drug is the mainstay of therapy. Failure rates were high when aminoglycosides were used as single agents, possibly because of their poor penetration into the airways and their binding to airway secretions. Nonetheless, for the treatment of patients at high risk of death, some experts suggest the combination of a β-lactam agent and an antipseudomonal fluoroquinolone or aminoglycoside. As for the duration of therapy, recent IDSA/American Thoracic Society (ATS) guidelines recommend 7 days of treatment for HAP or VAP, even when *P. aeruginosa* is the offending organism. However, the outcome in neutropenic patients is poor, especially if accompanied by bacteremia; thus, therapy needs to be extended until neutropenia resolves.

Chronic Respiratory Tract Infections *P. aeruginosa* is responsible for chronic infections of the airways associated with a number of underlying or predisposing conditions—most commonly CF **(Chap. 291)**. A state of chronic colonization beginning early in childhood is seen in some Asian populations with chronic or diffuse panbronchiolitis, a disease of unknown etiology. *P. aeruginosa* is one of the organisms that colonizes damaged bronchi in bronchiectasis, a disease secondary to multiple causes in which profound structural abnormalities of the airways result in mucus stasis.

TREATMENT

Chronic Respiratory Tract Infections

Optimal management of chronic *P. aeruginosa* lung infection has not been determined. Patients respond clinically to antipseudomonal therapy, but the organism is rarely eradicated. Because eradication is unlikely, the aim of treatment for chronic infection is to quell exacerbations of inflammation. The regimens used are similar to those used for pneumonia, but an aminoglycoside is almost always added because resistance is common in chronic disease.

However, it may be appropriate to use an inhaled aminoglycoside preparation in order to maximize airway drug levels. MDR strains are now commonly found in such patients given their increased life span and the repeated courses of antibiotics they receive.

Endovascular Infections Infective endocarditis due to *P. aeruginosa* is a disease of IV drug users whose native valves are involved. This organism has also been reported to cause prosthetic-valve endocarditis. Sites of prior native-valve injury due to the injection of foreign material such as talc or fibers probably serve as niduses for bacterial attachment to the heart valve. The manifestations of *P. aeruginosa* endocarditis resemble those of other forms of endocarditis in IV drug users except that the disease is more indolent than *S. aureus* endocarditis. While most disease involves the right side of the heart, left-sided involvement is not rare, and multivalvular disease is common. Fever is a common manifestation, as is pulmonary involvement (due to septic emboli to the lungs). Thus, patients may also experience chest pain and hemoptysis. Involvement of the left side of the heart may lead to signs of cardiac failure, systemic emboli, and local cardiac involvement with sinus of Valsalva abscesses and conduction defects. Skin manifestations are rare in this disease, and ecthyma gangrenosum is not commonly seen in these patients. Vertebral **osteomyelitis** and sternoclavicular joint septic arthritis are uncommon but pathognomic complications of this disease. The diagnosis is based on positive blood cultures along with clinical signs of endocarditis.

TREATMENT

Endovascular Infections

(Table 164-2) It has been customary to use synergistic antibiotic combinations in treating *P. aeruginosa* endocarditis because of the development of resistance during therapy with a single antipseudomonal β-lactam agent. Which combination therapy is preferable is unclear, as all combinations have failed. Treatment is likely to more often be successful in cases of right-sided endocarditis. Cases of *P. aeruginosa* endocarditis that relapse during or fail to respond to therapy are often caused by resistant organisms and may require surgical therapy. Other considerations for valve replacement are similar to those in other forms of endocarditis **(Chap. 128)**.

Bone and Joint Infections *P. aeruginosa* is an infrequent cause of bone and joint infections. However, *Pseudomonas* bacteremia or infective endocarditis caused by the injection of contaminated illicit drugs has been documented to result in vertebral osteomyelitis and sternoclavicular joint arthritis. The clinical presentation of vertebral *P. aeruginosa* osteomyelitis is more indolent than that of staphylococcal osteomyelitis. The duration of symptoms in IV drug users with vertebral osteomyelitis due to *P. aeruginosa* varies from weeks to months. Fever is not uniformly present; when present, it tends to be low grade. There may be mild tenderness at the site of involvement. Blood cultures are usually negative unless there is concomitant endocarditis. The erythrocyte sedimentation rate (ESR) is generally elevated. Vertebral osteomyelitis due to *P. aeruginosa* has also been reported in the elderly, in whom it originates from urinary tract infections (UTIs). The infection generally involves the lumbosacral area because of a shared venous drainage (Batson's plexus) between the lumbosacral spine and the pelvis. Sternoclavicular septic arthritis due to *P. aeruginosa* is seen almost exclusively in IV drug users. This disease may occur with or without endocarditis, and a primary site of infection often is not found. Plain radiographs show joint or bone involvement. Treatment of these forms of disease is generally successful.

Pseudomonas osteomyelitis of the foot most often follows puncture wounds through sneakers and mostly affects children. The main manifestation is pain in the foot, sometimes with superficial cellulitis around the puncture wound and tenderness on deep palpation of the wound. Multiple joints or bones of the foot may be involved. Systemic symptoms are generally absent, and blood cultures are usually negative. Radiographs may or may not be abnormal, but the bone scan is usually positive, as are MRI studies. Needle aspiration usually yields a diagnosis. Prompt surgery, with exploration of the nail puncture tract and debridement of the involved bones and cartilage, is generally recommended in addition to antibiotic therapy.

Osteomyelitis due to *P. aeruginosa* is also seen following trauma and with decubitus ulcers. In these settings, the cause of osteomyelitis is often polymicrobial, and the role of *P. aeruginosa* can be questioned. It is therefore critical that deep bone biopsies be requested to ascertain its significance.

TREATMENT

Bone and Joint Infections

The treatment of bone and joint infections due to *P. aeruginosa* is often governed by the primary *Pseudomonas* infection. Since endocarditis is often the primary infection, the agents used for endocarditis will dictate treatment. In other situations, a 6-week course of therapy with an antipseudomonal β-lactam is recommended, and in case of puncture-wound osteomyelitis, oral ciprofloxacin may be used.

Central Nervous System (CNS) Infections CNS infections due to *P. aeruginosa* are relatively rare. Involvement of the CNS is almost always secondary to a surgical procedure, head trauma, implanted devices, and rarely bacteremia. The entity seen most often is postoperative or posttraumatic meningitis. Subdural or epidural infection occasionally results from contamination of these areas. Embolic disease arising from endocarditis in IV drug users and leading to brain abscesses has also been described. The cerebrospinal fluid (CSF) profile of *P. aeruginosa* meningitis is no different from that of pyogenic meningitis of any other etiology.

TREATMENT

Central Nervous System Infections

(Table 164-2) Treatment of *Pseudomonas* meningitis is difficult; little information has been published. However, the general principles involved in the treatment of meningitis apply, including the need for high doses of bactericidal antibiotics to attain high drug levels in the CSF. The agent with which there is the most published experience in *P. aeruginosa* meningitis is ceftazidime, but other antipseudomonal β-lactam drugs that reach reasonable CSF concentrations, such as cefepime, piperacillin/tazobactam, and meropenem, have also been used successfully. Other forms of *P. aeruginosa* CNS infection, such as brain abscesses and epidural and subdural empyema, generally require surgical drainage in addition to antibiotic therapy.

Eye Infections Eye infections due to *P. aeruginosa* occur mainly as a result of direct inoculation into the tissue during trauma or surface injury by contact lenses. Keratitis and corneal ulcers are the most common types of eye disease and are often associated with contact lenses (especially the extended-wear variety). Keratitis can be slowly or rapidly progressive, but the classic description is disease progressing over 48 h to involve the entire cornea, with opacification and sometimes perforation. *P. aeruginosa* keratitis should be considered a medical emergency because of the rapidity with which it can progress to loss of sight. *P. aeruginosa* endophthalmitis secondary to bacteremia is the most devastating of *P. aeruginosa* eye infections. The disease is fulminant, with severe pain, chemosis, decreased visual acuity, anterior uveitis, vitreous involvement, and panophthalmitis. It is also a rare complication of cataract removal with lens insertion.

TREATMENT

Eye Infections

(Table 164-2) The usual therapy for keratitis is the administration of topical antibiotics. Therapy for endophthalmitis includes the use of high-dose local and systemic antibiotics (to achieve higher drug concentrations in the eye) and vitrectomy.

Ear Infections *P. aeruginosa* infections of the ears vary from mild swimmer's ear to serious life-threatening infections with neurologic sequelae. Swimmer's ear is common among children and results from infection of moist macerated skin of the external ear canal. Most cases resolve with treatment, but some patients develop chronic drainage. Swimmer's ear is managed with topical antibiotic agents (otic solutions). The use of hearing aids may also predispose to this type of infection. The most serious form of *Pseudomonas* infection involving the ear has been given various names: two of these designations, *malignant otitis externa* and *necrotizing otitis externa*, are now used for the same entity. This disease was originally described in elderly diabetic patients, in whom the majority of cases still occur. However, it has also been described in patients with AIDS and in elderly patients without underlying diabetes or immunocompromise. The usual presenting symptoms are decreased hearing and ear pain, which may be severe and lancinating. The pinna is usually painful, and the external canal may be tender. The ear canal almost always shows signs of inflammation, with granulation tissue and exudate. Tenderness anterior to the tragus may extend as far as the temporomandibular joint and mastoid process. A small minority of patients have systemic symptoms. Patients in whom the diagnosis is made late may present with cranial nerve palsies, most commonly cranial nerve VII or even with cavernous venous sinus thrombosis. The ESR is invariably elevated (≥100 mm/h). The diagnosis is made on clinical grounds in severe cases; however, the "gold standard" is a positive technetium-99 bone scan in a patient with otitis externa due to *P. aeruginosa*. In diabetic patients, a positive bone scan constitutes presumptive evidence for this diagnosis and should prompt biopsy or empirical therapy.

TREATMENT

Ear Infections

(Table 164-2) Given the infection of the ear cartilage, sometimes with mastoid or petrous ridge involvement, patients with malignant (necrotizing) otitis externa are treated as for osteomyelitis.

Urinary Tract Infections UTIs due to *P. aeruginosa* generally occur as a complication of a catheter in the urinary tract, an obstruction or stone in the genitourinary system, urinary tract instrumentation, or surgery. A *P. aeruginosa* UTI occurring in the community often signals the presence of an abnormality in the urinary tract. It has been reported that the urinary tract is the second most important site of infection leading to *Pseudomonas* bacteremia.

TREATMENT

Urinary Tract Infections

(Table 164-2) Most *P. aeruginosa* UTIs are considered complicated infections that must be treated longer than uncomplicated cystitis. In general, a 7- to 10-day course of treatment suffices, with 10–14 days of therapy in cases of pyelonephritis. Urinary catheters, stents, or stones should be removed to prevent relapse, which is common and may not be due to antibiotic resistance but rather to factors such as a foreign body that has been left in place or an ongoing obstruction. Removal of a urinary catheter will allow shorter courses of antibiotic therapy if that is the only predisposing factor.

Skin and Soft Tissue Infections Besides pyoderma (ecthyma) gangrenosum in neutropenic patients, folliculitis and other papular or vesicular lesions due to *P. aeruginosa* have been extensively described and are collectively referred to as *dermatitis*. Multiple outbreaks have been linked to whirlpools, spas, and swimming pools. To prevent such outbreaks, the growth of *P. aeruginosa* in the home and in recreational environments must be controlled by proper chlorination of water. Most cases of hot-tub folliculitis are self-limited, requiring only the avoidance of exposure to the contaminated source of water.

Toe-web infections occur especially often in the tropics, and the "green-nail syndrome" is caused by *P. aeruginosa* paronychia, which results from frequent submersion of the hands in water. In the latter entity, the green discoloration results from diffusion of pyocyanin into the nail bed. *P. aeruginosa* remains a prominent cause of burn wound infections in some parts of the world. The management of these infections is best left to specialists in burn wound care.

Infections in Febrile Neutropenic Patients In febrile neutropenia, *P. aeruginosa* has historically been the organism against which empirical coverage is always essential. Although in Western countries these infections are now less common, their importance has not diminished because of persistently high mortality rates. In other parts of the world, *P. aeruginosa* continues to be a significant problem in febrile neutropenia, causing a larger proportion of infections in febrile neutropenic patients than any other single organism. For example, *P. aeruginosa* was responsible for 28% of documented infections in 499 febrile neutropenic patients in one study from the Indian subcontinent and for 31% of such infections in another. In a large study of infections in leukemia patients from Japan, *P. aeruginosa* was the most frequently documented cause of bacterial infection. In studies performed in North America, northern Europe, and Australia, the incidence of *P. aeruginosa* bacteremia in febrile neutropenia was quite variable. In a review of 97 reports published between 1987 and 1994, the incidence was reported to be 1–2.5% among febrile neutropenic patients given empirical therapy and 5–12% among patients with microbiologically documented infections. The most common clinical syndromes encountered were bacteremia, pneumonia, and soft tissue infections manifesting mainly as ecthyma gangrenosum.

TREATMENT

Infections in Febrile Neutropenic Patients

(Table 164-2) Compared with rates three decades ago, improved rates of response to antibiotic therapy have been reported in many studies. A study of 127 patients demonstrated a reduction in the mortality rate from 71 to 25% with the introduction of ceftazidime and imipenem. Because neutrophils—the normal host defenses against this organism—are absent in febrile neutropenic patients, maximal doses of antipseudomonal β-lactam antibiotics should be used for the management of *P. aeruginosa* bacteremia in this setting.

Infections in Patients with AIDS *P. aeruginosa* infections were well documented in patients with AIDS before the advent of antiretroviral therapy. Since the introduction of protease inhibitors, *P. aeruginosa* infections in AIDS patients have been seen less frequently but still occur, particularly in the form of sinusitis. While this entity is now uncommon in developed nations, there are still large numbers of patients with untreated HIV infection or poorly controlled disease in developing nations who are likely to suffer from *P. aeruginosa* infections. The clinical presentation of *Pseudomonas* infection (especially pneumonia and bacteremia) in AIDS patients is remarkable in that, although the illness may appear not to be severe, the infection may nonetheless be fatal. Patients with bacteremia may have only a low-grade fever and may present with ecthyma gangrenosum. Pneumonia, with or without bacteremia, is perhaps the most common type of *P. aeruginosa* infection. Patients with *P. aeruginosa* pneumonia exhibit the classic clinical signs and symptoms of pneumonia, such as fever, productive cough, and chest pain. The infection may be lobar or multilobar and shows no predisposition for any particular location. The most striking feature is the high frequency of cavitary disease.

TREATMENT

Infections in Patients with AIDS

Therapy for any of these conditions in AIDS patients is no different from that in other patients. However, relapse is the rule unless the patient's CD4+ T-cell count rises to >50/μL or suppressive antibiotic therapy is given. In attempts to achieve cures and prevent relapses, therapy tends to be more prolonged than in the case of an immunocompetent patient.

Gastrointestinal Infections A poorly understood syndrome caused by *P. aeruginosa* has been described in the Far East and has been called *Shanghai fever* and *Pseudomonas enterocolitis*. This syndrome occurs in young children; its occurrence in adults appears to be rare. Shanghai fever manifests as severe enteric disease, sepsis with invasive disease, and complications, whereas *Pseudomonas* enterocolitis is characterized by prolonged fever with bloody or mucoid diarrhea mimicking bacterial enterocolitis. The mortality rate ranges between 23 and 89%, with ecthyma gangrenosum occurring in >50% of cases. Early recognition and treatment have led to a reduction in the mortality rate. There is an above-average occurrence of the *exoU* gene among *Pseudomonas* isolates from patients with this syndrome.

Multidrug-Resistant Infections (Table 164-2) *P. aeruginosa* has a notorious propensity to develop antibiotic resistance. Over three decades, the impact of resistance was minimized by the rapid development of several potent antipseudomonal β-lactams and fluoroquinolones. However, rates of resistance to these agents that revolutionized the treatment of *P. aeruginosa* have risen to the point where some are almost unusable empirically because of the worldwide emergence of strains carrying determinants that mediate resistance. Extremely high rates of MDR strains have been reported from Eastern and Southern Europe, Latin America, India, and China, especially in ICUs. Physicians have had to resort to drugs such as colistin and polymyxin B, which were discarded decades ago. This surge in resistance is mediated by multiple mechanisms sometimes converging in individual strains. Chief among these are chromosomal or plasmid-borne penicillinases, extended-spectrum β-lactamases, cephalosporinases, and carbapenemases. Any of these may be combined with permeability mutations and efflux pump overexpression. The greatest nemesis in this regard is the worldwide presence of carbapenemases in *P. aeruginosa* leading to resistance to most β-lactams except some of the newest agents recently developed. These new agents are generally combinations of a cephalosporin or a carbapenem most often with a novel β-lactamase inhibitor. Several have been approved for clinical use, and all are active against MDR *P. aeruginosa* to varying degrees. Currently approved agents include ceftolozane/tazobactam, ceftazidime/avibactam, meropenem/vaborbactam, and imipenem/relebactam. A novel cephalosporin, cefiderocol, which uses the iron uptake pathway of *P. aeruginosa*, also demonstrates activity against MDR strains. Since MDR and XDR *P. aeruginosa* are unpredictable in regard to the underlying mechanisms of resistance, laboratory testing is absolutely required before the use of any of these agents. Most academic institutions restrict the use of these agents as there are concerns about the development of resistance, as has already been noted, as well the cost implications of misuse.

BURKHOLDERIA SPECIES

BURKHOLDERIA CEPACIA COMPLEX

The *B. cepacia* complex (BCC) gained notoriety as the cause of a rapidly fatal syndrome of respiratory distress and septicemia (the "cepacia syndrome") in CF patients. Of the more than 20 species of this complex, the three most frequently seen in CF patients are *B. cenocepacia*, *B. multivorans*, and *B. stabilis*. In addition to their occurrence in CF, members of this complex were not uncommonly encountered in ICU patients (previously designated *Pseudomonas cepacia*) and patients with chronic granulomatous disease, in whom they caused lung disease. BCC organisms are environmental organisms that inhabit moist environments and are found in the rhizosphere. They possess multiple virulence factors that may play roles in disease as well as colonizing factors that are capable of binding to lung mucus—an ability that may explain the predilection of *B. cepacia* for the lungs in CF. *B. cenocepacia* is motile, secretes elastase, and possesses components of an injectable toxin-secretion system like that of *P. aeruginosa*; its LPS is among the most potent of all LPSs in stimulating an inflammatory response in the lungs. Inflammation may be the major cause of the lung disease seen in the "cepacia" syndrome. Besides infecting the lungs in CF, the BCC organisms appear as airway colonizers during broad-spectrum antibiotic therapy and are causes of VAP, catheter-associated infections, and wound infections.

TREATMENT

B. cepacia Complex Infections

BCC organisms are intrinsically resistant to many antibiotics, rendering empiric treatment difficult. Therefore, treatment must be tailored according to sensitivities. Trimethoprim-sulfamethoxazole (TMP-SMX), meropenem, and minocycline are the most active agents in vitro and may be started as first-line agents (Table 164-2). However, recent reports indicate that there has been increasing resistance to these agents especially in CF patients. Some strains are susceptible to third-generation ureidopenicillins, advanced cephalosporins, and fluoroquinolones, and these agents may be used against isolates known to be susceptible. Newer antibiotics such as ceftolozane/tazobactam and ceftazidime/avibactam show good activity against MDR strains in vitro. However, there is very limited clinical experience with these agents.

BURKHOLDERIA PSEUDOMALLEI

B. pseudomallei is the causative agent of melioidosis, a disease of humans and animals that is geographically restricted to Southeast Asia and northern Australia, with occasional cases in countries such as India and China. This organism may be isolated from individuals returning directly from these endemic regions and from military personnel who have served in endemic regions. Symptoms of this illness may develop only at a later date because of the organism's ability to cause latent infections, which has been attributed to its ability to survive within cells. *B. pseudomallei* is found in soil and water. Humans and animals are infected by inoculation, inhalation, or ingestion; only rarely is the organism transmitted from person to person. Humans are not colonized without being infected. Among the pseudomonads, *B. pseudomallei* is perhaps the most virulent. Host compromise is not an essential prerequisite for disease, although many patients have common underlying medical diseases (e.g., diabetes renal failure or alcohol abuse). *B. pseudomallei* is a facultative intracellular organism whose replication in PMNs and macrophages may be aided by the possession of a polysaccharide capsule. The organism also possesses elements of a type III secretion system that plays a role in its intracellular survival. During infection, there is a florid inflammatory response whose role in disease is unclear.

B. pseudomallei causes a wide spectrum of conditions, ranging from asymptomatic infection to abscesses, pneumonia, and disseminated disease. It is a significant cause of fatal community-acquired pneumonia and septicemia in endemic areas, with mortality rates as high as 44% reported in Thailand. Acute pulmonary infection is the most commonly diagnosed form of melioidosis. Pneumonia may be asymptomatic (with routine chest radiographs showing mainly upper-lobe infiltrates) or may present as severe necrotizing disease. *B. pseudomallei* also causes chronic pulmonary infections with systemic manifestations that mimic those of tuberculosis, including chronic cough, fever, hemoptysis, night sweats, and cavitary lung disease. Besides pneumonia, the other principal form of *B. pseudomallei* disease is skin ulceration with associated lymphangitis and regional lymphadenopathy. Spread from the lungs or skin, which is most often documented in debilitated individuals, gives rise to septicemic forms of melioidosis that carry a high mortality rate.

TREATMENT

B. pseudomallei Infections

B. pseudomallei is susceptible to advanced penicillins, cephalosporins, and carbapenems (Table 164-2). Treatment is divided into two stages: an intensive 2-week phase of therapy with ceftazidime or a carbapenem followed by at least 12 weeks of oral TMP-SMX to eradicate the organism and prevent relapse. Australian guidelines for treating this condition recommend longer periods of intensive therapy—4–8 weeks for severe infections, osteomyelitis, and CNS infections. The recognition of this bacterium as a potential agent of biologic warfare has stimulated interest in the development of a vaccine.

BURKHOLDERIA MALLEI

B. mallei causes the equine disease glanders in Africa, Asia, and South America. The organism was eradicated from Europe and North America decades ago. The last case seen in the United States occurred in 2001 in a laboratory worker; before that, *B. mallei* had last been seen in this country in 1949. In contrast to the other organisms discussed in this chapter, *B. mallei* is not an environmental organism and does not persist outside its equine hosts. Consequently, *B. mallei* infection is an occupational risk for handlers of horses, equine butchers, and veterinarians in areas of the world where it still exists. The polysaccharide capsule is a critical virulence determinant; diabetics are thought to be especially susceptible to infection by this organism. The organism is transmitted from animals to humans by inoculation into the skin, where it causes local infection with nodules and lymphadenitis. Regional lymphadenopathy is common. Respiratory secretions from infected horses are extremely infectious. Inhalation results in clinical signs of typical pneumonia but may also cause an acute febrile illness with ulceration of the trachea. The organism may disseminate from the skin or lungs to cause septicemia with signs of sepsis. The septicemic form is frequently associated with shock and a high mortality rate. The infection may also enter a chronic phase and present as disseminated abscesses. *B. mallei* infection may present as early as 1–2 days after inhalation or (in cutaneous disease) may not become evident for months.

TREATMENT

B. mallei Infections

The antibiotic susceptibility pattern of *B. mallei* is similar to that of *B. pseudomallei*; in addition, the organism is susceptible to the macrolides azithromycin and clarithromycin. *B. mallei* infection should be treated with the same drugs and for the same duration as melioidosis.

STENOTROPHOMONAS MALTOPHILIA

S. maltophilia is the only potential human pathogen among a genus of ubiquitous organisms found in the rhizosphere (i.e., the soil that surrounds the roots of plants). The organism is an opportunist that is acquired from the environment but is even more limited than *P. aeruginosa* in its ability to colonize patients or cause infections. Immunocompromise is not sufficient to permit these events; rather, major perturbations of the human flora are usually necessary for the establishment of *S. maltophilia*. Accordingly, most cases of human infection occur in the setting of very broad-spectrum antibiotic therapy with agents such as advanced cephalosporins and carbapenems, which eradicate the normal flora and other pathogens. The remarkable ability of *S. maltophilia* to resist virtually all classes of antibiotics is attributable to the possession of antibiotic efflux pumps and of two β-lactamases (L1 and L2) that mediate β-lactam resistance, including that to carbapenems. It is fortunate that the virulence of *S. maltophilia* appears to be limited. Although a serine protease is present in some strains, virulence is probably a result of the host's inflammatory response to components of the organism such as LPS and flagellin. *S. maltophilia* is most commonly found in the respiratory tract of ventilated patients, where the distinction between its roles as a colonizer and as a pathogen is often difficult to make. However, *S. maltophilia* does cause pneumonia and bacteremia in such patients, and these infections have led to septic shock. Also common is central venous line–associated infection (with or without bacteremia), which has been reported most often in patients with cancer. *S. maltophilia* is a rare cause of ecthyma gangrenosum in neutropenic patients. It has been isolated from ~5% of CF patients but is not believed to be a significant pathogen in this setting.

TREATMENT

S. maltophilia Infections

The intrinsic resistance of *S. maltophilia* to most antibiotics renders infection difficult to treat. The antibiotics to which it is most often (although not uniformly) susceptible are TMP-SMX, ticarcillin/clavulanate, levofloxacin, and tigecycline (Table 164-2). Consequently, a combination of TMP-SMX and ticarcillin/clavulanate is recommended for initial therapy pending susceptibility testing. Catheters must be removed in the treatment of bacteremia. The treatment of VAP due to *S. maltophilia* is much more difficult than that of bacteremia, with frequent development of resistance during therapy. The newest β-lactam/β-lactamase inhibitor combinations show mixed results against this organism.

165 Salmonellosis

David A. Pegues, Samuel I. Miller

Bacteria of the genus *Salmonella* are highly adapted for growth in both humans and animals and cause a wide spectrum of disease. The growth of serotypes *Salmonella* Typhi and *Salmonella* Paratyphi is restricted to human hosts, in whom these organisms cause enteric (typhoid) fever. The remaining serotypes (nontyphoidal *Salmonella*, or NTS) can colonize the gastrointestinal tracts of a broad range of animals, including mammals, reptiles, birds, and insects. More than 200 serotypes of *Salmonella* are pathogenic to humans, in whom they often cause gastroenteritis and can be associated with localized infections and/or bacteremia.

ETIOLOGY

This large genus of gram-negative bacilli within the family Enterobacteriaceae consists of two species: *Salmonella enterica*, which contains six subspecies, and *Salmonella bongori*. *S. enterica* subspecies I includes almost all the serotypes pathogenic for humans. Members of the seven

Salmonella subspecies are classified into >2500 serotypes (serovars); for simplicity, *Salmonella* serotypes (most of which are named for the city where they were identified) are often used as the species designation. For example, the full taxonomic designation *S. enterica* subspecies *enterica* serotype Typhimurium can be shortened to *Salmonella* serotype Typhimurium or simply *S.* Typhimurium. Serotyping is based on antigenically diverse surface structures: the somatic O antigen (lipopolysaccharide cell-wall components), the surface Vi antigen (restricted to *S.* Typhi and *S.* Paratyphi C), and the flagellar H antigen.

Salmonellae are gram-negative, non-spore-forming, facultatively anaerobic bacilli that measure 2–3 μm by 0.4–0.6 μm. The initial identification of salmonellae in the clinical microbiology laboratory is based on growth characteristics. Salmonellae, like other Enterobacteriaceae, produce acid on glucose fermentation, reduce nitrates, and do not produce cytochrome oxidase. In addition, all salmonellae except *Salmonella* Gallinarum-Pullorum are motile by means of peritrichous flagella, and all but *S.* Typhi produce gas (H_2S) on sugar fermentation. Notably, only 1% of clinical isolates ferment lactose; a high level of suspicion must be maintained to detect these rare clinical lactose-fermenting isolates.

Although serotyping of all surface antigens can be used for formal identification, most laboratories perform a few simple agglutination reactions that define specific O-antigen serogroups, designated A, B, C_1, C_2, D, and E. Strains in these six serogroups cause ~99% of *Salmonella* infections in humans and other warm-blooded animals. Molecular typing methods, including pulsed-field gel electrophoresis, multiple-locus variable-number tandem repeat analysis, and whole-genome sequencing, are used in epidemiologic investigations to differentiate *Salmonella* strains of a common serotype.

PATHOGENESIS

All *Salmonella* infections begin with ingestion of organisms, most commonly in contaminated food or water. The infectious dose ranges from 200 colony-forming units (CFU) to 10^6 CFU, and the ingested dose is an important determinant of incubation period and disease severity. Conditions that decrease either stomach acidity (an age of <1 year, acid suppression therapy, or achlorhydric disease) or intestinal integrity (inflammatory bowel disease, cytotoxic chemotherapy, prior gastrointestinal surgery, or alteration of the intestinal microbiome by antibiotic administration) increase susceptibility to *Salmonella* infection.

Once *S.* Typhi and *S.* Paratyphi reach the small intestine, they penetrate the mucus layer of the gut and traverse the intestinal layer through phagocytic microfold (M) cells that reside within Peyer's patches. Salmonellae can trigger the formation of membrane ruffles in normally nonphagocytic epithelial cells. These ruffles reach out and enclose adherent bacteria within large vesicles by *bacterium-mediated endocytosis*. This process is dependent on the direct delivery of *Salmonella* proteins into the cytoplasm of epithelial cells by the specialized bacterial type III secretion system. These bacterial proteins mediate alterations in the actin cytoskeleton that are required for *Salmonella* uptake.

After crossing the epithelial layer of the small intestine, *S.* Typhi and *S.* Paratyphi, which cause enteric (typhoid) fever, are phagocytosed by macrophages. These salmonellae survive the antimicrobial environment of the macrophage by sensing environmental signals that trigger alterations in regulatory systems of the phagocytosed bacteria. For example, PhoP/PhoQ (the best-characterized regulatory system) triggers the alteration of the outer membrane by increasing the synthesis and transport of different outer-membrane proteins, lipopolysaccharides, and glycerophospholipids, so that the altered bacterial surface can resist microbicidal activities and potentially alter host cell signaling. In addition, salmonellae encode a second type III secretion system that directly delivers bacterial proteins across the phagosome membrane into the macrophage cytoplasm. This secretion system functions to remodel the *Salmonella*-containing vacuole, promoting bacterial survival and replication.

Once phagocytosed, typhoidal salmonellae disseminate throughout the body in macrophages via the lymphatics and colonize reticuloendothelial tissues (liver, spleen, lymph nodes, and bone marrow). Patients have relatively few or no signs and symptoms during this initial incubation stage. Signs and symptoms, including fever and abdominal pain, probably result from secretion of cytokines by macrophages and epithelial cells in response to bacterial products that are recognized by innate immune receptors when a critical number of organisms have replicated. Over time, the development of hepatosplenomegaly is likely to be related to the recruitment of mononuclear cells and the development of a specific acquired cell-mediated immune response to *S.* Typhi colonization. The recruitment of additional mononuclear cells and lymphocytes to Peyer's patches during the several weeks after initial colonization/infection can result in marked enlargement and necrosis of the Peyer's patches, which may be mediated by bacterial products that promote cell death as well as the inflammatory response. In the case of *S.* Typhi, many strains produce a toxin, which probably contributes to systemic symptoms as well as the unusual neuropsychiatric states that can be seen in severe typhoidal illness.

In contrast to enteric fever, which is characterized by an infiltration of mononuclear cells into the small-bowel mucosa, NTS gastroenteritis is characterized by massive polymorphonuclear leukocyte infiltration into both the large- and small-bowel mucosa. This response appears to depend on the induction of interleukin 8, a strong neutrophil chemotactic factor, which is secreted by intestinal cells as a result of nontyphoidal *Salmonella* colonization and translocation of bacterial proteins into host cell cytoplasm. The degranulation and release of toxic substances by neutrophils may result in damage to the intestinal mucosa, causing the inflammatory diarrhea observed with nontyphoidal gastroenteritis. An additional important factor in the persistence of NTS in the intestinal tract and the organism's capacity to compete with endogenous flora is the ability to utilize the sulfur-containing compound tetrathionate for metabolism in a microaerophilic environment. In the presence of intestinal inflammation, tetrathionate is generated from thiosulfate produced by epithelial cells through inflammatory cell production of reactive oxygen species.

ENTERIC (TYPHOID) FEVER

Enteric (typhoid) fever is a systemic disease characterized by fever and abdominal pain and caused by dissemination of *S.* Typhi or *S.* Paratyphi. The disease was initially called *typhoid fever* because of its clinical similarity to typhus. In the early 1800s, typhoid fever was clearly defined pathologically as a unique illness on the basis of its association with enlarged Peyer's patches and mesenteric lymph nodes. In 1869, given the anatomic site of infection, the term *enteric fever* was proposed as an alternative designation to distinguish typhoid fever from typhus. However, to this day, the two designations are used interchangeably.

EPIDEMIOLOGY

In contrast to other *Salmonella* serotypes, the etiologic agents of enteric fever—*S.* Typhi and *S.* Paratyphi serotypes A, B, and C—have no known hosts other than humans. Most commonly, food-borne or waterborne transmission results from fecal contamination by ill or asymptomatic chronic carriers. Sexual transmission between male partners has been described. Health care workers occasionally acquire enteric fever after exposure to infected patients or during processing of clinical specimens and cultures.

With improvements in food handling and water/sewage treatment, enteric fever has become rare in developed nations. In 2017, worldwide there were an estimated 14.3 million cases of enteric fever with 136,000 deaths. The annual incidence is highest (>100 cases/100,000 population) in South Central and Southeast Asia; medium (10–100 cases/100,000) in the rest of Asia, Africa, Latin America, and Oceania (excluding Australia and New Zealand); and low in other parts of the world **(Fig. 165-1)**. A high incidence of enteric fever correlates with mixing of drinking water with human sewage. In endemic regions, enteric fever is more common in poor neighborhoods in large cities than rural areas and among young children and adolescents than among other age groups. Risk factors include fecally contaminated drinking water or ice, flooding, food and drinks purchased from street vendors, raw fruits and vegetables grown in fields fertilized with sewage, ill household contacts, lack of hand washing and toilet access, and evidence of prior *Helicobacter pylori* infection (an association probably

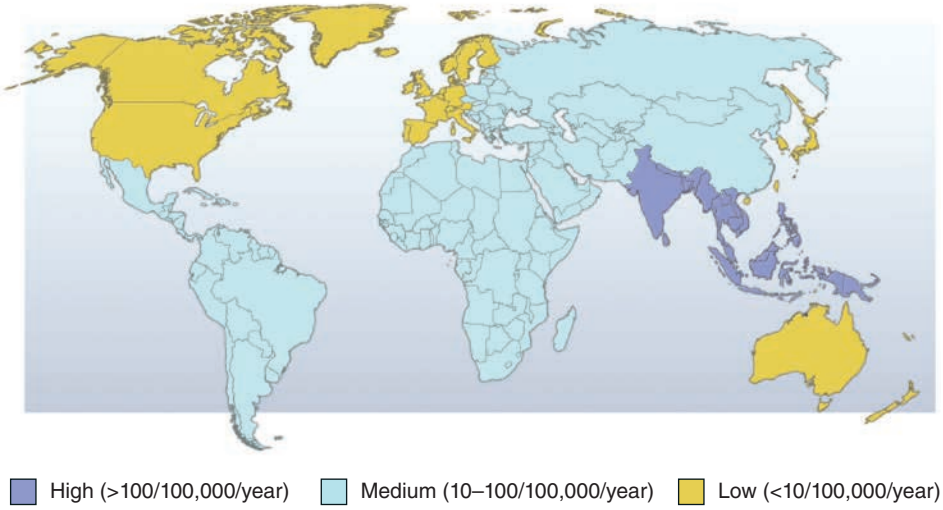

FIGURE 165-1 Annual incidence of typhoid fever per 100,000 population. *(Reproduced with permission from JA Crump: The global burden of typhoid fever. Bull World Health Organ 82:346, 2004.)*

related to chronically reduced gastric acidity). It is estimated that there is one case of paratyphoid fever for every four cases of typhoid fever, but the incidence of infection associated with *S.* Paratyphi A appears to be increasing, especially in India; this increase may be a result of vaccination for *S.* Typhi.

Multidrug-resistant (MDR) strains of *S.* Typhi emerged in the 1980s in China and Southeast Asia and have since disseminated widely. These strains contain plasmids encoding resistance to chloramphenicol, ampicillin, and trimethoprim—antibiotics long used to treat enteric fever. With the increased use of fluoroquinolones to treat MDR enteric fever in the 1990s, MDR strains of *S.* Typhi and *S.* Paratyphi with decreased susceptibility to ciprofloxacin (DSC; minimal inhibitory concentration [MIC], ≥0.125 μg/mL) or ciprofloxacin resistance (MIC, ≥1 μg/mL) emerged on the Indian subcontinent and have spread with human migration first to southern Asia and more recently to Eastern and Southern Africa. These strains represent clone H58, which increasingly has been associated with clinical treatment failure of fluoroquinolones. Testing of isolates for resistance to the first-generation quinolone nalidixic acid detects many but not all strains with reduced susceptibility to ciprofloxacin and is no longer recommended. Since 2017, a large outbreak of plasmid-mediated ceftriaxone-resistant *S.* Typhi H58 has been ongoing, centered in urban slums in Pakistan. The outbreak predominantly has affected children aged 15 and younger and is associated with fecally contaminated drinking water.

In 2015, there were 309 cases of typhoid fever and 71 cases of paratyphoid fever reported in the United States. Median age of patients with typhoid fever was 23 years and paratyphoid fever 29 years. Most cases of enteric fever were associated with international travel (78%), predominantly to Indian, Pakistan, and Bangladesh, and visiting friends and family. Only 3% of travelers diagnosed with typhoid fever had received *S.* Typhi vaccine within the previous 5 years. In 2015, 66% of *S.* Typhi in the United States were DSC, and ~10% were resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX). Infection with DSC *S.* Typhi was associated with travel to the Indian subcontinent. In the United States, domestically acquired cases of enteric fever are less often DSC or MDR compared to travel-associated cases and are most often sporadic, although outbreaks linked to contaminated food products and previously unrecognized chronic carriers continue to occur.

CLINICAL COURSE

Enteric fever is a misnomer, in that the hallmark features of this disease—fever and abdominal pain—are variable. While fever is documented at presentation in >75% of cases, abdominal pain is reported in only 30–40%. Thus, a high index of suspicion for this potentially fatal systemic illness is necessary when a person presents with fever and a history of recent travel to a developing country.

The mean incubation period for *S.* Typhi is 10–14 days but ranges from 5 to 21 days, depending on the inoculum size and the host's health and vaccination status. The most prominent symptom is prolonged fever (38.8°–40.5°C [101.8°–104.9°F]), which can continue for up to 4 weeks if untreated. *S.* Paratyphi A is thought to cause milder disease than *S.* Typhi, with predominantly gastrointestinal symptoms. However, a prospective study of 669 consecutive cases of enteric fever in Kathmandu, Nepal, found that the infections caused by these organisms were clinically indistinguishable. In this series, symptoms reported on initial medical evaluation included headache (80%), chills (35–45%), cough (30%), sweating (20–25%), myalgias (20%), malaise (10%), and arthralgia (2–4%). Gastrointestinal manifestations included anorexia (55%), abdominal pain (30–40%), nausea (18–24%), vomiting (18%), and diarrhea (22–28%) more commonly than constipation (13–16%). Physical findings included coated tongue (51–56%), splenomegaly (5–6%), and abdominal tenderness (4–5%).

Early physical findings of enteric fever include rash ("rose spots"; 30%), hepatosplenomegaly (3–6%), epistaxis, and relative bradycardia at the peak of high fever (<50%). Rose spots **(Fig. 165-2; see also Fig. A1-9)** make up a faint, salmon-colored, blanching, maculopapular rash located primarily on the trunk and chest. The rash is evident in ~30% of patients at the end of the first week and resolves without a trace after 2–5 days. Patients can have two or three crops of lesions, and *Salmonella* can be cultured from punch biopsies of these lesions. The faintness of the rash makes it difficult to detect in highly pigmented patients.

Complications of typhoid fever are estimated to occur in ~27% of hospitalized patients and correlate with a longer duration of symptoms before hospitalization, host factors (host genetics, immunosuppression, acid suppression therapy, previous exposure, and vaccination status), strain virulence and inoculum, and choice of antibiotic therapy. Gastrointestinal bleeding (6%) and intestinal perforation (1%) most commonly occur in the third and fourth weeks of illness and result from hyperplasia, ulceration, and necrosis of the ileocecal Peyer's patches at the initial site of *Salmonella* infiltration **(Fig. 165-3)**. Both complications are life-threatening and require immediate fluid resuscitation and surgical intervention, with broadened antibiotic coverage for polymicrobial peritonitis **(Chap. 132)** and treatment of gastrointestinal hemorrhages, including bowel resection. Neurologic manifestations

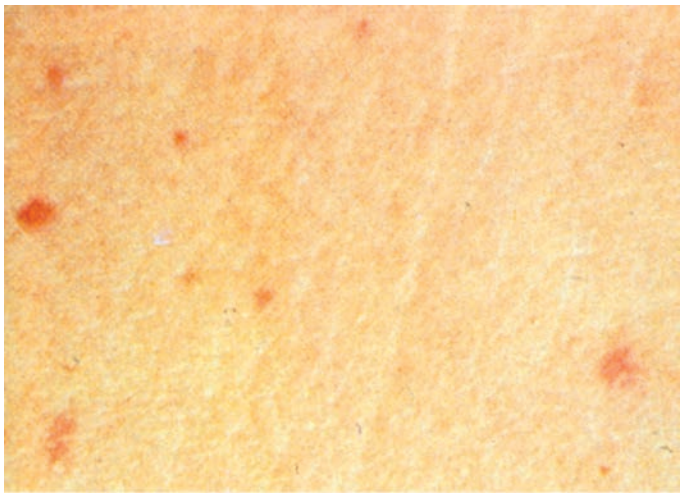

FIGURE 165-2 "Rose spots," the rash of enteric fever due to *Salmonella* Typhi or *Salmonella* Paratyphi.

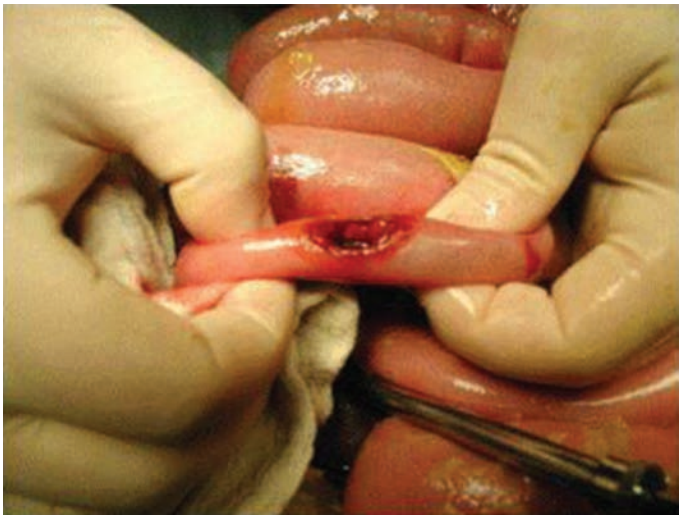

FIGURE 165-3 Typical ileal perforation associated with *Salmonella* Typhi infection. *(From JM Saxe, R Cropsey: Is operative management effective in treatment of perforated typhoid? Am J Surg 189:342, 2005.)*

occur in 2–40% of patients and include meningitis, Guillain-Barré syndrome, neuritis, and neuropsychiatric symptoms (described as "muttering delirium" or "coma vigil"), with picking at bedclothes or imaginary objects.

Uncommon complications whose incidences are reduced by prompt antibiotic treatment include disseminated intravascular coagulation, hematophagocytic syndrome, pancreatitis, hepatic and splenic abscesses and granulomas, endocarditis, pericarditis, myocarditis, orchitis, hepatitis, glomerulonephritis, pyelonephritis and hemolytic-uremic syndrome, severe pneumonia, arthritis, osteomyelitis, endophthalmitis, and parotitis. Up to 10% of patients develop mild relapse, usually within 2–3 weeks of fever resolution and in association with the same strain type and susceptibility profile.

Up to 10% of untreated patients with typhoid fever excrete *S.* Typhi in the feces for up to 3 months, and 2–5% develop chronic asymptomatic carriage, shedding *S.* Typhi in either urine or stool for >1 year. Chronic carriage is more common among women, infants, and persons who have biliary abnormalities or concurrent bladder infection with *Schistosoma haematobium*. *S.* Typhi and other salmonellae are adapted to survive in the gallbladder environment by forming biofilms on gallstones and invading gallbladder epithelial cells. Chronic carriage is associated with an increased risk of gallbladder cancer, which is much more common in locales where *S.* Typhi is common, such as the Indian subcontinent.

DIAGNOSIS

Because the clinical presentation of enteric fever is relatively nonspecific, the diagnosis needs to be considered in any febrile traveler returning from a developing region, especially the Indian subcontinent, the Philippines, or Latin America. Other diagnoses that should be considered in these travelers include malaria, hepatitis, bacterial enteritis, dengue fever, rickettsial infections, leptospirosis, amebic liver abscesses, and acute HIV infection **(Chap. 124)**. Other than a positive culture, no specific laboratory test is diagnostic for enteric fever. In 15–25% of cases, leukopenia and neutropenia are detectable. Leukocytosis is more common among children, during the first 10 days of illness, and in cases complicated by intestinal perforation or secondary infection. Other nonspecific laboratory findings include moderately elevated values in liver function tests and muscle enzyme levels.

The definitive diagnosis of enteric fever requires the isolation of *S.* Typhi or *S.* Paratyphi from blood, bone marrow, other sterile sites, rose spots, stool, or intestinal secretions. The diagnostic sensitivity of blood culture is only ~60% and is lower with low blood sample volume and among patients with prior antimicrobial use or in the first week of illness, reflecting the small number of *S.* Typhi organisms (i.e., <15/mL) typically present in the blood. Because almost all *S.* Typhi organisms in blood are associated with the mononuclear cell/platelet fraction, centrifugation of blood and culture of the buffy coat can substantially reduce the time to isolation of the organism but do not increase sensitivity.

Bone marrow culture is >80% sensitive, and, unlike that of blood culture, its yield is not reduced by up to 5 days of prior antibiotic therapy. Culture of intestinal secretions (best obtained by a noninvasive duodenal string test) can be positive despite a negative bone marrow culture. If blood, bone marrow, and intestinal secretions are all cultured, the yield is >90%. Stool cultures, although negative in 60–70% of cases during the first week, can become positive during the third week of infection in untreated patients.

The classic Widal serologic test for "febrile agglutinins" is simple and rapid but has limited sensitivity and specificity, especially in endemic regions because of inability to differentiate active from prior infection or vaccination. Other rapid serologic tests, including IDL Tubex and Typhidot, have greater accuracy than the Widal test, but cost has limited their routine use in developing countries. Nucleic acid–based identification methods are not yet commercially available.

TREATMENT

Enteric (Typhoid) Fever

Enteric fever is associated with an overall case–fatality rate of 2.5%, and it rises to 4.5% among hospitalized patients. Prompt administration of appropriate antibiotic therapy prevents severe complications of enteric fever and reduces mortality to <1%. The initial choice of antibiotics depends on the susceptibility of the *S.* Typhi and *S.* Paratyphi strains in the area of residence or travel **(Table 165-1)**. For treatment of drug-susceptible typhoid fever,

TABLE 165-1 Antibiotic Therapy for Enteric Fever in Adults

INDICATION	AGENT	DOSAGE (ROUTE)	DURATION, DAYS
Empirical Treatment			
	Ceftriaxone[a]	2 g/d (IV)	10–14
	Azithromycin[b]	1 g/d (PO)	5
Fully Susceptible			
Optimal treatment	Ciprofloxacin[c]	500 mg bid (PO) or 400 mg q12h (IV)	5–7
	Azithromycin	1 g/d (PO)	5
Alternative treatment	Amoxicillin	1 g tid (PO) or 2 g q6h (IV)	14
	Chloramphenicol	25 mg/kg tid (PO or IV)	14–21
	Trimethoprim-sulfamethoxazole	160/800 mg bid (PO)	7–14
Multidrug-Resistant, Fluoroquinolone-Susceptible			
Optimal treatment	Ceftriaxone[a]	2 g/d (IV)	10–14
	Azithromycin	1 g/d (PO)	5
Alternative treatment	Ciprofloxacin	500 mg bid (PO) or 400 mg q12h (IV)	5–14
Fluroquinolone-Resistant			
Optimal treatment	Ceftriaxone	2 g/d (IV)	10–14
	Azithromycin	1 g/d (PO)	5
Ceftriaxone-Resistant			
Optimal treatment	Meropenem[d]	1 g q8h (IV)	10–14
	Azithromycin	1 g/d (PO)	5
Eradication of Carriage			
Optimal treatment	Ciprofloxacin	500–750 mg bid (PO)	28
Alternative treatment	Amoxicillin[e]	2 g tid (PO)	28–42

[a]Or another third-generation cephalosporin (e.g., cefotaxime, 2 g q8h IV; or cefixime, 400 mg bid PO). [b]Or 1 g on day 1 followed by 500 mg/d PO for 6 days. [c]Or ofloxacin, 400 mg bid PO for 2–5 days. [d]Or imipenem 500 mg q6h IV. [e]If fluroquinolone resistant and ampicillin susceptible.

fluoroquinolones are the most effective class of agents, with cure rates of ~98% and relapse and fecal carriage rates of <2%. Experience is most extensive with ciprofloxacin. Short-course ofloxacin therapy is similarly successful against infection caused by quinolone-susceptible strains. However, because of the high prevalence of strains of *S.* Typhi and *S.* Paratyphi with decreased susceptibility to ciprofloxacin (MIC >0.125 μg/mL) on the Indian subcontinent, in Nepal, and in some locales in Africa, fluoroquinolones should no longer be used for empirical treatment of enteric fever in these regions. Patients infected with DSC strains of *S.* Typhi or *S.* Paratyphi should be treated with ceftriaxone or azithromycin. Patients with concern for ceftriaxone-resistant *S.* Typhi infection should be treated empirically with a carbapenem.

Ceftriaxone, cefotaxime, and (oral) cefixime are effective for treatment of MDR enteric fever, including that caused by DSC and fluoroquinolone-resistant strains. These agents clear fever in ~1 week, with failure rates of ~5–10%, fecal carriage rates of <3%, and relapse rates of 3–6%. Oral azithromycin results in defervescence in 4–6 days, with rates of relapse and convalescent stool carriage of <3%. Against DSC strains, azithromycin is associated with lower rates of treatment failure and shorter durations of hospitalization than are fluoroquinolones. Despite efficient in vitro killing of *Salmonella*, first- and second-generation cephalosporins as well as aminoglycosides are ineffective in the treatment of clinical infections.

Most patients with uncomplicated enteric fever can be managed at home with oral antibiotics and antipyretics. Patients with persistent vomiting, diarrhea, and/or abdominal distension should be hospitalized and given supportive therapy as well as a parenteral third-generation cephalosporin, a fluoroquinolone, or carbapenem depending on the susceptibility profile. Therapy should be administered for at least 10 days or for 5 days after fever resolution.

In a randomized, prospective, double-blind study of critically ill patients with enteric fever (i.e., those with shock and obtundation) in Indonesia in the early 1980s, the administration of dexamethasone (an initial dose of 3 mg/kg followed by eight doses of 1 mg/kg every 6 h) with chloramphenicol was associated with a substantially lower mortality rate than was treatment with chloramphenicol alone (10% vs 55%). Although this study has not been repeated in the "post-chloramphenicol era," severe enteric fever remains one of the few indications for glucocorticoid treatment of an acute bacterial infection.

The 2–5% of patients who develop chronic carriage of *Salmonella* can be treated for 4 weeks with oral ciprofloxacin or other fluoroquinolones, with an eradication rate of ~80%. Oral amoxicillin is associated with lower eradication rates than fluoroquinolones but can be considered in persons with fluoroquinolone-resistant strains that are susceptible to ampicillin. In cases of anatomic abnormality (e.g., biliary or kidney stones), eradication often requires both antibiotic therapy and surgical correction.

PREVENTION AND CONTROL

Theoretically, it is possible to eliminate the salmonellae that cause enteric fever because they survive only in human hosts and are spread by contaminated food and water. However, given the high prevalence of the disease in developing countries that lack adequate sewage disposal and water treatment, this goal is currently unrealistic. Thus, travelers to developing countries should be advised to monitor their food and water intake carefully and to strongly consider immunization against *S.* Typhi.

Two typhoid vaccines are commercially available in the United States: (1) Ty21a, an oral live attenuated *S.* Typhi vaccine (given on days 1, 3, 5, and 7, with revaccination with a full four-dose series every 5 years); in January 2021, manufacture of Ty21a was suspended due to COVID-19-related reductions in international travel; and (2) Vi CPS, a parenteral vaccine consisting of purified Vi polysaccharide from the bacterial capsule (given in a single dose, with a booster every 2 years). The minimal age for vaccination is 6 years for Ty21a and 2 years for Vi CPS. In a recent meta-analysis of 18 randomized clinical trials of vaccines for preventing typhoid fever in populations in endemic areas, the cumulative efficacy was 50% for Ty21a at 2.5 to 3 years and 55% for Vi CPS at 3 years. Although data on typhoid vaccines in travelers are limited, recent evidence suggests that typhoid vaccines are moderate effective (80%) in U.S. travelers. Currently, there is no licensed vaccine for paratyphoid fever.

Vi CPS typhoid vaccine is poorly immunogenic in children <5 years of age because of T cell–independent properties. In contrast, in a 2001 study, a prototype conjugated typhoid vaccine Vi-rEPA (Vi antigen conjugated to *Pseudomonas aeruginosa* exotoxin A) had 91% efficacy at 27 months in preventing typhoid fever in Vietnamese children 2–5 years of age. This vaccine is not commercially available. In a 2019 randomized clinical trial, a Vi polysaccharide–tetanus toxoid conjugate vaccine (Vi-TT) reduced the incidence of blood culture–confirmed typhoid fever by 82% compared to a control meningococcal vaccine among 6-month-old to 16-year-old children in Nepal. Seroconversion was 99% after Vi-TT vaccination. The World Health Organization now recommends Vi-TT administered as a single 0.5-mL dose for infants and children from 9 months to 15 years of age in high-burden settings. In typhoid-endemic areas, immunization with Vi-TT or Vi CPS is recommended for HIV-infected and other immunocompromised persons. The Vi-TT vaccine is not licensed in the United States.

Typhoid vaccine is not required for international travel, but it is recommended for travelers to areas where there is a moderate to high risk of exposure to *S.* Typhi, especially those who are traveling to southern Asia and other developing regions of Asia, Africa, the Caribbean, and Central and South America and who will be exposed to potentially contaminated food and drink. Typhoid vaccine should be considered even for persons planning <2 weeks of travel to high-risk areas. In addition, clinical microbiology or research laboratory staff at risk of occupational exposure to *S.* Typhi and household contacts of known *S.* Typhi carriers should be vaccinated. Because the protective efficacy of vaccine can be overcome by the high inocula that are commonly encountered in food-borne exposures, immunization is an adjunct and not a substitute for the avoidance of high-risk foods and beverages. Immunization is not recommended for the management of persons who may have been exposed in a common-source outbreak.

Enteric fever is a notifiable disease in the United States. Individual health departments have their own guidelines for allowing ill or colonized food handlers or health care workers to return to their jobs. The reporting system enables public health departments to identify potential source patients and to treat chronic carriers in order to prevent further outbreaks. In addition, because 1–4% of patients with *S.* Typhi infection become chronic carriers, it is important to monitor patients (especially child-care providers and food handlers) for chronic carriage and to treat this condition if indicated.

NONTYPHOIDAL SALMONELLOSIS

EPIDEMIOLOGY

Worldwide, NTS causes ~93 million enteric infections and 155,000 deaths annually. In the United States, NTS causes ~12 million illnesses annually, and the incidence has remained relatively unchanged during the past two decades. In 2017, the incidence of NTS infection in the United States was 16.0 cases per 100,000 persons—the second highest rate after *Campylobacter* (19.1 cases per 100,000 persons) among the 10 food-borne enteric pathogens under active surveillance. The four most common serotypes were Enteritidis, Typhimurium, Newport, and Javiana, which together accounted for ~40% of U.S. NTS infections.

The incidence of nontyphoidal salmonellosis is highest during the rainy season in tropical climates and during the warmer months in temperate climates—a pattern coinciding with the peak in food-borne outbreaks. Rates of morbidity and mortality associated with NTS are highest among the elderly, infants, and immunocompromised individuals, including those with hemoglobinopathies, HIV infection, or infections that cause blockade of the reticuloendothelial system (e.g., bartonellosis, malaria, schistosomiasis, histoplasmosis). NTS account for a significant majority of illnesses and hospitalizations associated with U.S. multistate food-borne outbreaks.

Invasive NTS disease is a major cause of global morbidity and mortality, especially in sub-Saharan Africa and Southeast Asia, causing an estimated annual 535,00 cases and 77,500 deaths. Invasive NTS disease is not as common as *Salmonella* enterocolitis but is associated with a much higher case–fatality rate (14.5%), especially in children; the elderly; those with poor nutrition, malaria, or HIV infection; and in areas of low sociodemographic development. In sub-Saharan Africa, specific endemic NTS strain types, including *S.* Typhimurium sequence type (ST) 131, *S.* Enteritidis sequence type 11, *S.* Dublin, and *S.* Isangi, are the predominant cause of invasive NTS disease.

Unlike *S.* Typhi and *S.* Paratyphi, whose only reservoir is humans, NTS can be acquired from multiple animal and plant reservoirs that are part of the typical food supply. Transmission is most commonly associated with food products of animal origin (especially eggs, poultry, undercooked ground meat, and dairy products), fresh produce contaminated with animal waste, and contact with animals or their environments. In the United States, NTS are the second most common cause of food-borne outbreaks after norovirus, causing 30% of outbreaks and 35% of outbreak-associated illnesses.

S. Enteritidis infection associated with chicken eggs emerged as a major cause of food-borne disease during the 1980s and 1990s. *S.* Enteritidis infection of the ovaries and upper oviduct tissue of hens results in contamination of egg contents before shell deposition. Infection is spread to egg-laying hens from breeding flocks and through contact with rodents and manure. The number of *S.* Enteritidis outbreaks and the proportion attributable to egg-containing foods have continued to decline since the mid-1990s; these declines have coincided with interventions in the egg-producing and food service industries. Despite these control efforts, outbreaks of *S.* Enteritidis infection associated with shell eggs continue to occur. In 2010, a national outbreak of *S.* Enteritidis infection resulted in >1900 reported illnesses and the recall of 500 million eggs. Transmission via contaminated eggs can be prevented by cooking eggs until the yolk is solidified and pasteurizing egg products.

Salmonella serotype 4,[5],12:i:-, an antigenic variant of *S.* Typhimurium that lacks the second stage flagellar antigen, has dramatically emerged as a foodborne pathogen associated with pigs and pork products. This serotype is now the second most common NTS in Europe and the fifth most common in the United States. These strains are multidrug resistant; in addition to resistance to ampicillin, streptomycin, sulfonamides, and tetracycline, strains from the United States also have phenotypic resistance to the veterinary antimicrobials enrofloxacin and cefdinir, which are widely used in pork production.

Centralization of food processing and widespread food distribution have contributed to the increased incidence of NTS in developed countries. NTS account for a significant majority of illnesses and hospitalizations associated with multistate foodborne outbreaks in the United States. Manufactured foods to which recent multistate *Salmonella* outbreaks have been traced include peanut butter; milk products, including infant formula; and various processed foods, including packaged breakfast cereal, salsa, frozen prepared meals, and snack foods. Large outbreaks also have been linked to fresh produce, including alfalfa sprouts, nuts/seeds, cantaloupe, mangoes, papayas, tomatoes, and raw meal replacement powder; these items become contaminated by manure or water at a single site and then are widely distributed.

An estimated 6% of sporadic *Salmonella* infections in the United States are attributed to contact with reptiles or amphibians, especially iguanas, snakes, turtles, and lizards. Other pets, including hedgehogs, birds, rodents, baby chicks, ducklings, dogs, and cats, also are potential sources of NTS. Compared to foodborne outbreaks, outbreaks of NTS linked to animal contact more commonly affect young children (<1–4 years of age), result in hospitalization, and are more sustained.

Increasing antibiotic resistance in NTS species is a global problem and has been linked to the widespread use of antimicrobial agents in food animals and especially in animal feed. In the early 1990s, *S.* Typhimurium definitive phage type 104 (DT104), characterized by resistance to at least five antibiotics (ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracyclines; R-type ACSSuT), emerged worldwide. In 2015, resistance to at least ACSSuT was reported in 2.7% of U.S. NTS isolates, including 10.8% of *S.* Typhimurium isolates. Acquisition is associated with exposure to ill farm animals and to various meat products, including uncooked or undercooked ground beef. Although probably no more virulent than susceptible *S.* Typhimurium strains, DT104 strains are associated with an increased risk of bloodstream infection and hospitalization.

Because of increased resistance to conventional antibiotics such as ampicillin and TMP-SMX, extended-spectrum cephalosporins and fluoroquinolones have emerged as the agents of choice for the treatment of MDR NTS infections. In 2015, 2.7% of NTS strains in the United States were resistant to ceftriaxone. Most ceftriaxone-resistant isolates contain plasmid-encoded AmpC β-lactamases that were probably acquired by horizontal genetic transfer from *Escherichia coli* strains in food-producing animals—an event linked to the widespread use of the veterinary cephalosporin ceftiofur.

Since the early 2000s, strains of DSC NTS (MIC, ≥0.125 μg/mL) have emerged and have been associated with delayed response and treatment failure. In 2015, 5.8% of NTS isolates in the United States were DSC. These strains have diverse resistance mechanisms, including single and multiple mutations in the DNA gyrase genes *gyr*A and *gyr*B, mutations in the chromosomally encoded quinolone resistance–determining region, and plasmid-encoded quinolone resistance genes that are not reliably detected by nalidixic acid susceptibility testing or standard ciprofloxacin disk diffusion. In 2012, the U.S. Clinical Laboratory Standards Institute proposed a lower ciprofloxacin susceptibility breakpoint (≥0.06 μg/mL) for all *Salmonella* species to address this issue. Because commercial test systems do not contain ciprofloxacin concentrations low enough to allow use of this breakpoint, laboratories need to determine the ciprofloxacin MIC by Etest or another alternative method.

While NTS strains with decreased susceptibility to azithromycin (MIC, ≥32 μg/mL) remain uncommon in the United States (0.3% in 2015), in 2018–2019, there was an outbreak of 255 cases of azithromycin-resistant *S.* Newport infection in 32 states linked to beef obtained in the United States and soft cheese obtained in Mexico. Sporadic cases of carbapenemase-resistant NTS have been reported in Europe, North Africa, and southern Asia.

CLINICAL MANIFESTATIONS

Gastroenteritis Infection with NTS most often results in gastroenteritis indistinguishable from that caused by other enteric pathogens. Nausea, vomiting, and diarrhea occur 6–48 h after the ingestion of contaminated food or water. Patients often experience abdominal cramping and fever (38–39°C [100.5–102.2°F]). Diarrheal stools are usually loose, nonbloody, and of moderate volume. However, large-volume watery stools, bloody stools, or symptoms of dysentery may occur. Rarely, NTS causes pseudoappendicitis or an illness that mimics inflammatory bowel disease.

Gastroenteritis caused by NTS is usually self-limited. Diarrhea resolves within 3–7 days and fever within 72 h. Stool cultures remain positive for 4–5 weeks after infection and—in rare cases of chronic carriage (<1%)—for >1 year. Persistent NTS infection and relapsing diarrhea have been described in a small fraction of Israeli patients and were associated with in-host single nucleotide mutations in key virulence regulators. For acute NTS gastroenteritis, antibiotic treatment usually is not recommended and may prolong fecal carriage. Neonates, the elderly, and immunosuppressed patients (e.g., transplant recipients, HIV-infected persons) with NTS gastroenteritis are especially susceptible to dehydration and invasive infection and may require hospitalization and antibiotic therapy. Acute NTS gastroenteritis was associated with a threefold increased risk of dyspepsia and irritable bowel syndrome at 1 year in a study from Spain.

Bacteremia and Endovascular Infections Up to 8% of patients with NTS gastroenteritis develop bacteremia; of these, 5–10% develop localized infections. Bacteremia and metastatic infection are most common with *Salmonella* Choleraesuis and *Salmonella* Dublin and

among infants, the elderly, and immunocompromised patients, especially those with HIV infection. NTS endovascular infection should be suspected in high-grade or persistent bacteremia, especially with preexisting valvular heart disease, atherosclerotic vascular disease, prosthetic vascular graft, or aortic aneurysm. Arteritis should be suspected in elderly patients with prolonged fever and back, chest, or abdominal pain developing after an episode of gastroenteritis. Endocarditis and arteritis are rare (<1% of cases) but are associated with potentially fatal complications, including valve perforation, endomyocardial abscess, infected mural thrombus, pericarditis, mycotic aneurysms, aneurysm rupture, aortoenteric fistula, and vertebral osteomyelitis.

Invasive NTS disease is among the most common causes of bacteremia in children and in HIV-infected adults in sub-Saharan Africa and Southeast Asia, causing 39% of community-acquired bloodstream infection in one study. NTS bacteremia among these children is not associated with diarrhea and has been associated with poor nutritional status, malaria, sickle cell disease, and HIV infection. *S.* Typhimurium ST 131, the most common cause of invasive NTS disease in sub-Saharan Africa, forms a specific clade that is associated with genome reduction and loss of traits required for environmental stress resistance, likely contributing to making this strain more human adapted, perhaps as a result of carriage by immunosuppressed individuals with HIV.

Localized Infections • **INTRAABDOMINAL INFECTIONS** Intraabdominal infections due to NTS are rare and usually manifest as hepatic or splenic abscesses or as cholecystitis. Risk factors include hepatobiliary anatomic abnormalities (e.g., gallstones), abdominal malignancy, and sickle cell disease (especially with splenic abscesses). Eradication of the infection often requires surgical correction of abnormalities and percutaneous drainage of abscesses.

CENTRAL NERVOUS SYSTEM INFECTIONS NTS meningitis most commonly develops in infants 1–4 months of age and in adults with HIV infection. It often results in severe sequelae (including seizures, hydrocephalus, brain infarction, and mental retardation), with death in up to 60% of cases. Other rare central nervous system infections include ventriculitis, subdural empyema, and brain abscesses.

PULMONARY INFECTIONS NTS pulmonary infections usually present as lobar pneumonia, and complications include lung abscess, empyema, and bronchopleural fistula formation. The majority of cases occur in patients with lung cancer, structural lung disease, sickle cell disease, or glucocorticoid use.

URINARY AND GENITAL TRACT INFECTIONS Urinary tract infections caused by NTS present as either cystitis or pyelonephritis. Risk factors include malignancy, urolithiasis, structural abnormalities, HIV infection, and renal transplantation. NTS genital infections are rare and include ovarian and testicular abscesses, prostatitis, and epididymitis. Like other focal infections, both genital and urinary tract infections can be complicated by abscess formation.

BONE, JOINT, AND SOFT TISSUE INFECTIONS *Salmonella* osteomyelitis most commonly affects the femur, tibia, humerus, or lumbar vertebrae and is most often seen in association with sickle cell disease, hemoglobinopathies, or preexisting bone disease (e.g., fractures). Prolonged antibiotic treatment is recommended to decrease the risk of relapse and chronic osteomyelitis. Septic arthritis occurs in the same patient population as osteomyelitis and usually involves the knee, hip, or shoulder joints. Reactive arthritis can follow NTS gastroenteritis and is seen most frequently in persons with the HLA-B27 histocompatibility antigen. NTS rarely can cause soft tissue infections, usually at sites of local trauma in immunosuppressed patients.

DIAGNOSIS

The diagnosis of NTS infection is based on isolation of the organism from freshly passed stool or from blood or another ordinarily sterile body fluid. *Salmonella* is increasingly identified by culture-independent diagnostic tests due to increased sensitivity, rapid turnaround, and ability to detect multiple enteric pathogens in one test. Culture-independent positive specimens should have primary isolation performed to replicate results and recover NTS isolates. All NTS isolates should be referred to local public health departments for serotyping. Blood cultures should be obtained whenever a patient has prolonged or recurrent fever. Endovascular infection should be suspected if there is high-grade bacteremia (>50% of three or more blood cultures positive). Echocardiography, CT, and indium-labeled white cell scanning are used to identify localized infection. When another localized infection is suspected, joint fluid, abscess drainage, or cerebrospinal fluid should be cultured, as clinically indicated.

TREATMENT

Nontyphoidal Salmonellosis

Antibiotics should not be used routinely to treat uncomplicated NTS gastroenteritis. The symptoms are usually self-limited, and the duration of fever and diarrhea is not significantly decreased by antibiotic therapy. In addition, antibiotic treatment has been associated with increased rates of relapse, prolonged gastrointestinal carriage, and adverse drug reactions. Dehydration secondary to diarrhea should be treated with fluid and electrolyte replacement.

Preemptive antibiotic treatment **(Table 165-2)** should be considered for patients at increased risk for invasive NTS infection, including neonates (probably up to 3 months of age); persons >50 years of age with known or suspected atherosclerosis; and patients with immunosuppression, cardiac valvular or endovascular abnormalities, or significant joint disease. Treatment should consist of an oral or IV antibiotic administered for 48–72 h or

TABLE 165-2 Antibiotic Therapy for Nontyphoidal *Salmonella* Infection in Adults

INDICATION	AGENT	DOSAGE (ROUTE)	DURATION, DAYS
Preemptive Treatment[a]			
	Ciprofloxacin[b]	500 mg bid (PO)	2–3
Severe Gastroenteritis[c]			
	Ciprofloxacin	500 mg bid (PO) or 400 mg q12h (IV)	7
	Azithromycin	500 mg once daily	5
	Trimethoprim-sulfamethoxazole	160/800 mg bid (PO)	7
	Amoxicillin	1 g tid (PO)	7
	Ceftriaxone	1–2 g/d (IV)	7
Bacteremia			
	Ceftriaxone[d]	2 g/d (IV)	7–14
	Ciprofloxacin	400 mg q12h (IV), then 500 mg bid (PO)	
Endocarditis or Arteritis			
	Ceftriaxone	2 g/d (IV)	42
	Ciprofloxacin	400 mg q8h (IV), then 750 mg bid (PO)	
	Ampicillin	2 g q4h (IV)	
Meningitis			
	Ceftriaxone	2 g q12h (IV)	14–21
	Ampicillin	2 g q4h (IV)	
Other Localized Infection			
	Ceftriaxone	2 g/d (IV)	14–28
	Ciprofloxacin	500 mg bid (PO) or 400 mg q12h (IV)	
	Ampicillin	2 g q6h (IV)	

[a]Consider for neonates; persons >50 years of age with possible atherosclerotic vascular disease; and patients with immunosuppression, endovascular graft, or joint prosthesis. [b]Or ofloxacin, 400 mg bid (PO). [c]Consider on an individualized basis for patients with severe diarrhea and high fever who require hospitalization. [d]Or cefotaxime, 2 g q8h (IV).

until the patient becomes afebrile. Immunocompromised persons may require up to 7–14 days of therapy. The <1% of persons who develop chronic carriage of NTS should receive a prolonged antibiotic course, as described above for chronic carriage of *S.* Typhi.

Because of the increasing prevalence of antibiotic resistance, empirical therapy for life-threatening NTS bacteremia or focal NTS infection should include a third-generation cephalosporin or a fluoroquinolone (Table 165-2). If the bacteremia is low-grade (<50% of blood cultures positive), the patient should be treated for 7–14 days. Patients with HIV/AIDS and NTS bacteremia should receive 1–2 weeks of IV antibiotic therapy followed by 4 weeks of oral therapy with a fluoroquinolone. Patients whose infections relapse after this regimen should receive long-term suppressive therapy with a fluoroquinolone or TMP-SMX, as indicated by bacterial sensitivities.

If the patient has endocarditis or arteritis, treatment for 6 weeks with an IV β-lactam antibiotic (such as ceftriaxone or ampicillin) is indicated. IV ciprofloxacin followed by prolonged oral therapy is an option. Early surgical resection of infected aneurysms or other infected endovascular sites is recommended. Patients with infected prosthetic vascular grafts that cannot be resected have been maintained successfully on chronic suppressive oral therapy. For extraintestinal nonvascular infections, a 2- to 4-week course of antibiotic therapy (depending on the infection site) is usually recommended. In chronic osteomyelitis, abscess, or urinary or hepatobiliary infection associated with anatomic abnormalities, surgical resection or drainage may be required in addition to prolonged antibiotic therapy for eradication of infection.

PREVENTION AND CONTROL

Despite widespread efforts to prevent or reduce bacterial contamination of animal-derived food products and to improve food-safety education and training, recent declines in the incidence of NTS in the United States have been modest compared with those of other food-borne pathogens. This observation probably reflects the complex epidemiology of NTS. Identifying effective risk-reduction strategies requires monitoring of every step of the food supply chain, including farm sources, slaughter and processing of raw animal or plant products, storage and transport, and preparation of finished foods. Contaminated food can be made safe for consumption by pasteurization, irradiation, or proper cooking. All cases of NTS infection should be reported to local public health departments because tracking and monitoring of these cases can identify the source(s) of infection and help authorities anticipate large outbreaks. Prudent use of antimicrobial agents in both humans and animals is needed to limit the emergence of MDR *Salmonella*. In developing countries, immunogenic conjugated vaccines against NTS and rapid, point-of-care diagnostics are critically needed to reduce the morbidity and mortality associated with invasive NTS infection.

166 Shigellosis

Philippe J. Sansonetti, Jean Bergounioux

The discovery of *Shigella* as the etiologic agent of dysentery—a clinical syndrome of fever, intestinal cramps, and frequent passage of small, bloody, mucopurulent stools—is attributed to the Japanese microbiologist Kiyoshi Shiga, who isolated the Shiga bacillus (now known as *Shigella dysenteriae* type 1) from patients' stools in 1897 during a large and devastating dysentery epidemic. *Shigella* cannot be distinguished from *Escherichia coli* by DNA hybridization and remains a separate species only on historical and clinical grounds.

ETIOLOGIC AGENT

Shigella is a non-spore-forming, gram-negative bacterium that, unlike *E. coli*, is nonmotile and does not produce gas from sugars, decarboxylate lysine, or hydrolyze arginine. Some serovars produce indole, and occasional strains utilize sodium acetate. *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei* (serogroups A, B, C, and D, respectively) can be differentiated on the basis of biochemical and serologic characteristics.

Genome sequencing of *E. coli* K12, *S. flexneri* 2a, *S. sonnei*, *S. dysenteriae* type 1, and *S. boydii* has revealed that these species have ~93% of genes in common. The three major genomic "signatures" of *Shigella* are (1) a 215-kb virulence plasmid that carries most of the genes required for pathogenicity (particularly invasive capacity); (2) the lack or alteration of genetic sequences encoding products (e.g., lysine decarboxylase) that, if expressed, would attenuate pathogenicity; and (3) in *S. dysenteriae* type 1, the presence of genes encoding Shiga toxin, a potent cytotoxin.

EPIDEMIOLOGY

The human intestinal tract represents the major reservoir of *Shigella*, which is also found (albeit rarely) in the higher primates. Because excretion of shigellae is greatest in the acute phase of disease, the bacteria are transmitted most efficiently by the fecal–oral route via hand carriage; however, some outbreaks reflect foodborne or waterborne transmission. In impoverished areas, *Shigella* can be transmitted by flies. The high-level infectivity of *Shigella* is reflected by the very small inoculum required for experimental infection of volunteers (100 colony-forming units [CFU]), by the very high attack rates during outbreaks in day-care centers (33–73%), and by the high rates of secondary cases among family members of sick children (26–33%). Shigellosis can also be transmitted sexually.

Throughout history, *Shigella* epidemics have often occurred in settings of human crowding under conditions of poor hygiene—e.g., among soldiers in campaigning armies, inhabitants of besieged cities, groups on pilgrimages, and refugees in camps. Epidemics follow a cyclical pattern in areas such as the Indian subcontinent and sub-Saharan Africa. These devastating epidemics, which are most often caused by *S. dysenteriae* type 1, are characterized by high attack and mortality rates. In Bangladesh, for instance, an epidemic caused by *S. dysenteriae* type 1 was associated with a 42% increase in mortality rate among children 1–4 years of age. Apart from these epidemics, shigellosis is mostly an endemic disease, with 99% of cases occurring in the developing world and the highest prevalences in the most impoverished areas, where personal and general hygiene is below standard. *S. flexneri* isolates predominate in the least developed areas, whereas *S. sonnei* is more prevalent in economically emerging countries and in the industrialized world.

Prevalence in the Developing World In a review published under the auspices of the World Health Organization (WHO), the total annual number of cases in 1966–1997 was estimated at 165 million, and 69% of these cases occurred in children <5 years of age. In this review, the annual number of deaths was calculated to range between 500,000 and 1.1 million. Data (2000–2004) from six Asian countries

indicate that, even though the incidence of shigellosis remains stable, mortality rates associated with this disease may have decreased significantly, possibly as a result of improved nutritional status. However, extensive and essentially uncontrolled use of antibiotics, which may also account for declining mortality rates, has increased the rate of emergence of multidrug-resistant *Shigella* strains. A 2013 prospective matched case-control study of children <5 years of age emphasizes the importance of *Shigella* in the burden and etiology of diarrheal diseases in developing countries. *Shigella* is one of the top four pathogens associated with moderate to severe diarrhea and is now ranked first among children 12–59 months of age. These moderate to severe cases account for an 8.5-fold increase in mortality incidence over the average diarrheal disease-related mortality. The study's authors conclude that *Shigella* remains a major pathogen to be targeted by health care programs.

An often-overlooked complication of shigellosis is the short- and long-term impairment of the nutritional status of infected children in endemic areas. Combined with anorexia, the exudative enteropathy resulting from mucosal abrasions contributes to rapid deterioration of the patient's nutritional status. Shigellosis is thus a major contributor to stunted growth among children in developing countries.

Peaking in incidence in the pediatric population, endemic shigellosis is rare among young and middle-aged adults, probably because of naturally acquired immunity. Incidence then increases again in the elderly population.

Prevalence in the Industrialized World In pediatric populations, local outbreaks occur when proper and adapted hygiene policies are not implemented in group facilities such as day-care centers and institutions for the mentally retarded. In adults, as in children, sporadic cases occur among travelers returning from endemic areas, and rare outbreaks of varying size can follow waterborne or foodborne infections.

PATHOGENESIS AND PATHOLOGY

Shigella infection occurs essentially through oral contamination via direct fecal–oral transmission, the organism being poorly adapted to survive in the environment. Resistance to low-pH conditions allows *Shigella* to survive passage through the gastric barrier, an ability that may explain in part why a small inoculum (as few as 100 CFU) is sufficient to cause infection.

The watery diarrhea that usually precedes the dysenteric syndrome is attributable to active secretion and abnormal water reabsorption—a secretory effect at the jejunal level described in experimentally infected rhesus monkeys. This initial purge is probably due to the combined action of an enterotoxin (ShET-1) and mucosal inflammation. The dysenteric syndrome, manifested by bloody and mucopurulent stools, reflects invasion of the mucosa.

The pathogenesis of *Shigella* is essentially determined by a large virulence plasmid of 214 kb comprising ~100 genes, of which 25 encode a type III secretion system that inserts into the membrane of the host cell to allow effectors to transit from the bacterial cytoplasm to the host cell cytoplasm **(Fig. 166-1)**. Bacteria are thereby able to invade intestinal epithelial cells by inducing their own uptake either directly at the opening of colonic crypts, or following the initial crossing of the epithelial barrier through M cells (the specialized translocating epithelial cells in the follicle-associated epithelium that covers mucosal lymphoid nodules). *Shigella* induces apoptosis of subepithelial resident macrophages. Once inside the cytoplasm of intestinal epithelial cells, *Shigella* effectors trigger the cytoskeletal rearrangements necessary to direct uptake of the organism into the epithelial cell. The *Shigella*-containing vacuole is then quickly lysed, releasing bacteria into the cytosol.

Intracellular shigellae next use cytoskeletal components to propel themselves inside the infected cell; when the moving organism and the host cell membrane come into contact, cellular protrusions form and are engulfed by neighboring cells. This series of events permits bacterial cell-to-cell spread.

Cytokines released by a growing number of infected intestinal epithelial cells attract increased numbers of immune cells (particularly polymorphonuclear leukocytes [PMNs]) to the infected site, thus further destabilizing the epithelial barrier, exacerbating inflammation, and leading to the acute colitis that characterizes shigellosis. Evidence indicates that some type III secretion system–injected effectors can control the extent of inflammation, thus facilitating bacterial survival.

Shiga toxin produced by *S. dysenteriae* type 1 increases disease severity. This toxin belongs to a group of A1-B5 protein toxins whose B subunit binds to the receptor globotriaosylceramide on the target cell surface and whose catalytic A subunit is internalized by receptor-mediated endocytosis and interacts with the subcellular machinery to inhibit protein synthesis by expressing RNA *N*-glycosidase activity on 28S ribosomal RNA. This process leads to inhibition of binding of the amino-acyl-tRNA to the 60S ribosomal subunit and thus to a general shutoff of cell protein biosynthesis. Shiga toxins are translocated from the bowel into the circulation. After binding of the toxins to target cells in the kidney, pathophysiologic alterations may result in hemolytic-uremic syndrome (HUS; see below).

CLINICAL MANIFESTATIONS

The presentation and severity of shigellosis depend to some extent on the infecting serotype but even more on the age and the immunologic and nutritional status of the host. Poverty and poor standards of hygiene are strongly related to the number and severity of diarrheal episodes, especially in children <5 years old who have been weaned.

Shigellosis typically evolves through four phases: incubation, watery diarrhea, dysentery, and the postinfectious phase. The incubation period usually lasts 1–4 days but may be as long as 8 days. Typical initial manifestations are transient fever, limited watery diarrhea, malaise, and anorexia. Signs and symptoms may range from mild abdominal discomfort to severe cramps, diarrhea, fever, vomiting, and tenesmus. The manifestations are usually exacerbated in children, with temperatures up to 40°–41°C (104.0°–105.8°F) and more severe anorexia and watery diarrhea. This initial phase may represent the only clinical manifestation of shigellosis, especially in developed countries. Otherwise, dysentery follows within hours or days and is characterized by uninterrupted excretion of small volumes of bloody mucopurulent stools with increased tenesmus and abdominal cramps. At this stage, *Shigella* produces acute colitis involving mainly the distal colon and the rectum. Unlike most diarrheal syndromes, dysenteric syndromes rarely present with dehydration as a major feature. Endoscopy shows an edematous and

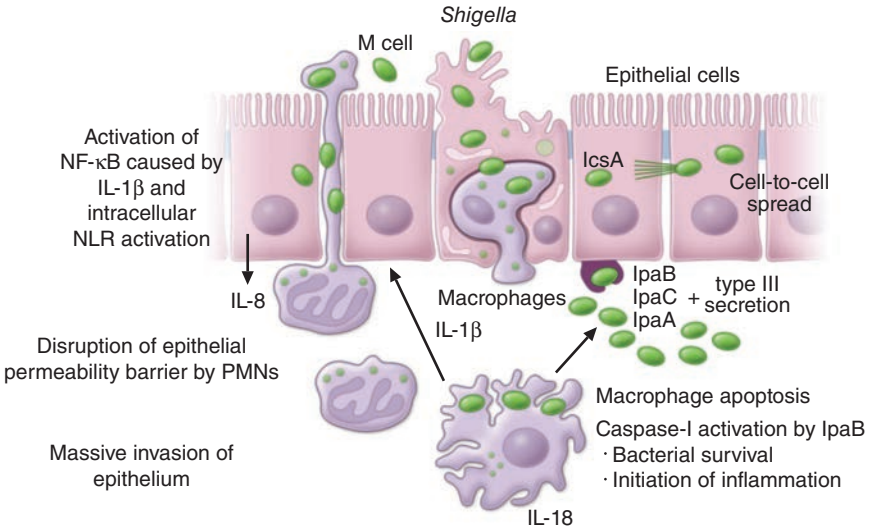

FIGURE 166-1 Invasive strategy of *Shigella flexneri*. IL, interleukin; NF-κB, nuclear factor κB; NLR, NOD-like receptor; PMN, polymorphonuclear leukocyte.

hemorrhagic mucosa, with ulcerations and possibly overlying exudates resembling pseudomembranes. The extent of the lesions correlates with the number and frequency of stools and with the degree of protein loss by exudative mechanisms. Most episodes are self-limited and resolve without treatment in 1 week. With appropriate treatment, recovery takes place within a few days to a week, with no sequelae.

Acute life-threatening complications are seen most often in children <5 years of age (particularly those who are malnourished) and in elderly patients. Risk factors for death in a clinically severe case include nonbloody diarrhea, moderate to severe dehydration, bacteremia, absence of fever, abdominal tenderness, and rectal prolapse. Major complications are predominantly intestinal (e.g., toxic megacolon, intestinal perforations, rectal prolapse) or metabolic (e.g., hypoglycemia, hyponatremia, dehydration). Bacteremia is rare and is reported most frequently in severely malnourished and HIV-infected patients. Alterations of consciousness, including seizures, delirium, and coma, may occur, especially in children <5 years old, and are associated with a poor prognosis; fever and severe metabolic alterations are more often the major causes of altered consciousness than is meningitis or the Ekiri syndrome (toxic encephalopathy associated with bizarre posturing, cerebral edema, and fatty degeneration of viscera), which has been reported mostly in Japanese children. Pneumonia, vaginitis, and keratoconjunctivitis due to *Shigella* are rarely reported. In the absence of serious malnutrition, severe and very unusual clinical manifestations, such as meningitis, may be linked to genetic defects in innate immune functions (i.e., deficiency in interleukin 1 receptor–associated kinase 4 [IRAK-4]) and may require genetic investigation.

Two complications of particular importance are toxic megacolon and HUS. Toxic megacolon is a consequence of severe inflammation extending to the colonic smooth-muscle layer and causing paralysis and dilation. The patient presents with abdominal distention and tenderness, with or without signs of localized or generalized peritonitis. The abdominal x-ray characteristically shows marked dilation of the transverse colon (with the greatest distention in the ascending and descending segments); thumbprinting caused by mucosal inflammatory edema; and loss of the normal haustral pattern associated with pseudopolyps, often extending into the lumen. Pneumatosis coli is an occasional finding. If perforation occurs, radiographic signs of pneumoperitoneum may be apparent. Predisposing factors (e.g., hypokalemia and use of opioids, anticholinergics, loperamide, psyllium seeds, and antidepressants) should be investigated.

Shiga toxin produced by *S. dysenteriae* type 1 has been linked to HUS in developing countries but rarely in industrialized countries, where enterohemorrhagic *E. coli* (EHEC) predominates as the etiologic agent of this syndrome. HUS is an early complication that most often develops after several days of diarrhea. Clinical examination shows pallor, asthenia, and irritability and, in some cases, bleeding of the nose and gums, oliguria, and increasing edema. HUS is a nonimmune (Coombs-negative) hemolytic anemia defined by a diagnostic triad: microangiopathic hemolytic anemia (hemoglobin level typically <80 g/L [<8 g/dL]), thrombocytopenia (mild to moderate in severity; typically <60,000 platelets/μL), and acute renal failure due to thrombosis of the glomerular capillaries (with markedly elevated creatinine levels). Anemia is severe, with fragmented red blood cells (*schizocytes*) in the peripheral smear, high serum concentrations of lactate dehydrogenase and free circulating hemoglobin, and elevated reticulocyte counts. Acute renal failure occurs in 55–70% of cases; however, renal function recovers in most of these cases (up to 70% in various series). Leukemoid reactions, with leukocyte counts of 50,000/μL, are sometimes noted in association with HUS.

The postinfectious immunologic complication known as *reactive arthritis* can develop weeks or months after shigellosis, especially in patients expressing the histocompatibility antigen HLA-B27. About 3% of patients infected with *S. flexneri* later develop this syndrome, with arthritis, ocular inflammation, and urethritis—a condition that can last for months or years and can progress to difficult-to-treat chronic arthritis. Postinfectious arthritis occurs only after infection with *S. flexneri* and not after infection with the other *Shigella* serotypes.

LABORATORY DIAGNOSIS

The differential diagnosis in patients with a dysenteric syndrome depends on the clinical and environmental context. In developing areas, infectious diarrhea caused by other invasive pathogenic bacteria (*Salmonella*, *Campylobacter jejuni*, *Clostridium difficile*, *Yersinia enterocolitica*) or parasites (*Entamoeba histolytica*) should be considered. Only bacteriologic and parasitologic examinations of stool can truly differentiate among these pathogens. A first flare of inflammatory bowel disease, such as Crohn's disease or ulcerative colitis **(Chap. 326)**, should be considered in patients in industrialized countries. Despite the similarity in symptoms, anamnesis discriminates between shigellosis, which usually follows recent travel in an endemic zone, and these other conditions.

Microscopic examination of stool smears shows erythrophagocytic trophozoites with very few PMNs in *E. histolytica* infection, whereas bacterial enteroinvasive infections (particularly shigellosis) are characterized by high PMN counts in each microscopic field. However, because shigellosis often manifests only as watery diarrhea, systematic attempts to isolate *Shigella* are necessary.

The "gold standard" for the diagnosis of *Shigella* infection remains the isolation and identification of the pathogen from fecal material. One major difficulty, particularly in endemic areas where laboratory facilities are not immediately available, is the fragility of *Shigella* and its common disappearance during transport, especially with rapid changes in temperature and pH. In the absence of a reliable enrichment medium, buffered glycerol saline or Cary-Blair medium can be used as a holding medium, but prompt inoculation onto isolation medium is essential. The probability of isolation is higher if the portion of stools that contains bloody and/or mucopurulent material is directly sampled. Rectal swabs can be used, as they offer the highest rate of successful isolation during the acute phase of disease. Blood cultures are positive in fewer than 5% of cases but should be done when a patient presents with a clinical picture of severe sepsis.

In addition to quick processing, the use of several media increases the likelihood of successful isolation: a nonselective medium such as bromocresol-purple agar lactose; a low-selectivity medium such as MacConkey or eosin-methylene blue; and a high-selectivity medium such as Hektoen, *Salmonella-Shigella*, or xylose-lysine-deoxycholate agar. After incubation on these media for 12–18 h at 37°C (98.6°F), shigellae appear as non-lactose-fermenting colonies that measure 0.5–1 mm in diameter and have a convex, translucent, smooth surface. Suspected colonies on nonselective or low-selectivity medium can be subcultured on a high-selectivity medium before being specifically identified or can be identified directly by standard commercial systems on the basis of four major characteristics: glucose positivity (usually without production of gas), lactose negativity, H_2S negativity, and lack of motility. The four *Shigella* serogroups (A–D) can then be differentiated by additional characteristics. This approach adds time and difficulty to the identification process; however, after presumptive diagnosis, the use of serologic methods (e.g., slide agglutination, with group- and then type-specific antisera) should be considered. Group-specific antisera are widely available; in contrast, because of the large number of serotypes and subserotypes, type-specific antisera are rare and more expensive and thus are often restricted to reference laboratories.

TREATMENT

Shigellosis

ANTIBIOTIC SUSCEPTIBILITY OF *SHIGELLA*

As an enteroinvasive disease, shigellosis requires antibiotic treatment. Since the mid-1960s, however, increasing resistance to multiple drugs has been a dominant factor in treatment decisions. Resistance rates are highly dependent on the geographic area. Clonal spread of particular strains and horizontal transfer of resistance determinants, particularly via plasmids and transposons, contribute to multidrug resistance. The current global status—i.e., high rates of resistance to classic first-line antibiotics such as amoxicillin—has led to a rapid switch to quinolones such as

nalidixic acid. However, resistance to such early-generation quinolones has also emerged and spread quickly as a result of chromosomal mutations affecting DNA gyrase and topoisomerase IV; this resistance has necessitated the use of later-generation quinolones as first-line antibiotics in many areas. For instance, a review of the antibiotic resistance history of *Shigella* in India found that, after their introduction in the late 1980s, the second-generation quinolones norfloxacin, ciprofloxacin, and ofloxacin were highly effective in the treatment of shigellosis, including cases caused by multidrug-resistant strains of *S. dysenteriae* type 1. However, investigations of subsequent outbreaks in India and Bangladesh detected resistance to norfloxacin, ciprofloxacin, and ofloxacin in 5% of isolates. In the United States, the resistance rate of *Shigella* to fluoroquinolones reached 87% during 2014–2015. The incidence of multidrug resistance parallels the widespread, uncontrolled use of antibiotics and calls for the rational use of effective drugs. Despite the alarming proportion of resistant *Shigella*, there is a lack of studies assessing the resistance of community-acquired strains.

ANTIBIOTIC TREATMENT OF SHIGELLOSIS (TABLE 166-1)

With effective antibiotic therapy clinical improvement occurs within 48 h, resulting in a decreased risk of complications and death, shorter duration of symptoms, and elimination of *Shigella* from the stool. Because of the ready transmissibility of *Shigella*, current public health recommendations in the United States are that every case be treated with antibiotics. The use of fluoroquinolones (first-line, preferably ciprofloxacin), and cephalosporins and β-lactams (second-line) for 7–10 days is recommended for the treatment of shigellosis. Whereas infections caused by non-*dysenteriae Shigella* in immunocompetent individuals are routinely treated with a 3-day course of antibiotics, it is recommended that *S. dysenteriae* type 1 infections be treated for 5 days and that *Shigella* infections in immunocompromised patients be treated for 7–10 days.

Treatment for shigellosis must be adapted to the clinical context, with the recognition that the most fragile patients are children <5 years old, who represent two-thirds of all cases worldwide. There are few data on the use of quinolones in children, but *Shigella*-induced dysentery is a well-recognized indication for their use. The half-life of ciprofloxacin is longer in infants than in older individuals. The ciprofloxacin dose generally recommended for children is 30 mg/kg per day in two divided doses. Adults living in areas with high standards of hygiene are likely to develop milder, shorter-duration disease, whereas infants in endemic areas can develop severe, sometimes fatal, dysentery. In the former setting, treatment will remain minimal and bacteriologic proof of infection will often come after symptoms have resolved; in the latter setting, antibiotic treatment and more aggressive measures, possibly including resuscitation, are often required.

Vaccine studies for *S. flexneri* have been impaired by the lack of optimal animal models. New findings document the immunogenicity and preclinical efficacy effects of *S. flexneri* vaccine in mice and suggest that further work can help elucidate relevant immune responses and, ultimately, its clinical efficacy in humans.

TABLE 166-1 Recommended Antimicrobial Therapy for Shigellosis

ANTIMICROBIAL AGENT	TREATMENT SCHEDULE		LIMITATIONS
	CHILDREN	ADULTS	
First-Line			
Ciprofloxacin	15 mg/kg	500 mg	
	2 times per day for 3 days, PO		
Second-Line			
Pivmecillinam	20 mg/kg	100 mg	Cost
	4 times per day for 5 days PO		No pediatric formulation Frequent administration Emerging resistance
Ceftriaxone	50–100 mg/kg	–	Efficacy not validated Must be injected
	Once a day IM for 2–5 days		
Azithromycin	6–20 mg/kg	1–1.5 g	Cost
	Once a day for 1–5 days PO		Efficacy not validated Minimum inhibitory concentration near serum concentration Rapid emergence of resistance and spread to other bacteria

REHYDRATION AND NUTRITION

Shigella infection rarely causes significant dehydration. Cases requiring aggressive rehydration (particularly in industrialized countries) are uncommon. In developing countries, malnutrition remains the primary indicator for diarrhea-related death, highlighting the importance of nutrition in early management. Rehydration should be oral unless the patient is comatose or presents in shock. Because of the improved effectiveness of reduced-osmolarity oral rehydration solution (especially for children with acute noncholera diarrhea), the WHO and UNICEF now recommend a standard solution of 245 mOsm/L (sodium, 75 mmol/L; chloride, 65 mmol/L; glucose [anhydrous], 75 mmol/L; potassium, 20 mmol/L; citrate, 10 mmol/L). In shigellosis, the coupled transport of sodium and glucose may be variably affected, but oral rehydration therapy remains the easiest and most efficient form of rehydration, especially in severe cases.

Nutrition should be started as soon as possible after completion of initial rehydration. Early refeeding is safe, well tolerated, and clinically beneficial. Because breast-feeding reduces diarrheal losses and the need for oral rehydration in infants, it should be maintained in the absence of contraindications (e.g., maternal HIV infection).

NONSPECIFIC, SYMPTOM-BASED THERAPY

Antimotility agents have been implicated in prolonged fever in volunteers with shigellosis. These agents are suspected of increasing the risk of toxic megacolon and are thought to have been responsible for HUS in children infected by EHEC strains. For safety reasons, it is better to avoid antimotility agents in bloody diarrhea.

TREATMENT OF COMPLICATIONS

There is no consensus regarding the best treatment for toxic megacolon. The patient should be assessed frequently by both medical and surgical teams. Anemia, dehydration, and electrolyte deficits (particularly hypokalemia) may aggravate colonic atony and should be actively treated. Nasogastric aspiration helps to deflate the colon. Parenteral nutrition has not been proven to be beneficial. Fever persisting beyond 48–72 h raises the possibility of local perforation or abscess. Most studies recommend colectomy if, after 48–72 h, colonic distention persists. However, some physicians recommend continuation of medical therapy for up to 7 days if the patient seems to be improving clinically despite persistent megacolon without free perforation. Intestinal perforation, either isolated or complicating toxic megacolon, requires surgical treatment and intensive medical support.

Rectal prolapse must be treated as soon as possible. With the health care provider using surgical gloves or a soft warm wet cloth and the patient in the knee-chest position, the prolapsed rectum is gently pushed back into place. If edema of the rectal mucosa is evident (rendering reintegration difficult), it can be osmotically reduced by the application of gauze impregnated with a warm solution of saturated magnesium sulfate. Rectal prolapse often relapses but usually resolves along with the resolution of dysentery.

HUS must be treated by water restriction, including discontinuation of oral rehydration solution and potassium-rich alimentation. Hemofiltration is usually required.

PREVENTION

Hand washing after defecation or handling of children's feces and before handling of food is recommended. Stool decontamination (e.g., with sodium hypochlorite), together with a cleaning protocol for medical staff as well as for patients, has proven useful in limiting the spread of infection during *Shigella* outbreaks. Ideally, patients should have a negative stool culture before their infection is considered cured. Recurrences are rare if therapeutic and preventive measures are correctly implemented.

Although several live attenuated oral and subunit parenteral vaccine candidates have been produced and are undergoing clinical trials, no vaccine against shigellosis is currently available. Especially given the rapid progression of antibiotic resistance in *Shigella*, a vaccine is urgently needed.

167 Infections Due to *Campylobacter* and Related Organisms

Martin J. Blaser

DEFINITION

Bacteria of the genus *Campylobacter* and of the related genera *Arcobacter* and *Helicobacter* **(Chap. 163)** cause a variety of inflammatory conditions. Although acute diarrheal illnesses are most common, these organisms may cause infections in virtually all parts of the body, especially in compromised hosts, and these infections may have late nonsuppurative sequelae. The designation *Campylobacter* comes from the Greek for "curved rod" and refers to the organism's vibrio-like morphology.

ETIOLOGY

Campylobacters are motile, non-spore-forming, curved, gram-negative rods. Originally known as *Vibrio fetus*, these bacilli were reclassified as a new genus in 1973 after their dissimilarity to other vibrios was recognized. More than 20 species have since been identified. These species are currently divided into three genera: *Campylobacter*, *Arcobacter*, and *Helicobacter*. Not all of the species are pathogens of humans. The human pathogens fall into two major groups: those that primarily cause diarrheal disease and those that cause extraintestinal infection. The principal diarrheal pathogen is *Campylobacter jejuni*, which accounts for 80–90% of all cases of recognized illness due to campylobacters and related genera. Other organisms that can cause diarrheal disease include *Campylobacter coli, Campylobacter upsaliensis, Campylobacter lari, Campylobacter hyointestinalis, Campylobacter fetus, Arcobacter butzleri, Arcobacter cryaerophilus, Helicobacter cinaedi*, and *Helicobacter fennelliae*. The two *Helicobacter* species causing diarrheal disease, *H. cinaedi* and *H. fennelliae*, are intestinal rather than gastric organisms; in terms of the clinical features of the illnesses they cause, these species most closely resemble *Campylobacter* rather than *Helicobacter pylori* **(Chap. 163)** and thus are considered in this chapter. The pathogenic roles of *Campylobacter concisus, Campylobacter ureolyticus*, and *Campylobacter troglodytis* are uncertain. A new subspecies—*C. fetus* subspecies *testudinum*—has been described, chiefly in Asian patients; the very close resemblance of human isolates to strains isolated from reptiles suggests a food source.

The major species causing extraintestinal illnesses is *C. fetus*. However, any of the diarrheal agents listed above may cause systemic or localized infection as well, especially in compromised hosts. Neither aerobes nor strict anaerobes, these microaerophilic organisms are adapted for survival in the gastrointestinal mucous layer. This chapter focuses on *C. jejuni* and *C. fetus* as the major pathogens and prototypes for their groups. The key features of infection are listed by species (excluding *C. jejuni*, described in detail in the text below) in **Table 167-1**.

EPIDEMIOLOGY

Campylobacters are found in the gastrointestinal tract of many animals used for food (including poultry, cattle, sheep, and swine) and many household pets (including birds, dogs, and cats). These microorganisms often do not cause illness in their animal hosts, but occasionally this can occur (especially in puppies). In most cases, campylobacters are transmitted to humans in raw or undercooked food products or through direct contact with infected animals. In the United States and other developed countries, ingestion of contaminated poultry that has not been sufficiently cooked is the most common mode of acquisition (30–70% of cases). Other modes include ingestion of raw (unpasteurized) milk or untreated water, contact with infected household pets, ingestion of contaminated seafood, travel to developing countries (campylobacters being a leading cause of traveler's diarrhea; **Chaps. 124 and 133**), oral–anal sexual contact, cross-contamination from any of these sources, and (occasionally) contact with an index case who is incontinent of stool.

Campylobacter infections are common. Active surveillance of foodborne infections in the United States estimates the incidence of diarrheal disease due to campylobacters at ~20 cases per 100,000 persons—similar in incidence to *Salmonella* and more common than *Shigella*. Infections occur throughout the year, but the incidence peaks during summer and early autumn. Persons of all ages are affected; however, attack rates for *C. jejuni* are highest among young children and young adults, whereas those for *C. fetus* are highest at the extremes of age. Systemic infections due to *C. fetus* (and to other *Campylobacter* and related species) are most common among compromised hosts. Persons at increased risk include those with AIDS, immunoglobulin deficiencies, neoplasia, liver disease, diabetes mellitus, and generalized atherosclerosis as well as neonates and pregnant women; proton pump inhibitor use also increases risk. However, apparently healthy nonpregnant persons occasionally develop transient *Campylobacter* bacteremia as part of a gastrointestinal illness (0.1–1% of cases).

In contrast, in many developing countries where sanitation is poor, *C. jejuni* infections are hyperendemic, with the highest rates among children <2 years old. According to large prospective cohort studies in low- to middle-income countries, *Campylobacter* infections—even when asymptomatic—are associated with short stature (stunting). Rates of clinically apparent infection fall with age, as does the illness-to-infection ratio, consistent with development of immunity.

TABLE 167-1 Clinical Features Associated with Infection Due to "Atypical" *Campylobacter* and Related Species Implicated as Causes of Human Illness

SPECIES	COMMON CLINICAL FEATURES	LESS COMMON CLINICAL FEATURES	ADDITIONAL INFORMATION
Campylobacter coli	Fever, diarrhea, abdominal pain	Bacteremia[a]	Clinically indistinguishable from *C. jejuni*
Campylobacter fetus	Bacteremia,[a] sepsis, meningitis, vascular infections	Diarrhea, relapsing fevers	Not usually isolated from media containing cephalothin or incubated at 42°C
Campylobacter upsaliensis	Watery diarrhea, low-grade fever, abdominal pain	Bacteremia, abscesses	Difficult to isolate because of cephalothin susceptibility
Campylobacter lari	Abdominal pain, diarrhea	Colitis, appendicitis	Seagulls frequently colonized; organism often transmitted to humans via contaminated water
Campylobacter hyointestinalis	Watery or bloody diarrhea, vomiting, abdominal pain	Bacteremia	Causes proliferative enteritis in swine
Helicobacter fennelliae	Chronic mild diarrhea, abdominal cramps, proctitis	Bacteremia[a]	Best treated with fluoroquinolones
Helicobacter cinaedi	Chronic mild diarrhea, abdominal cramps, proctitis	Bacteremia[a]	Best treated with fluoroquinolones; identified in healthy hamsters
Campylobacter jejuni subspecies *doylei*	Diarrhea	Chronic gastritis, bacteremia[b]	Uncertain role as human pathogen
Arcobacter cryaerophilus	Diarrhea	Bacteremia	Poultry, seafood sources. Cultured under aerobic conditions
Arcobacter butzleri	Fever, diarrhea, abdominal pain, nausea; or asymptomatic	Bacteremia, appendicitis	Cultured under aerobic conditions; enzootic in nonhuman primates
Campylobacter sputorum	Pulmonary, perianal, groin, and axillary abscesses; diarrhea	Bacteremia	Three clinically relevant biovars: *sputorum, faecalis,* and *paraureolyticus*

[a]In immunocompromised hosts, especially HIV-infected persons. [b]In children.

Source: Adapted from BM Allos, MJ Blaser: Clin Infect Dis 20:1092, 1995.

PATHOLOGY AND PATHOGENESIS

C. jejuni infections may be subclinical, especially in hosts in developing countries who have had multiple prior infections and may be partially immune. Symptomatic infections mostly occur within 2–4 days (range, 1–7 days) of exposure to the organism. The sites of tissue injury include the jejunum, ileum, and colon. Biopsies show an acute nonspecific inflammatory reaction, with neutrophils, monocytes, and eosinophils in the lamina propria, as well as damage to the epithelium, including loss of mucus, glandular degeneration, and crypt abscesses. Biopsy findings may be consistent with Crohn's disease or ulcerative colitis, but these "idiopathic" chronic inflammatory diseases should not be diagnosed unless infectious colitis, *specifically including* that due to infection with *Campylobacter* species and related organisms, has been ruled out.

The components of protective immunity to *Campylobacter* in humans are poorly understood. The high frequency of *C. jejuni* infections and their severity and recurrence among immunoglobulin-deficient patients suggest that antibodies are important in protective immunity. Experience from field studies and human experimental infection models suggests that immune protection may be short-lived or incomplete in the absence of continuous exposure. Knowledge of the pathogenesis of infection is also incomplete. Both the motility of the strain and its capacity to adhere to host tissues appear to favor disease, but classic enterotoxins and cytotoxins (including cytolethal distending toxin) appear not to play substantial roles in tissue injury or disease production. The organisms have been visualized within the epithelium, albeit in low numbers. The documentation of a significant tissue response and occasionally of *C. jejuni* bacteremia further suggests that tissue invasion is clinically significant, and in vitro studies are consistent with this pathogenic feature.

The pathogenesis of *C. fetus* infections is better defined. Virtually all clinical isolates of *C. fetus* possess a proteinaceous capsule-like structure (an S-layer) that renders the organisms resistant to complement-mediated killing and opsonization. As a result, *C. fetus* can cause bacteremia and can seed sites beyond the intestinal tract. The ability of the organism to switch the S-layer proteins expressed—a phenomenon that results in antigenic variability—may contribute to the chronicity and high rate of recurrence of *C. fetus* infections in compromised hosts.

CLINICAL MANIFESTATIONS

The clinical features of infections due to *Campylobacter* and the related *Arcobacter* and intestinal *Helicobacter* species causing enteric disease appear to be highly similar. *C. jejuni* can be considered the prototype, in part because it is by far the most common enteric pathogen in the group. A prodrome of fever, headache, myalgia, and/or malaise often occurs 12–48 h before the onset of diarrheal symptoms. The most common signs and symptoms of the intestinal phase are diarrhea, abdominal pain, and fever. The degree of diarrhea varies from several loose watery stools to visibly bloody stools (~10% of cases in adults); most patients presenting for medical attention have ≥10 bowel movements on the worst day of illness. Abdominal pain usually consists of cramping and may be the most prominent symptom. Pain is usually generalized but may become localized; *C. jejuni* infection may cause pseudoappendicitis. Fever may be the only initial manifestation of *C. jejuni* infection, a situation mimicking the early stages of typhoid fever. Febrile young children may develop convulsions. *Campylobacter* enteritis is generally self-limited; however, symptoms persist for >1 week in 10–20% of patients seeking medical attention, and clinical relapses occur in 5–10% of untreated patients. Studies of common-source epidemics indicate that milder illnesses or asymptomatic infections may commonly occur.

C. fetus may cause a diarrheal illness similar to that due to *C. jejuni*, especially in immunocompetent hosts. This organism also may cause either intermittent diarrhea or nonspecific abdominal pain without localizing signs. Sequelae are uncommon, and the outcome is benign. *C. fetus* may also cause a prolonged relapsing systemic illness (with fever, chills, and myalgias) that has no obvious primary source; this manifestation is especially common among compromised hosts. Secondary seeding of an organ (e.g., meninges, brain, bone, urinary tract, or soft tissue) complicates the course, which may be fulminant. *C. fetus* infections have a tropism for vascular sites: endocarditis, mycotic aneurysm, and septic thrombophlebitis may all occur. Infection during pregnancy often leads to fetal death. A variety of *Campylobacter* species and *H. cinaedi* can cause recurrent cellulitis with fever and bacteremia in immunocompromised hosts.

COMPLICATIONS

Except in infection with *C. fetus*, bacteremia is uncommon, developing most often in immunocompromised hosts and at the extremes of age. Three patterns of extraintestinal infection have been noted: (1) transient bacteremia in a normal host with enteritis (benign course, no specific treatment needed); (2) sustained bacteremia or focal infection in a normal host (bacteremia originating from enteritis, with patients

responding well to antimicrobial therapy); and (3) sustained bacteremia or focal infection in a compromised host. Enteritis may not be clinically apparent. Antimicrobial therapy, possibly prolonged, is necessary for suppression or cure of these infections.

Campylobacter, Arcobacter, and intestinal *Helicobacter* infections in patients with AIDS or immunoglobulin-deficient patients (most often common variable immunodeficiency) may be severe, persistent, and extraintestinal; relapse after cessation of therapy is common. Immunoglobulin-deficient patients also may develop osteomyelitis and an erysipelas-like rash or cellulitis.

Local suppurative complications of infection include cholecystitis, pancreatitis, and cystitis; distant complications include meningitis, endocarditis, arthritis, peritonitis, cellulitis, and septic abortion. All these complications are rare, except in immunocompromised hosts. Hepatitis, interstitial nephritis, and the hemolytic-uremic syndrome occasionally complicate acute infection. The two most common postinfectious sequelae are reactive arthritis and Guillain-Barré syndrome. Reactive arthritis has been reported in up to 2.5% of cases, although nonspecific rheumatologic symptoms are more common (~10%). Reactive arthritis may develop several weeks after infection, especially in persons with the HLA-B27 phenotype. The knees are most frequently involved, but involvement of the ankles, wrists, and small joints of the hands is common, with an average of 3.2 joints affected. Guillain-Barré syndrome or its Miller Fisher (cranial polyneuropathy) variant follow either symptomatic or asymptomatic *Campylobacter* infections uncommonly—i.e., in 1 of every 1000–2000 cases or, for certain *C. jejuni* serotypes (such as O19), in 1 of every 100–200 cases. Despite the low frequency of this complication, it is estimated that *Campylobacter* infections, because of their high incidence, may trigger 20–40% of all cases of Guillain-Barré syndrome. The presence of sialylated lipopolysaccharides on *C. jejuni* strains prompts a form of molecular mimicry that promotes autoimmune recognition of sialylated cell-surface molecules on axons. Immunoproliferative small-intestinal disease (*alpha chain disease*), a form of lymphoma that originates in small-intestinal mucosa-associated lymphoid tissue (MALToma), has been associated with *C. jejuni*; antimicrobial therapy has led to marked clinical improvement.

DIAGNOSIS

In patients with *Campylobacter* enteritis, peripheral leukocyte counts reflect the severity of the inflammatory process. In addition, stools from nearly all *Campylobacter*-infected patients presenting for medical attention in the United States contain leukocytes or erythrocytes. Gram- or Wright-stained fecal smears should be examined in all suspected cases. When the diagnosis of *Campylobacter* enteritis is suspected on the basis of findings indicating inflammatory diarrhea (fever, fecal leukocytes), clinicians can ask the microbiology laboratory to attempt the visualization of organisms with characteristic vibrioid morphology by direct microscopic examination of stools with Gram's staining or to use phase-contrast or dark-field microscopy to identify the organisms' characteristic "darting" motility. Confirmation of the diagnosis of *Campylobacter* infection is based on identification of an isolate from cultures of stool, blood, or another site; specific species can be identified by MALDI-TOF (matrix-assisted laser desorption/ionization–time of flight) mass spectrometry. *Campylobacter*-specific media should be used to culture stools from all patients with inflammatory or bloody diarrhea. Because all *Campylobacter* species are fastidious, they will not be isolated unless selective media or other selective techniques are used. Failure to isolate campylobacters from stool by culture does not entirely rule out their presence. Although culture remains the diagnostic gold standard, species-specific real-time polymerase chain reaction (PCR) techniques appear more sensitive than culture. Although PCR and other culture-independent diagnostic test (CIDTs), including antigen detection tests, may detect nonviable bacteria and may be falsely positive, they are now used frequently to diagnose infection with *Campylobacter* and other enteric bacteria in clinical microbiology laboratories. The detection of the organisms in stool in the United States by culture almost always implies active or recent infection, but CIDT positivity is more questionable.

In any event, follow-up testing after the clinical resolution of an acute infection is rarely needed. *Campylobacter sputorum* and related organisms found in the oral cavity are commensals that only rarely have pathogenic significance. Because of the low levels of metabolic activity of *Campylobacter* species in standard blood culture media, *Campylobacter* bacteremia is difficult to detect.

DIFFERENTIAL DIAGNOSIS

The symptoms of *Campylobacter* enteritis are not sufficiently unusual to distinguish this illness from that due to *Salmonella, Shigella, Yersinia*, enterohemorrhagic *Escherichia coli*, and other pathogens. The combination of fever and fecal leukocytes or erythrocytes is indicative of inflammatory diarrhea, and definitive diagnosis is based on culture, CIDTs, or demonstration of the characteristic organisms on stained fecal smears. Extraintestinal *Campylobacter* illness is diagnosed by culture. Infection due to *Campylobacter* should be suspected in the setting of septic abortion, and that due to *C. fetus* should be suspected specifically in the setting of septic thrombophlebitis. It is important to reiterate that (1) the presentation of *Campylobacter* enteritis may mimic that of ulcerative colitis or Crohn's disease, (2) *Campylobacter* enteritis is much more common than either of the latter (especially among young adults), and (3) biopsy may not distinguish among these entities. Thus, a diagnosis of inflammatory bowel disease should not be made until *Campylobacter* infection has been ruled out, especially in persons with a history of foreign travel, significant animal contact, immunodeficiency, or exposure incurring a high risk of transmission.

TREATMENT

Campylobacter Infection

Fluid and electrolyte replacement is central to the treatment of diarrheal illnesses **(Chap. 133)**. Even among patients presenting for medical attention with *Campylobacter* enteritis, not all clearly benefit from specific antimicrobial therapy. Indications for therapy include high fever, bloody diarrhea, severe diarrhea, persistence for >1 week, and worsening of symptoms. A 3-day course of azithromycin (500 mg once daily) is the regimen of choice. A 1-day regimen of azithromycin (1000 mg given as two 500-mg tablets) can also be used. Alternative regimens for adults consist of fluoroquinolones—ciprofloxacin (500 mg by mouth twice daily for 3 days) or levofloxacin (750 mg daily for 3 days)—but resistance to this class of agents as well as to tetracyclines is substantial; ~27% of U.S. human isolates of *Campylobacter* in 2014 were resistant to ciprofloxacin, and rates are higher in many other countries; thus, travel-related *Campylobacter* infections should be considered a priori to be fluoroquinolone-resistant. Because macrolide resistance usually is much less common (<10%), these drugs are the empirical agents of choice. Patients infected with antibiotic-resistant strains are at increased risk of adverse outcomes. Use of antimotility agents, which may prolong the duration of symptoms and have been associated with toxic megacolon and with death, is not recommended. Of note, *C. jejuni* and *C. coli* are resistant to trimethoprim and β-lactam antibiotics, including penicillin and most cephalosporins.

For patients with immunocompromising conditions and uncomplicated enteritis caused by *C. jejuni*, therapy duration should be extended to 7–14 days. For systemic infections, treatment with a carbapenem (imipenem, 500 mg IV every 6 h; or meropenem, 1–2 g IV every 8 h) should be started empirically, and susceptibility testing should always be performed. For life-threatening illness, gentamicin (1.0–1.7 mg/kg IV every 8 h after a loading dose of 1.5–2 mg/kg) can be added. In the absence of endovascular involvement, therapy for systemic infections should be administered for 7–14 days. For immunocompromised patients with systemic infections due to *C. fetus* and for patients with endovascular infections due to any species, prolonged therapy (up to 4 weeks) is usually necessary. For recurrent infections in immunocompromised hosts, lifelong therapy/prophylaxis is sometimes necessary.

PROGNOSIS

Nearly all patients recover fully from *Campylobacter* enteritis, either spontaneously or after antimicrobial therapy. Volume depletion probably contributes to the few deaths that are reported. As stated above, occasional patients develop reactive arthritis or Guillain-Barré syndrome or its variants. Systemic infection with *C. fetus* is much more often fatal than that due to related species; this higher mortality rate reflects in part the population affected. Prognosis depends on the rapidity with which appropriate therapy is begun. Otherwise healthy hosts usually survive *C. fetus* infections without sequelae. Compromised hosts often have recurrent and/or life-threatening infections due to a variety of *Campylobacter* species.

168 Cholera and Other Vibrioses

Matthew K. Waldor, Edward T. Ryan

Members of the genus *Vibrio* cause a number of important infectious syndromes. Classic among them is cholera, a devastating diarrheal disease caused by *Vibrio cholerae* that has been responsible for seven global pandemics and much suffering over the past two centuries. Epidemic cholera remains a significant public-health concern in the developing world today. Other vibrioses caused by other *Vibrio* species include syndromes of diarrhea, soft tissue infection, or primary sepsis. All *Vibrio* species are highly motile, facultatively anaerobic, curved gram-negative rods with one or more flagella. In nature, vibrios most commonly reside in tidal rivers and bays under conditions of moderate salinity. They proliferate in the summer months when water temperatures exceed 20°C. As might be expected, the illnesses they cause also increase in frequency during the warm months.

CHOLERA

DEFINITION

Cholera is an acute diarrheal disease that can, in a matter of hours, result in profound, rapidly progressive dehydration and death. Accordingly, *cholera gravis* (the severe form) is a much-feared disease, particularly in its epidemic presentation. Fortunately, prompt aggressive fluid repletion and supportive care can obviate the high mortality that is historically associated with cholera. Although the term *cholera* has occasionally been applied to any severely dehydrating secretory diarrheal illness, whether infectious in etiology or not, it now refers to disease caused by *V. cholerae* serogroup O1 or O139—i.e., the serogroups with epidemic potential.

MICROBIOLOGY AND EPIDEMIOLOGY

The species *V. cholerae* is classified into >200 serogroups based on the carbohydrate constituents of their lipopolysaccharide (LPS) O antigens. Although some non-O1 *V. cholerae* serogroups (strains that do not agglutinate in antisera to the O1 group antigen) have occasionally caused sporadic outbreaks of diarrhea, serogroup O1 was, until the emergence of serogroup O139 in 1992 (see below), the exclusive cause of epidemic cholera. The O1 serogroup is further subdivided into two serotypes, termed *Inaba* and *Ogawa*. Two biotypes of *V. cholerae* O1, classical and El Tor, have been described, but the former is thought to be extinct.

The natural habitat of *V. cholerae* is coastal salt water and brackish estuaries, where the organism lives in close relation to plankton. *V. cholerae* can also exist in freshwater in the presence of adequate nutrients and warmth. Humans become infected incidentally but, once infected, can act as vehicles for spread. Ingestion of water contaminated by human feces is the most common means of acquisition of *V. cholerae*. Consumption of contaminated food also can contribute to spread. There is no known animal reservoir. Although the infectious dose is relatively high, it is markedly reduced in hypochlorhydric persons, in those using antacids, and when gastric acidity is buffered by a meal. Cholera is predominantly a pediatric disease in endemic areas, but it affects adults and children equally when newly introduced into a population. In endemic areas, the burden of disease is often greatest during "cholera seasons" associated with high temperatures, heavy rainfall, and flooding, but cholera can occur year-round.

Cholera is native to the Ganges delta on the Indian subcontinent. Since 1817, seven global pandemics have occurred. The current (seventh) pandemic—the first due to the El Tor biotype—began in Indonesia in 1961 and spread in serial waves throughout Asia as *V. cholerae* El Tor displaced the endemic classical biotype, which is thought to have caused the previous six pandemics. In the early 1970s, El Tor cholera erupted in Africa, causing major epidemics before becoming a persistent endemic problem. Currently, >95% of cholera cases reported annually to the World Health Organization (WHO) are from Africa and Asia **(Fig. 168-1)**, but the true burden and distribution of cholera are unknown because the diagnosis is often syndromic and many countries with endemic cholera do not report cholera to the WHO. It is possible that >1–4 million cases of cholera occur yearly (of which only ~200,000 are reported to the WHO) and that these cases result in >20,000–140,000 deaths annually (of which <2000 are reported to the WHO).

After a century without cholera in Latin America, the current cholera pandemic reached Central and South America in 1991. Following an initial explosive spread that affected millions, the burden of disease has markedly decreased in Latin America. In 2010, a severe cholera outbreak began in Haiti, a country with no recorded history of this disease. Several lines of evidence indicate that cholera was likely introduced into Haiti by United Nations security forces from Asia, raising the possibility that asymptomatic carriers of *V. cholerae* play an important role in transmitting cholera over long distances. The Haitian outbreak involved >800,000 individuals, resulting in thousands of deaths. In 2016, an outbreak of cholera occurred in Yemen in the setting of a civil war and population displacement and the breakdown of health infrastructure. The outbreak is still ongoing and has resulted

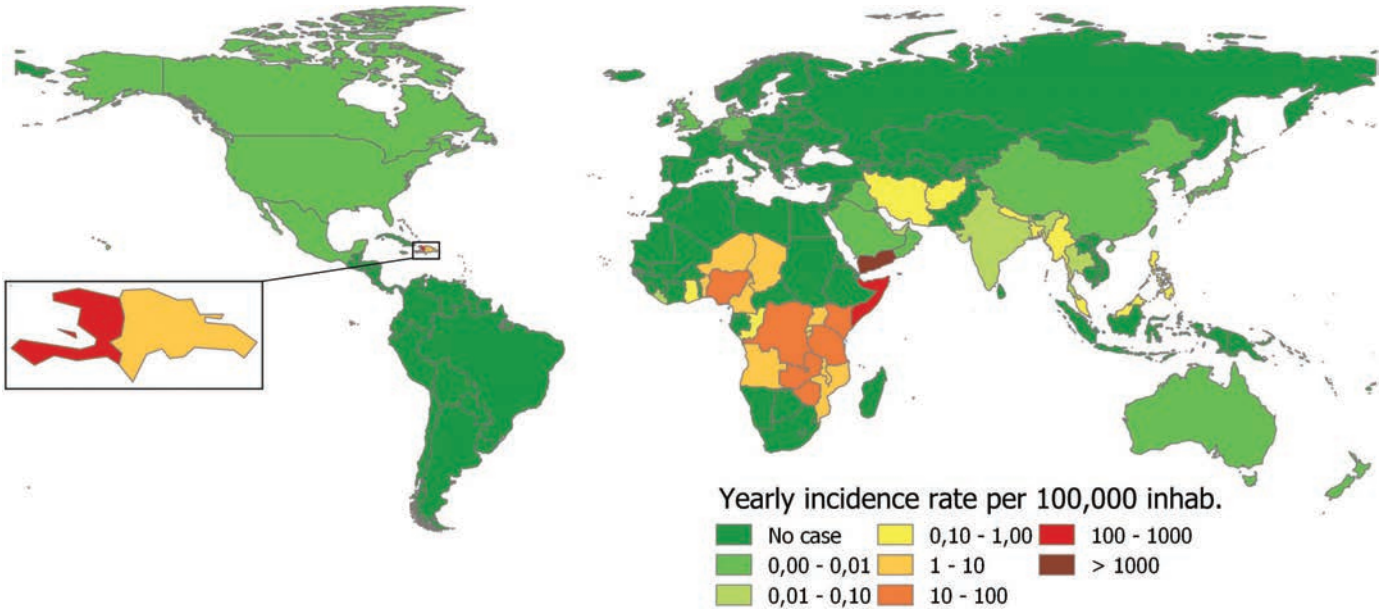

FIGURE 168-1 World distribution of cholera in 2016–2018. WHO, World Health Organization. *(Reproduced with permission from Dr. M. Piarroux, Université de la Méditerranée, France.)*

in over 1.2 million cases and thousands of deaths. The recent history of cholera has been punctuated by such severe outbreaks, especially among impoverished or displaced persons. These outbreaks are often precipitated by war or other circumstances that lead to the breakdown of public-health measures. Such was similarly the case in the camps for Rwandan refugees set up in 1994 around Goma, Zaire; in 2008–2009 in Zimbabwe; and in 2015 in South Sudan and the Democratic Republic of the Congo.

Sporadic endemic infections due to *V. cholerae* O1 strains related to the seventh-pandemic strain have been recognized along the U.S. Gulf Coast of Louisiana and Texas. These infections are typically associated with the consumption of contaminated, locally harvested shellfish. Occasionally, cases in U.S. locations remote from the Gulf Coast have been linked to shipped-in Gulf Coast seafood.

In October 1992, a large-scale outbreak of clinical cholera caused by a new serogroup, O139, occurred in southeastern India. The organism appears to be a derivative of El Tor O1 but has a distinct LPS and an immunologically related O-antigen polysaccharide capsule. (O1 organisms are not encapsulated.) After an initial spread across 11 Asian countries, *V. cholerae* O139 has once again been almost entirely replaced by O1 strains. The clinical manifestations of disease caused by *V. cholerae* O139 are indistinguishable from those of O1 cholera. Immunity to one, however, is not protective against the other.

PATHOGENESIS

In the final analysis, cholera is a toxin-mediated disease. The watery diarrhea characteristic of cholera is due to the action of cholera toxin, a potent protein enterotoxin elaborated by the organism in the small intestine. The toxin-coregulated pilus (TCP), so named because its synthesis is regulated in parallel with that of cholera toxin, is essential for *V. cholerae* to survive and multiply in (colonize) the small intestine. Production of cholera toxin, TCP, and several other virulence factors are coordinately regulated by ToxR. This protein modulates the expression of genes coding for virulence factors in response to environmental signals via a cascade of regulatory proteins. Additional regulatory processes, including bacterial responses to the density of the bacterial population (in a phenomenon known as *quorum sensing*), modulate the virulence of *V. cholerae*.

Once established in the human small bowel, the organism produces cholera toxin, which consists of a monomeric enzymatic moiety (the A subunit) and a pentameric binding moiety (the B subunit). The B pentamer binds to GM_1 ganglioside, a glycolipid on the surface of epithelial cells that serves as the toxin receptor and makes possible the delivery of the A subunit to its cytosolic target. The activated A subunit (A_1) irreversibly transfers ADP-ribose from nicotinamide adenine dinucleotide to its specific target protein, the GTP-binding regulatory component of adenylate cyclase. The ADP-ribosylated G protein upregulates the activity of adenylate cyclase; the result is the intracellular accumulation of high levels of cyclic adenosine monophosphate (AMP). In intestinal epithelial cells, cyclic AMP inhibits the absorptive sodium-transport system in villus cells and activates the secretory chloride-transport system in crypt cells, and these events lead to the accumulation of sodium chloride in the intestinal lumen. Because water moves passively to maintain osmolality, isotonic fluid accumulates in the lumen. When the volume of that fluid exceeds the capacity of the rest of the gut to resorb it, watery diarrhea results. Unless the wasted fluid and electrolytes are adequately replaced, shock (due to profound dehydration) and acidosis (due to loss of bicarbonate) follow. Although perturbation of the adenylate cyclase pathway is the primary mechanism by which cholera toxin causes excess fluid secretion, cholera toxin also enhances intestinal secretion via prostaglandins and/or neural histamine receptors.

The *V. cholerae* genome is composed of two circular chromosomes. Lateral gene transfer has played a key role in the evolution of epidemic *V. cholerae*. The genes encoding cholera toxin (*ctxAB*) are part of the genome of a bacteriophage, CTXΦ. The receptor for this phage on the *V. cholerae* surface is the intestinal colonization factor TCP. Because *ctxAB* is part of a mobile genetic element (CTXΦ), horizontal transfer of this bacteriophage may account for the emergence of new toxigenic *V. cholerae* serogroups. Many of the other genes important for *V. cholerae* pathogenicity, including the genes encoding the biosynthesis of TCP, those encoding accessory colonization factors, and those regulating virulence gene expression, are clustered together in the *V. cholerae* pathogenicity island. Similar clustering of virulence genes is found in other bacterial pathogens. It is believed that pathogenicity islands are acquired by horizontal gene transfer. *V. cholerae* O139 is probably derived from an El Tor O1 strain that acquired the genes for O139 O-antigen synthesis by horizontal gene transfer.

CLINICAL MANIFESTATIONS

Individuals infected with *V. cholerae* O1 or O139 exhibit a range of clinical manifestations. Some individuals are asymptomatic or have only mild diarrhea; others present with the sudden onset of explosive and life-threatening diarrhea (*cholera gravis*). The reasons for the range in signs and symptoms of disease are incompletely understood

FIGURE 168-2 Rice-water cholera stool. Note floating mucus and gray watery appearance. *(Courtesy of Dr. A. S. G. Faruque, International Centre for Diarrhoeal Disease Research, Dhaka; with permission.)*

but include the level of preexisting immunity, blood type (persons with type O blood are at greatest risk of severe disease if infected, whereas those with type AB are at least risk), and nutritional status. In a nonimmune individual, after a 24- to 48-h incubation period, cholera characteristically begins with the sudden onset of painless watery diarrhea that may quickly become voluminous. Patients often vomit. In severe cases, volume loss can exceed 250 mL/kg in the first 24 h. If fluids and electrolytes are not replaced, hypovolemic shock and death may ensue. Fever is usually absent. Muscle cramps due to electrolyte disturbances are common. The stool has a characteristic appearance: a nonbilious, gray, slightly cloudy fluid with flecks of mucus, no blood, and a somewhat fishy, inoffensive odor. It has been called "rice-water" stool because of its resemblance to the water in which rice has been washed **(Fig. 168-2)**. Clinical symptoms parallel volume contraction: at losses of <5% of normal body weight, thirst develops; at 5–10%, postural hypotension, weakness, tachycardia, and decreased skin turgor are documented; and at >10%, oliguria, weak or absent pulses, sunken eyes (and, in infants, sunken fontanelles), wrinkled ("washerwoman") skin, somnolence, and coma are characteristic. Complications derive exclusively from the effects of volume and electrolyte depletion and include renal failure due to acute tubular necrosis. Thus, if the patient is adequately treated with fluid and electrolytes, complications are averted and the process is self-limited, resolving in a few days.

Laboratory data usually reveal an elevated hematocrit (due to hemoconcentration) in nonanemic patients; mild neutrophilic leukocytosis; elevated levels of blood urea nitrogen and creatinine consistent with prerenal azotemia; normal sodium, potassium, and chloride levels; a markedly reduced bicarbonate level (<15 mmol/L); and an elevated anion gap (due to increases in serum lactate, protein, and phosphate). Arterial pH is usually low (~7.2).

DIAGNOSIS

Cholera should be suspected when a patient ≥5 years of age develops acute watery diarrhea in an area known to have cholera or develops severe dehydration or dies from acute watery diarrhea, even in an area where cholera is not known to be present. The clinical suspicion of cholera can be confirmed by the identification of *V. cholerae* in stool; however, the organism must be specifically sought. With experience, it can be detected directly by dark-field microscopy on a wet mount of fresh stool, and its serotype can be discerned by immobilization with specific antisera. Laboratory isolation of the organism requires the use

TABLE 168-1 Assessing the Degree of Dehydration in Patients with Cholera

DEGREE OF DEHYDRATION	CLINICAL FINDINGS
None or mild, but diarrhea	Thirst in some cases; <5% loss of total body weight
Moderate	Thirst, postural hypotension, weakness, tachycardia, decreased skin turgor, dry mouth/tongue, no tears; 5–10% loss of total body weight
Severe	Unconsciousness, lethargy, or "floppiness"; weak or absent pulse; inability to drink; sunken eyes (and, in infants, sunken fontanelles); >10% loss of total body weight

of a selective medium such as taurocholate–tellurite–gelatin (TTG) agar or thiosulfate–citrate–bile salts–sucrose (TCBS) agar. If a delay in sample processing is expected, Carey-Blair transport medium and/or alkaline-peptone water-enrichment medium may be used as well. In endemic areas, there is little need for biochemical confirmation and characterization, although these tasks may be worthwhile in places where *V. cholerae* is an uncommon isolate. Standard microbiologic biochemical testing for Enterobacteriaceae will suffice for identification of *V. cholerae*. All vibrios are oxidase-positive. Point-of-care antigen-detection cholera dipstick assays are now commercially available for use in the field or where laboratory facilities are lacking.

TREATMENT

Cholera

Death from cholera is due to hypovolemic shock; thus, treatment of individuals with cholera first and foremost requires fluid resuscitation and management. In light of the level of dehydration **(Table 168-1)** and the patient's age and weight, euvolemia should first be rapidly restored, and adequate hydration should then be maintained to replace ongoing fluid losses **(Table 168-2)**. Administration of oral rehydration solution (ORS) takes advantage of the

TABLE 168-2 Treatment of Cholera, Based on Degree of Dehydration[a]

DEGREE OF DEHYDRATION, PATIENT'S AGE (WEIGHT)	TREATMENT[b]
None or Mild, but Diarrhea[c]	
<2 years	1/4–1/2 cup (50–100 mL) of ORS, to a maximum of 0.5 L/d
2–9 years	1/2–1 cup (100–200 mL) of ORS, to a maximum of 1 L/d
≥10 years	As much ORS as desired, to a maximum of 2 L/d
Moderate[c,d]	
<4 months (<5 kg)	200–400 mL of ORS
4–11 months (5–<8 kg)	400–600 mL of ORS
12–23 months (8–<11 kg)	600–800 mL of ORS
2–4 years (11–<16 kg)	800–1200 mL of ORS
5–14 years (16–<30 kg)	1200–2200 mL of ORS
≥15 years (≥30 kg)	2200–4000 mL of ORS
Severe[c]	
All ages and weights	Undertake IV fluid replacement with Ringer's lactate (or, if not available, normal saline). Give 100 mL/kg in the first 3-h period (or the first 6-h period for children <12 months old); start rapidly, then slow down. Give a total of 200 mL/kg in the first 24 h. Continue until the patient is awake, can ingest ORS, and no longer has a weak pulse.

[a]Adapted from World Health Organization: First steps for managing an outbreak of acute diarrhoea. Global Task Force on Cholera Control, 2009 (updated 2010; *http://www.who.int/cholera/publications/firststeps/en/*). [b]Continue normal feeding during treatment. [c]Reassess regularly; monitor stool and vomit output. [d]Volumes of ORS listed should be given within the first 4 h.

Abbreviation: ORS, oral rehydration solution.

TABLE 168-3 Composition of World Health Organization Reduced-Osmolarity Oral Rehydration Solution (ORS)[a,b]

CONSTITUENT	CONCENTRATION, mmol/L
Na^+	75
K^+	20
Cl^-	65
Citrate[c]	10
Glucose	75
Total osmolarity	245

[a]Contains (per package, to be added to 1 L of drinking water): NaCl, 2.6 g; $Na_3C_6H_5O_7 \cdot 2H_2O$, 2.9 g; KCl, 1.5 g; and glucose (anhydrous), 13.5 g. [b]If prepackaged ORS is unavailable, a simple homemade alternative can be prepared by combining 3.5 g (~1/2 teaspoon) of NaCl with either 50 g of precooked rice cereal or 6 teaspoons of table sugar (sucrose) in 1 L of drinking water. In that case, potassium must be supplied separately (e.g., in orange juice or coconut water). [c]10 mmol of citrate per liter, which supplies 30 mmol of HCO_3/L.

hexose-Na^+ co-transport mechanism to move Na^+ across the gut mucosa together with an actively transported molecule such as glucose (or galactose); Cl^- and water follow. This transport mechanism remains intact even when cholera toxin is active. ORS may be made by adding safe water to prepackaged sachets containing salts and sugar or by adding 0.5 teaspoon (i.e., a small spoonful) of table salt and 6 level teaspoons (i.e., 6 small spoonfuls) of table sugar to 1 L of safe water. Potassium intake in bananas or green coconut water should be encouraged. A number of ORS formulations are available, and the WHO now recommends "low-osmolarity" ORS for treatment of individuals with dehydrating diarrhea of any cause **(Table 168-3)**. If available, rice-based ORS is considered superior to standard ORS in the treatment of cholera. ORS can be administered via a nasogastric tube to individuals who cannot ingest fluid; however, optimal management of individuals with severe dehydration includes the administration of IV fluid and electrolytes. Because profound acidosis (pH <7.2) is common in this group, Ringer's lactate is the best choice among commercial products **(Table 168-4)**; it must be used with additional potassium supplements, preferably given by mouth. The total fluid deficit in severely dehydrated patients (>10% of body weight) can be replaced safely within the first 3–4 h of therapy, half within the first hour. Transient muscle cramps and tetany are common. Thereafter, oral therapy can usually be initiated, with the goal of maintaining fluid intake equal to fluid output. However, patients with continued large-volume diarrhea may require prolonged IV treatment to match gastrointestinal fluid losses. Severe hypokalemia can develop but will respond to potassium given either IV or orally. In the absence of adequate staff to monitor the patient's progress, the oral route of rehydration and potassium replacement is safer than the IV route.

Although not necessary for cure, the use of an antibiotic to which the organism is susceptible diminishes the duration and volume of fluid loss and hastens clearance of the organism from the stool. Adjunctive antibiotics should therefore be administered to patients with moderate or severe dehydration due to cholera. In many areas, macrolides such as erythromycin (adults, 250 mg orally four times a day for 3 days; children, 12.5 mg/kg per dose four times a day for 3 days) or azithromycin (adults, a single 1-g dose; children, a single 20-mg/kg dose) are the agents of choice. Increasing resistance to tetracyclines is widespread; however, in areas with confirmed susceptibility, tetracycline (nonpregnant adults, 500 mg orally four times a day for 3 days; children >8 years old, 12.5 mg/kg per dose four times a day for 3 days) or doxycycline (nonpregnant adults, a 300-mg single dose; children >8 years old, a single dose of 4–6 mg/kg) may be used. Similarly, increasing resistance to fluoroquinolones is being reported, but in areas with confirmed susceptibility, a fluoroquinolone such as ciprofloxacin may be used (adults, 500 mg twice a day for 3 days; children, 15 mg/kg twice a day for 3 days). Oral administration of supplemental zinc is associated with decreased volume and severity of diarrhea in young children, including in those with cholera. Children <6 months of age with cholera should be treated with 10 mg of zinc daily for 10 days; children from 6 to <60 months of age should be treated with 20 mg of oral zinc daily for 10 days.

TABLE 168-4 Electrolyte Composition of Cholera Stool and of Intravenous Rehydration Solution

	CONCENTRATION, mmol/L			
SUBSTANCE	NA^+	K^+	CL^-	BASE
Stool				
Adult	135	15	100	45
Child	100	25	90	30
Ringer's lactate	130	4[a]	109	28

[a]Potassium supplements, preferably administered by mouth, are required to replace the usual potassium losses from stool.

PREVENTION

Provision of safe water and of facilities for sanitary disposal of feces, improved nutrition, and attention to food preparation and storage in the household can significantly reduce the incidence of cholera. In addition, precautions should be taken to prevent the spread of cholera via infected and potentially asymptomatic persons from endemic to nonendemic regions of the world (as was probably the case in the outbreak in Haiti; see "Microbiology and Epidemiology," above).

Much effort has been devoted to the development of an effective cholera vaccine over the past few decades, with a particular focus on oral vaccine strains. In an attempt to maximize mucosal responses, two types of oral cholera vaccine have been developed: oral killed vaccines and live attenuated vaccines. Currently, three oral killed cholera vaccines have been prequalified by the WHO and are available internationally. BivWC (Shanchol™; Shantha Biotechnics, Hyderabad, India) contains both biotypes and serotypes of *V. cholerae* O1 and *V. cholerae* O139 without supplemental cholera toxin B subunit. A related vaccine is produced in South Korea (Euvichol™, Euvichol-Plus™; Eubiologics, Seoul). WC-rBS (Dukoral®; Valneva, Lyon, France) contains both biotypes and serotypes of *V. cholerae* O1 supplemented with 1 mg of recombinant cholera toxin B subunit per dose. The vaccines are administered as a two- or three-dose regimen, with doses usually separated by 14 days. They provide ~60–85% protection for the first few months. Booster immunizations of WC-rBS are recommended after 2 years for individuals ≥6 years of age and after 6 months for children 2–5 years of age. For BivWC, which was developed more recently, no formal recommendation regarding booster immunizations exists. However, BivWC was associated with ~60% protection over 5 years among recipients of all ages in a study in Kolkata, India; the rate of protection among children ≤5 years of age approximated 40%. In outbreak situations, even a single dose of BivWC can provide some protection: 40% and 63% adjusted protection for 6 months for all and severely dehydrating cholera, respectively; although there was no evidence of protection in children younger than 5 years of age. Models predict significant herd immunity when vaccination coverage rates exceed 50%. The killed vaccines have been safely administered among populations with high rates of HIV infection.

Oral live attenuated vaccines for *V. cholerae* O1 are also in development. These strains have in common their lack of the genes encoding cholera toxin. One such vaccine, CVD 103-HgR (Vaxchora™; PaxVax, Redwood City, CA), is approved by the U.S. Food and Drug Administration for use in travelers to cholera-endemic regions. The vaccine was 90 and 80% efficacious against severe cholera after experimental infection of North American volunteers 10 days and 90 days after vaccination, respectively. Vaxchora is approved for use in individuals 2–64 years of age; no recommendations concerning the timing or need for booster vaccinations are currently available. Other live attenuated vaccine candidate strains have been prepared from El Tor and O139 *V. cholerae* and have been tested in studies of volunteers. An advantage of live attenuated cholera vaccines is that they may induce protection after a single oral dose. Conjugate and subunit cholera vaccines are also being developed.

Recognizing that it may be decades before safe water and adequate sanitation become a reality for those most at risk of cholera, the WHO has recommended incorporation of cholera vaccination into comprehensive control strategies and has established an international stockpile of oral killed cholera vaccine to assist in outbreak responses. A global strategy on cholera control was launched in 2017. This country-by-country approach aims to reduce cholera deaths by 90% and to eliminate cholera in as many as 20 countries by 2030. Integral components of this strategy are advancing water, sanitation, and hygiene (WASH) programs, as well as use of cholera vaccine. From 2016–2020, >64 million doses of cholera vaccine have been requested from the Global Vaccine Stockpile, and >33 million doses have been shipped to requesting countries for use in control programs.

OTHER *VIBRIO* SPECIES

The genus *Vibrio* includes several human pathogens that do not cause cholera. Abundant in coastal waters throughout the world, noncholera vibrios can reach high concentrations in the tissues of filter-feeding mollusks. As a result, human infection commonly follows the ingestion of seawater or of raw or undercooked shellfish **(Table 168-5)**. Most noncholera vibrios can be cultured on blood or MacConkey agar, which contains enough salt to support the growth of these halophilic species. In the microbiology laboratory, the species of noncholera vibrios are distinguished by standard biochemical tests. The most important of these organisms are *Vibrio parahaemolyticus* and *Vibrio vulnificus*. Vibriosis causes an estimated 80,000 illnesses and 100 deaths in the United States every year.

The two major types of syndromes for which these noncholera vibrios are responsible are gastrointestinal illness (due to *V. parahaemolyticus*, non-O1/O139 *V. cholerae*, *Vibrio mimicus*, *Vibrio fluvialis*, *Vibrio hollisae*, and *Vibrio furnissii*) and soft tissue infections (due to *V. vulnificus*, *Vibrio alginolyticus*, and *Vibrio damselae*). *V. vulnificus* is also a cause of primary sepsis in some compromised individuals.

SPECIES ASSOCIATED PRIMARILY WITH GASTROINTESTINAL ILLNESS

V. parahaemolyticus Widespread in marine environments, the halophilic *V. parahaemolyticus* is the leading seafood-borne bacterial cause of enteritis worldwide. This species was originally implicated in enteritis in Japan in 1953, accounting for 24% of reported cases in one study—a rate that presumably was due to the common practice of eating raw seafood in that country. In the United States, common-source outbreaks of diarrhea caused by this organism have been linked to the consumption of undercooked or improperly handled seafood or of other foods contaminated by seawater. Since the mid-1990s, the incidence of *V. parahaemolyticus* infections has increased in several countries, including the United States. Serotypes O3:K6, O4:K68, and O1:K-untypable, which are genetically related to one another, account in part for this increase. The enteropathogenicity of *V. parahaemolyticus* is associated with its ability to cause hemolysis via a thermostable direct hemolysin (Vp-TDH). Although the mechanisms by which the organism causes diarrhea are not fully defined, most *V. parahaemolyticus* genomes encode two type III secretion systems, which directly inject toxic bacterial proteins into host cells. The activity of one of these secretion systems is required for intestinal colonization and virulence in animal models. *V. parahaemolyticus* should be considered a possible etiologic agent in all cases of diarrhea that can be linked epidemiologically to seafood consumption or to the sea itself. The incidence of *V. parahaemolyticus* infection in the United States may be increasing, with this species accounting for almost half of all *Vibrio* isolates reported in this country in 2014.

Infections with *V. parahaemolyticus* can result in two distinct gastrointestinal presentations. The more common of the two presentations (including nearly all cases in North America) is characterized by watery diarrhea, usually occurring in conjunction with abdominal cramps, nausea, and vomiting and accompanied in ~25% of cases by fever and chills. After an incubation period of 4 h to 4 days, symptoms develop and persist for a median of 3 days. Dysentery, the less common presentation, is characterized by severe abdominal cramps, nausea, vomiting, and bloody or mucoid stools. *V. parahaemolyticus* also causes rare cases of wound infection and otitis and very rare cases of sepsis.

Most cases of *V. parahaemolyticus*–associated gastrointestinal illness, regardless of the presentation, are self-limited. Fluid replacement should be stressed. Antimicrobial agents may be of benefit in moderate or severe disease. Doxycycline, fluoroquinolones, macrolides, or third-generation cephalosporins are usually used. Deaths are extremely rare among immunocompetent individuals. Severe infections are associated with underlying diseases, including diabetes, preexisting liver disease, iron-overload states, or immunosuppression.

Non-O1/O139 (Noncholera) *V. cholerae* The heterogeneous non-O1/O139 *V. cholerae* organisms cannot be distinguished from *V. cholerae* O1 or O139 by routine biochemical tests but do not agglutinate in O1 or O139 antiserum. Non-O1/O139 strains have caused several well-studied food-borne outbreaks of gastroenteritis and have also been responsible for sporadic cases of otitis media, wound infection, and bacteremia. Generally, non-O1/O139 *V. cholerae* strains do not produce cholera toxin and do not cause large epidemics of diarrheal disease. Like other vibrios, non-O1/O139 *V. cholerae* organisms are widely distributed in marine environments. In most instances, recognized cases in the United States have been associated with the consumption of raw oysters or with recent travel. The broad clinical spectrum of diarrheal illness caused by these organisms is probably due to the group's heterogeneous virulence attributes.

In the United States, about half of all non-O1/O139 *V. cholerae* isolates are from stool samples. The typical incubation period for gastroenteritis due to these organisms is <2 days, and the illness lasts for ~2–7 days. Patients' stools may be copious and watery or may be partly formed, less voluminous, and bloody or mucoid. Diarrhea can result in severe dehydration. Many cases include abdominal cramps, nausea, vomiting, and fever. Like those with cholera, patients who are seriously dehydrated should receive oral or IV fluids; the value of antibiotics is not clear.

Extraintestinal infections due to non-O1/O139 *V. cholerae* commonly follow occupational or recreational exposure to seawater.

TABLE 168-5 Features of Selected Noncholera Vibrioses

ORGANISM	VEHICLE OR ACTIVITY	HOST AT RISK	SYNDROME
Vibrio parahaemolyticus	Shellfish, seawater	Normal	Gastroenteritis
	Seawater	Normal	Wound infection
Non-O1/O139 *Vibrio cholerae*	Shellfish, travel	Normal	Gastroenteritis
	Seawater	Normal	Wound infection, otitis media
Vibrio vulnificus	Shellfish	Immunosuppressed[a]	Sepsis, secondary cellulitis
	Seawater	Normal, immunosuppressed[a]	Wound infection, cellulitis
Vibrio alginolyticus	Seawater	Normal	Wound infection, cellulitis, otitis
	Seawater	Burned, other immunosuppressed	Sepsis

[a]Especially with liver disease or hemochromatosis.

Source: Table 161-3 in *Harrison's Principles of Internal Medicine*, 14th edition.

Around 10% of non-O1/O139 *V. cholerae* isolates come from cases of wound infection, 10% from cases of otitis media, and 20% from cases of bacteremia (which is particularly likely to develop in patients with liver disease). Extraintestinal infections should be treated with antibiotics. Information to guide antibiotic selection and dosing is limited, but most strains are sensitive in vitro to tetracycline, ciprofloxacin, and third-generation cephalosporins.

SPECIES ASSOCIATED PRIMARILY WITH SOFT TISSUE INFECTION OR BACTEREMIA

(See also Chap. 129)

V. vulnificus Infection with *V. vulnificus* is rare, but this organism is the most common cause of severe *Vibrio* infections in the United States. Like most vibrios, *V. vulnificus* proliferates in the warm summer months and requires a saline environment for growth. In the United States, infections in humans typically occur in coastal states between May and October and most commonly affect men >40 years of age. *V. vulnificus* has been linked to two distinct syndromes: primary sepsis, which usually occurs in patients with underlying liver disease, and primary wound infection, which generally affects people without underlying disease. (*Vulnificus* is Latin for "wound maker.") Some authors have suggested that *V. vulnificus* also causes gastroenteritis independent of other clinical manifestations. *V. vulnificus* is endowed with a number of virulence attributes, including a capsule that confers resistance to phagocytosis and to the bactericidal activity of human serum as well as a cytolysin. Measured as the 50% lethal dose in mice, the organism's virulence is considerably increased under conditions of iron overload; this observation is consistent with the propensity of *V. vulnificus* to infect patients who have hemochromatosis.

Primary sepsis most often develops in patients who have cirrhosis or hemochromatosis. However, *V. vulnificus* bacteremia can also affect individuals who have hematopoietic disorders or chronic renal insufficiency, those who are using immunosuppressive medications or alcohol, or (in rare instances) those who have no known underlying disease. After a median incubation period of 16 h, the patient develops malaise, chills, fever, and prostration. One-third of patients develop hypotension, which is often apparent at admission. Cutaneous manifestations develop in most cases (usually within 36 h of onset) and characteristically involve the extremities (the lower more often than the upper). In a common sequence, erythematous patches are followed by ecchymoses, vesicles, and bullae. In fact, sepsis and hemorrhagic bullous skin lesions suggest the diagnosis in appropriate settings. Necrosis and sloughing may also be evident. Laboratory studies reveal leukopenia more often than leukocytosis, thrombocytopenia, or elevated levels of fibrin-split products. *V. vulnificus* can be cultured from blood or cutaneous lesions. The mortality rate approaches 50%, with most deaths due to uncontrolled sepsis (Chap. 304). Accordingly, prompt treatment is critical and should include empirical antibiotic administration, aggressive debridement, and general supportive care. *V. vulnificus* is sensitive in vitro to a number of antibiotics, including tetracycline, fluoroquinolones, and third-generation cephalosporins. Data from animal models suggest that either a fluoroquinolone or the combination of a tetracycline and a third-generation cephalosporin should be used in the treatment of *V. vulnificus* septicemia.

V. vulnificus–associated soft tissue infection can complicate either a fresh or an old wound that comes into contact with seawater; the patient may or may not have underlying disease. After a short incubation period (4 h to 4 days; mean, 12 h), the disease begins with swelling, erythema, and (in many cases) intense pain around the wound. These signs and symptoms are followed by cellulitis, which spreads rapidly and is sometimes accompanied by vesicular, bullous, or necrotic lesions. Metastatic events are uncommon. Most patients have fever and leukocytosis. *V. vulnificus* can be cultured from skin lesions and occasionally from the blood. Prompt antibiotic therapy and debridement are usually curative.

V. alginolyticus First identified as a pathogen of humans in 1973, *V. alginolyticus* occasionally causes eye, ear, and wound infections. This species is the most salt-tolerant of the vibrios and can grow in salt concentrations of >10%. Most clinical isolates come from superinfected wounds that presumably become contaminated at the beach. Although its severity varies, *V. alginolyticus* infection tends not to be serious and generally responds well to antibiotic therapy and drainage. Cases of otitis externa, otitis media, and conjunctivitis due to this pathogen have been described. Tetracycline treatment usually results in cure. *V. alginolyticus* is a rare cause of bacteremia in immunocompromised hosts.

169 Brucellosis

Nicholas J. Beeching

DEFINITION

Brucellosis is a bacterial zoonosis transmitted directly or indirectly to humans from infected animals, predominantly domesticated ruminants and swine. The disease is known colloquially as *undulant fever* because of its remittent character. Although brucellosis commonly presents as an acute febrile illness, its clinical manifestations vary widely, and definitive signs indicative of the diagnosis may be lacking. Thus the clinical diagnosis usually must be supported by the results of bacteriologic and/or serologic tests.

ETIOLOGIC AGENTS

Human brucellosis is caused by strains of *Brucella*, a bacterial genus that was previously suggested, on genetic grounds, to comprise a single species, *B. melitensis*, with a number of biologic variants exhibiting particular host preferences. This view was challenged on the basis of detailed differences in chromosomal structure and host preference. The traditional classification into nomen species is now favored both because of these differences and because this classification scheme closely reflects the epidemiologic patterns of the infection. The nomen system recognizes *B. melitensis*, which is the most common cause of symptomatic disease in humans and for which the main sources are sheep, goats, and camels; *B. abortus*, which is usually acquired from cattle or buffalo; *B. suis*, which is generally acquired from swine but has one variant enzootic in reindeer and caribou and another in rodents; and *B. canis*, which is acquired most often from dogs. *B. ovis*, which causes reproductive disease in sheep, has not been clearly implicated in human disease, while rare human infections have been reported with *B. neotomae*, which is found in desert rodents. Two relatively new species, *B. ceti* and *B. pinnipedialis*, have been identified in marine mammals, including seals and dolphins. At least one case of laboratory-acquired human disease due to one of these species has been described, and several cases of natural human infection have been reported. As infections in marine mammals appear to be widespread, more cases of zoonotic infection in humans may be identified. Other newly reported species include *B. microti* (isolated from field voles),

B. papionis (from baboons), *B. vulpis* (from foxes), and *B. inopinata* (from a patient with a breast implant). Additional novel strains have been described in diverse species, including frogs, bats, and various rodents, and the genus likely will expand further in forthcoming years. Moreover, it has become apparent that *Brucella* is closely related to the genus *Ochrobactrum*, which includes environmental bacteria sometimes associated with opportunistic infections. Genomics-based studies are beginning to elucidate the pathway of evolution from free-living soil bacteria to highly successful intracellular pathogens.

All brucellae are small, gram-negative, unencapsulated, nonsporulating rods or coccobacilli. They grow aerobically on peptone-based medium incubated at 37°C; the growth of some types is improved by supplementary CO_2. In vivo, brucellae behave as facultative intracellular parasites. The organisms are sensitive to sunlight, ionizing radiation, and moderate heat; they are killed by boiling and pasteurization but are resistant to freezing and drying. Their resistance to drying renders brucellae stable in aerosol form, facilitating airborne transmission. The organisms can survive for up to 2 months in soft cheeses made from goat's or sheep's milk; for at least 6 weeks in dry soil contaminated with infected urine, vaginal discharge, or placental or fetal tissues; and for at least 6 months in damp soil or liquid manure kept in cool dark conditions. Brucellae are easily killed by a wide range of common disinfectants used under optimal conditions but are likely to be much more resistant at low temperatures or in the presence of heavy organic contamination.

EPIDEMIOLOGY

Brucellosis is a zoonosis whose occurrence and control are closely related to its prevalence in domesticated animals. Its distribution is worldwide apart from the few countries where it has been eradicated from the animal reservoir. The true global prevalence of human brucellosis is unknown because of the imprecision of diagnosis and the inadequacy of reporting and surveillance systems in many countries. Recently, there has been increased recognition of the high incidence of brucellosis in India, Pakistan, Sri Lanka and parts of China, and of importations to countries in Oceania, such as Fiji, and in Asia, such as Thailand and Vietnam. In Europe, the incidence of brucellosis in a country is inversely related to gross domestic product, and, in both developed and less well-resourced settings, human brucellosis is related to rural poverty and inadequate access to medical care. Failure of veterinary control programs due to conflicts or for economic reasons contributes further to the emergence and re-emergence of disease, as seen currently in some eastern Mediterranean countries.

Even in well-resourced settings, the true incidence of brucellosis in domesticated animals may be 10–20 times higher than the reported figures. Bovine brucellosis has been the target of control programs in many parts of the world and has been eradicated from the cattle populations of much of northern Europe, Australia, New Zealand, and Canada, among other nations. Its incidence has been reduced to a low level in the United States and most western European countries, with a varied picture in other parts of the world. Efforts to eradicate *B. melitensis* infection from sheep and goat populations have been much less successful. These efforts have relied heavily on vaccination programs, which have tended to fluctuate with changing economic and political conditions. In some countries (e.g., Israel), *B. melitensis* has caused serious outbreaks in cattle. Infections with *B. melitensis* still pose a major public health problem in Mediterranean countries; in western, central, and southern Asia; and in parts of Africa and South and Central America. Infections with *B. abortus* are common in cattle-rearing communities in African countries such as Kenya and Uganda. Canine infection with *B. canis* is present on most continents—the incidence appears to be increasing in North America and in several European countries, often associated with importation of dogs from an endemic area.

Human brucellosis is usually associated with occupational or domestic exposure to infected animals or their products. Farmers, shepherds, goatherds, veterinarians, and employees in slaughterhouses and meat-processing plants in endemic areas are occupationally exposed to infection. Feral pig hunters are at risk of infection with *B. suis* in several countries, including Australia. Family members of individuals involved in animal husbandry may be at risk, although it is often difficult to differentiate food-borne infection from environmental contamination under these circumstances. Laboratory workers who handle cultures or infected samples also are at risk. Travelers and urban residents usually acquire the infection through consumption of contaminated foods. In countries that have eradicated the disease, new cases are most commonly acquired abroad. Dairy products, especially soft cheeses, unpasteurized milk, and ice cream, are the most frequently implicated sources of infection; raw meat and bone marrow may be sources under exceptional circumstances. Infections acquired through cosmetic treatments using materials of fetal origin have been reported. Person-to-person transmission is extremely rare, as is transfer of infection by blood or tissue donation. Although brucellosis is a chronic intracellular infection, there is no evidence for increased prevalence or severity among individuals with HIV infection or with immunodeficiency or immunosuppression of other etiologies.

Brucellosis may be acquired by ingestion, inhalation, or mucosal or percutaneous exposure. Accidental injection or ingestion of the live vaccine strains of *B. abortus* (S19 and RB51) and *B. melitensis* (Rev 1) can cause disease. *B. melitensis* and *B. suis* have historically been developed as biological weapons by several countries and could be exploited for bioterrorism **(Chap. S3)**. This possibility should be borne in mind in the event of sudden unexplained outbreaks.

IMMUNITY AND PATHOGENESIS

Exposure to brucellosis elicits both humoral and cell-mediated immune responses. The mechanisms of protective immunity against human brucellosis are presumed to be similar to those documented in laboratory animals, but such generalizations must be interpreted with caution. The response to infection and its outcome are influenced by the virulence, phase, and species of the infecting strain. Differences have been reported between *B. abortus* and *B. suis* in modes of cellular entry and subsequent compartmentalization and processing. Antibodies promote clearance of extracellular brucellae by bactericidal action and by facilitation of phagocytosis by polymorphonuclear and mononuclear phagocytes; however, antibodies alone cannot eradicate infection. Organisms taken up by macrophages and other cells can establish persistent intracellular infections. The key target cell is the macrophage, and bacterial mechanisms for suppressing intracellular killing and apoptosis result in very large intracellular populations. Opsonized bacteria are actively phagocytosed by neutrophilic granulocytes and by monocytes. In these and other cells, initial attachment takes place via specific receptors, including Fc, C3, fibronectin, and mannose-binding proteins. Opsonized—but not unopsonized—bacteria trigger an oxidative burst inside phagocytes. Unopsonized bacteria are internalized via similar receptors but at much lower efficiency. Smooth strains enter host cells via lipid rafts. Smooth lipopolysaccharide (LPS), β-cyclic glucan, and possibly an invasion–attachment protein (IalB) are involved in this process. Tumor necrosis factor α (TNF-α) produced early in the course of infection stimulates cytotoxic lymphocytes and activates macrophages, which can kill intracellular brucellae (probably mainly through production of reactive oxygen and nitrogen intermediates) and may clear infection. However, virulent *Brucella* cells can suppress the TNF-α response, and control of infection in this situation depends on macrophage activation and interferon γ (IFN-γ) responses. Cytokines such as interleukin 12(IL-12) promote production of IFN-γ, which drives T_H1-type responses and stimulates macrophage activation. Inflammatory cytokines, including IL-4, IL-6, and IL-10, downregulate the protective response. As in other types of intracellular infection, it is assumed that initial replication of brucellae takes place within cells of the lymph nodes draining the point of entry. Subsequent hematogenous spread may result in chronic localizing infection at almost any site, although the reticuloendothelial system, musculoskeletal tissues, and genitourinary system are most frequently targeted. Both acute and chronic inflammatory responses develop in brucellosis, and the local tissue response may include granuloma formation with or without necrosis and caseation. Abscesses may also develop, especially in chronic localized infection.

The determinants of pathogenicity of *Brucella* have not been fully characterized, and the mechanisms underlying the manifestations of brucellosis are incompletely understood. The organism is a "stealth" pathogen whose survival strategy is centered on several processes that avoid triggering innate immune responses and that permit survival within monocytic cells. These processes include evasion of intracellular destruction by restricting the fusion of type IV secretion system–dependent *Brucella*-containing vacuoles with lysosomal compartments, inhibition of apoptosis of infected mononuclear cells, and prevention of dendritic cell maturation, antigen presentation, and activation of naïve T cells. The smooth *Brucella* LPS, which has an unusual O-chain and core-lipid composition, has relatively low endotoxin activity and plays a key role in pyrogenicity and in resistance to phagocytosis and serum killing in the nonimmune host. In addition, LPS is believed to play a role in suppressing phagosome–lysosome fusion and diverting the internalized bacteria into vacuoles located in endoplasmic reticulum, where intracellular replication takes place. Specific exotoxins have not been isolated, but a type IV secretion system (VirB) that regulates intracellular survival and trafficking has been identified. In *B. abortus* this system can be activated extracellularly, but in *B. suis* it is activated (by low pH) only during intracellular growth. Brucellae then produce acid-stable proteins that facilitate the organisms' survival in phagosomes and may enhance their resistance to reactive oxygen intermediates. A type III secretion system based on modified flagellar structures also has been inferred, although not yet confirmed. Virulent brucellae are resistant to defensins and produce a Cu-Zn superoxide dismutase that increases their resistance to reactive oxygen intermediates. A hemolysin-like protein may trigger the release of brucellae from infected cells.

CLINICAL FEATURES

Brucellosis almost invariably causes fever, which may be associated with profuse sweats, especially at night. In endemic areas, brucellosis may be difficult to distinguish from the many other causes of fever. However, two features recognized in the nineteenth century distinguish brucellosis from other tropical fevers, such as typhoid and malaria: (1) Left untreated, the fever of brucellosis shows an undulating pattern that persists for weeks before the commencement of an afebrile period that may be followed by relapse. (2) The fever of brucellosis is associated with musculoskeletal symptoms and signs in about one-half of all patients.

The clinical syndromes caused by the different nomen species are similar, although *B. melitensis* tends to be associated with a more acute and aggressive presentation and *B. suis* with focal abscess induction. *B. abortus* infections may be more insidious in onset and more likely to become chronic. *B. canis* infections are generally regarded as less severe but, like other species, can cause serious disease such as endocarditis.

The incubation period varies from 1 week to several months, and the onset of fever and other symptoms may be abrupt or insidious. In addition to experiencing fever and sweats, patients become increasingly apathetic and fatigued; lose appetite and weight; and have nonspecific myalgia, headache, and chills. Overall, the presentation of brucellosis often fits one of three patterns: febrile illness that resembles typhoid but is less severe; fever and acute monoarthritis, typically of the hip or knee, in a young child; and long-lasting fever, misery, and low-back or hip pain in an older man. In an endemic area (e.g., much of the Middle East), a patient with fever and difficulty walking into the clinic would be regarded as having brucellosis until it was proven otherwise.

Diagnostic clues in the patient's history include travel to an endemic area, employment in a diagnostic microbiology laboratory, consumption of unpasteurized milk products (including soft cheeses), contact with animals, accidental inoculation with veterinary *Brucella* vaccines, and—in an endemic setting—a history of similar illness in the family (documented in almost 50% of cases). Focal features are present in the majority of patients. The most common are musculoskeletal pain and physical findings in the peripheral and axial skeleton (~40% of cases). Osteomyelitis more commonly involves the lumbar and low thoracic vertebrae than the cervical and high thoracic spine. Individual joints that are most commonly affected by septic arthritis are the knee, hip, sacroiliac, shoulder, and sternoclavicular joints; the pattern may be one of monoarthritis or polyarthritis. Osteomyelitis may also accompany septic arthritis.

TABLE 169-1 Radiology of the Spine: Differentiation of Brucellosis from Tuberculosis

	BRUCELLOSIS	TUBERCULOSIS
Site	Lumbar and others	Dorsolumbar
Vertebrae	Multiple or contiguous	Contiguous
Diskitis	Late	Early
Body	Intact until late	Morphology lost early
Canal compression	Rare	Common
Epiphysitis	Anterosuperior	General: upper and lower disk regions, central, subperiosteal
Osteophyte	Anterolateral (parrot beak)	Unusual
Deformity	Wedging uncommon	Anterior wedge, gibbus
Recovery	Sclerosis, whole-body	Variable
Paravertebral abscess	Small, well-localized	Common and discrete loss, transverse process
Psoas abscess	Rare	More likely

In addition to the usual causes of vertebral osteomyelitis or septic arthritis, the most important disease in the differential diagnosis is tuberculosis. This point influences the therapeutic approach as well as the prognosis, given that several antimicrobial agents used to treat brucellosis are also used to treat tuberculosis. Septic arthritis in brucellosis progresses slowly, starting with small pericapsular erosions. In the vertebrae, anterior erosions of the superior end plate are typically the first features to become evident, with eventual involvement and sclerosis of the whole vertebra. Anterior osteophytes eventually develop, but vertebral destruction or impingement on the spinal cord is rare and usually suggests tuberculosis **(Table 169-1)**.

Other systems may be involved in a manner that resembles typhoid. About one-quarter of patients have a dry cough, usually with few changes visible on the chest x-ray, although pneumonia, empyema, intrathoracic adenopathy, or lung abscess can occur. Sputum or pleural effusion cultures are rarely positive in such cases, which respond well to standard brucellosis treatment. One-quarter of patients have hepatosplenomegaly, and 10%–20% have significant lymphadenopathy; the differential diagnosis includes glandular fever–like illness such as that caused by Epstein-Barr virus, *Toxoplasma*, cytomegalovirus, HIV, or *Mycobacterium tuberculosis*. Up to 10% of men have acute epididymo-orchitis, which must be distinguished from mumps and from surgical problems such as torsion. Prostatitis, inflammation of the seminal vesicles, salpingitis, and pyelonephritis all occur. There is an increased incidence of fetal loss among infected pregnant women, although teratogenicity has not been described and the tendency toward abortion is much less pronounced in humans than in farm animals.

Neurologic involvement is common, with depression and lethargy whose severity may not be fully appreciated by either the patient or the physician until after treatment. A small proportion of patients develop lymphocytic meningoencephalitis that mimics neurotuberculosis, atypical leptospirosis, or noninfectious conditions and that may be complicated by intracerebral abscess, a variety of cranial nerve deficits, or ruptured mycotic aneurysms.

Endocarditis occurs in ~1% of cases, most often affecting the aortic valve (natural or prosthetic). Any site in the body may be involved in metastatic abscess formation or inflammation; the female breast and the thyroid gland are affected particularly often. Nonspecific maculopapular rashes and other skin manifestations are uncommon and are rarely noticed by the patient even if they develop.

DIAGNOSIS

Because the clinical picture of brucellosis is not distinctive, the diagnosis must be based on a history of potential exposure, a presentation

consistent with the disease, and supporting laboratory findings. Results of routine biochemical assays are usually within normal limits, although serum levels of hepatic enzymes and bilirubin may be elevated. Peripheral leukocyte counts are usually normal or low, with relative lymphocytosis. Mild anemia may be documented. Thrombocytopenia and disseminated intravascular coagulation with raised levels of fibrinogen degradation products can develop. The erythrocyte sedimentation rate and C-reactive protein levels are often normal but may be raised.

In body fluids such as cerebrospinal fluid (CSF) or joint fluid, lymphocytosis and low glucose levels are the norm. Elevated CSF levels of adenosine deaminase cannot be used to distinguish tubercular meningitis, as they may also be found in brucellosis. Biopsied samples of tissues such as lymph node or liver may show noncaseating granulomas without acid/alcohol-fast bacilli. The radiologic features of bony disease develop late and are much more subtle than those of tuberculosis or septic arthritis of other etiologies, with less bone and joint destruction. Isotope scanning is more sensitive than plain x-ray and continues to give positive results long after successful treatment.

Isolation of brucellae from blood, CSF, bone marrow, or joint fluid or from a tissue aspirate or biopsy sample is definitive, and attempts at isolation are usually successful in 50%–70% of cases. Blood culture using modern nonradiometric or similar signaling systems (e.g., Bactec) usually become positive within 7 days. Clinicians should alert the laboratory to the possibility of brucellosis if suspected, as all cultures should be handled under containment conditions appropriate for dangerous pathogens. *Brucella* species may be misidentified as *Agrobacterium*, *Ochrobactrum*, or *Psychrobacter (Moraxella) phenylpyruvicus* by the gallery identification strips commonly used in the diagnostic laboratory. In recent years, matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has emerged as a powerful tool in bacterial identification. The relative homogeneity of classical *Brucella* species makes identification beyond the genus level by routine approaches challenging, although further improvements may facilitate discrimination at the species level, particularly in reference laboratories. The place of this technique in routine diagnostic practice will depend on further refinements. Meanwhile, the author is aware of cases in which blood culture isolates have been identified incorrectly using MALDI-TOF MS.

The peripheral blood–based polymerase chain reaction (PCR) has enormous potential to detect bacteremia, to predict relapse, and to exclude "chronic brucellosis." This method is more sensitive and is certainly quicker than blood culture, and it does not carry the attendant biohazard risk posed by culture. Nucleic acid amplification techniques are now quite widely used, although no single standardized procedure has been adopted. Primers for the spacer region between the genes encoding the 16S and 23S ribosomal RNAs (*rrs-rrl),* various outer-membrane protein–encoding genes, the insertion sequence *IS711*, and the protein BCSP31 are sensitive and specific. Blood and other tissues are the most suitable samples for analysis. The clinical significance of prolonged PCR positivity, commonly seen in blood after successful treatment, remains controversial.

Serologic examination often provides the only positive laboratory findings in brucellosis. In acute infection, IgM antibodies appear early and are followed by IgG and IgA. All these antibodies are active in agglutination tests, whether performed by tube, plate, or microagglutination methods. The majority of patients have detectable agglutinins at this stage. As the disease progresses, IgM levels decline, and the avidity and subclass distribution of IgG and IgA change. The result is reduced or undetectable agglutinin titers. However, the antibodies are detectable by alternative tests, including the complement fixation test, Coomb's antiglobulin test, and enzyme-linked immunosorbent assays. There is no clear cutoff value for a diagnostic titer. Rather, serology results must be interpreted in the context of exposure history and clinical presentation. In endemic areas or in settings of potential occupational exposure, agglutinin titers of 1:320–1:640 or higher are considered diagnostic; in nonendemic areas, a titer of ≥1:160 is considered significant. Repetition of tests after 2–4 weeks may demonstrate a rising titer.

In most centers, the standard agglutination test (or a derivative such as the microagglutination test) is still the mainstay of serologic diagnosis. In an endemic setting, >90% of patients with acute bacteremia have standard agglutination titers of at least 1:320 at the time of clinical presentation. Some investigators rely on the Rose Bengal test, which has been only partially validated for human diagnostic use but can be used for screening. Dipstick assays for anti-*Brucella* IgM have been developed but are uncommonly utilized. Other near-patient or point-of-care tests are still in developmental stages.

Antibody to the *Brucella* LPS O chain—the dominant antigen—is detected by all the conventional tests that employ smooth *B. abortus* cells as antigen. Because *B. abortus* cross-reacts with *B. melitensis* and *B. suis*, there is no advantage in replicating the tests with these antigens. Cross-reactions also occur with the O chains of some other gram-negative bacteria, including *Yersinia enterocolitica* O:9, *Escherichia coli* O157, *Francisella tularensis*, *Salmonella enterica* group N, *Stenotrophomonas maltophilia*, and *Vibrio cholerae*. Cross-reactions do not occur with the cell-surface antigens of rough *Brucella* strains such as *B. canis* or *B. ovis*; serologic tests for these nomen species must employ an antigen prepared from either one. Similarly, the live *B. abortus* vaccine strain RB51 does not elicit antibody responses in serologic tests that use smooth antigens, and this fact must be taken into account if serologic tests are employed in attempts to identify or follow the course of infections in persons accidentally exposed to the vaccine.

TREATMENT

Brucellosis

The broad aims of antimicrobial therapy are to treat and relieve the symptoms of current infection and to prevent relapse. Focal disease presentations may require specific intervention in addition to more prolonged and tailored antibiotic therapy. In addition, tuberculosis must always be excluded, or—to prevent the emergence of resistance—therapy must be tailored to specifically exclude drugs active against tuberculosis (e.g., rifampin used alone) or to include a full antituberculous regimen.

Early experience with streptomycin monotherapy showed that relapse was common; thus dual therapy with tetracyclines became the norm. This is still the most effective combination, but alternatives may be used, with the options depending on local or national policy about the use of rifampin for the treatment of nonmycobacterial infection. For the several antimicrobial agents that are active in vivo, efficacy can usually be predicted by in vitro testing. However, numerous *Brucella* strains show in vitro sensitivity to a whole range of antimicrobials that are therapeutically ineffective, including assorted β-lactams. Moreover, the use of fluoroquinolones remains controversial despite the good in vitro activity and white-cell penetration of most agents of this class. Low intravacuolar pH is probably a factor in the poor performance of these drugs.

For adults with acute nonfocal brucellosis (duration, <1 month), a 6-week course of therapy incorporating at least two antimicrobial agents is required. Complex or focal disease may necessitate ≥3 months of therapy. Adherence to the therapeutic regimen is very important, and poor adherence underlies almost all cases of apparent treatment failure; such failure is rarely due to the emergence of drug resistance, although increasing resistance to trimethoprim-sulfamethoxazole (TMP-SMX) has been reported at one center. There is good retrospective evidence that a 3-week course of two agents is as effective as a 6-week course for treatment and prevention of relapse in children, but this has not yet been investigated in prospective studies.

The gold standard for the treatment of brucellosis in adults is IM streptomycin (0.75–1 g daily for 14–21 days) together with doxycycline (100 mg twice daily for 6 weeks). In both clinical trials and observational studies, relapse follows such treatment in 5%–10% of cases. The usual alternative regimen (and the current World Health Organization recommendation) is rifampin (600–900 mg/d) plus doxycycline (100 mg twice daily) for 6 weeks. The relapse/failure rate

is ~10% in trial conditions but rises to >20% in many nontrial situations, possibly because doxycycline levels are reduced and clearance rates increased by concomitant rifampin administration. Patients who cannot tolerate or receive tetracyclines (children, pregnant women) can be given high-dose TMP-SMX instead (two or three standard-strength tablets twice daily for adults, depending on weight).

Increasing evidence supports the use of an aminoglycoside such as gentamicin (5–6 mg/kg per day for at least 2 weeks) instead of streptomycin. Shorter courses have been associated with high failure rates in adults. A 5- to 7-day course of therapy with gentamicin and a 3-week course of TMP-SMX may be adequate for children with uncomplicated disease, but prospective trials are still needed to support this recommendation. Early experience with fluoroquinolone monotherapy was disappointing, although it was suggested that ofloxacin or ciprofloxacin, given together with rifampin for 6 weeks, might be an acceptable alternative to the other 6-week regimens for adults. A substantial meta-analysis did not support the use of fluoroquinolones in first-line treatment regimens, and these drugs are not recommended by an expert consensus group (the Ioannina Recommendations) except in the context of well-designed clinical trials. However, a more recent meta-analysis is more supportive of the efficacy of these drugs, and an adequately powered prospective study will be needed to resolve their role in standard combination therapy. A triple-drug regimen—doxycycline and rifampin combined with an initial course of an aminoglycoside—was superior to double-drug regimens in a meta-analysis. The triple-drug regimen should be considered for all patients with complicated disease and for those for whom treatment adherence is likely to be a problem.

Focal neurologic disease due to *Brucella* species requires prolonged treatment (i.e., for 3–6 months), usually with ceftriaxone supplementation of a standard regimen. *Brucella* endocarditis is treated with at least three drugs (an aminoglycoside, a tetracycline, and rifampin), and many experts add ceftriaxone and/or a fluoroquinolone to reduce the need for valve replacement. Treatment is usually given for at least 4–6 months, and clinical endpoints for its discontinuation are often difficult to define. Surgery is still required for the majority of cases of infection of prosthetic heart valves and prosthetic joints.

There is no evidence base to guide prophylaxis after exposure to *Brucella* organisms (e.g., in the laboratory), inadvertent immunization with live vaccine intended for use in animals, or exposure to deliberately released brucellae. Most authorities have recommended the administration of rifampin plus doxycycline for 3 weeks after a low-risk exposure (e.g., an unspecified laboratory accident) and for 6 weeks after a major exposure to aerosol or injected material. However, such regimens are poorly tolerated, and doxycycline monotherapy of the same duration may be substituted. (Monotherapy is the standard recommendation in the United Kingdom but not in the United States.) Rifampin should be omitted after exposure to vaccine strain RB51, which is resistant to rifampin, and replaced by another agent such as TMP-SMX in combination with doxycycline. After significant brucellosis exposure, expert consultation is advised for women who are (or may be) pregnant.

PROGNOSIS AND FOLLOW-UP

Relapse occurs in up to 30% of poorly compliant patients. Thus patients should ideally be followed clinically for up to 2 years to detect relapse, which responds to a prolonged course of the same therapy used originally. The general well-being and the body weight of the patient are more useful guides than serology to lack of relapse. IgG antibody levels detected by the standard agglutination test and its variants can remain in the diagnostic range for >2 years after successful treatment. Complement fixation titers usually fall to normal within 1 year of cure. Immunity is not solid; patients can be reinfected after repeated exposures. Fewer than 1% of patients die of brucellosis. When the outcome is fatal, death is usually a consequence of cardiac involvement; more rarely, it results from severe neurologic disease. Despite the low mortality rate, recovery from brucellosis is slow, and the illness can cause prolonged inactivity, with domestic and economic consequences.

The existence of a prolonged chronic brucellosis state after successful treatment remains controversial. Evaluation of patients in whom this state is considered (often those with work-related exposure to brucellae) includes careful exclusion of malingering, nonspecific chronic fatigue syndromes, and other causes of excessive sweating, such as alcohol abuse and obesity. In the future, the availability of more sensitive assays to detect *Brucella* antigen or DNA may help to identify patients with ongoing infection.

PREVENTION

Vaccines based on live attenuated *Brucella* strains, such as *B. abortus* strain 19BA or 104M, have been used in some countries to protect high-risk populations but have displayed only short-term efficacy and high reactogenicity. Subunit vaccines have been developed but are of uncertain value and cannot be recommended at present. Research in this area has been stimulated by interest in biodefense **(Chap. S3)** and may eventually yield new products. The mainstay of veterinary prevention is a national commitment to testing and slaughter of infected herds/flocks (with compensation for owners), control of animal movement, and active immunization of animals. These measures are usually sufficient to control human disease as well. In their absence, pasteurization of all milk products before consumption is sufficient to prevent nonoccupational animal-to-human transmission. All cases of brucellosis in animals and humans should be reported to the appropriate public health authorities.

170 Tularemia

Max Maurin, Didier Raoult

DEFINITION

Tularemia is a zoonosis caused by the gram-negative, facultative intracellular bacterium *Francisella tularensis*. This microorganism was isolated first in 1911 by McCoy and Chapin from rodents in Tulare County, California, and then from humans in 1914 by Wherry and Lamb. Because of taxonomic evolution, only two subspecies of *F. tularensis* are currently associated with tularemia: *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica* are responsible for type A and type B tularemia, respectively. These two subspecies are highly virulent human pathogens belonging to category A of potential biological threat agents, as defined by the U.S. Centers for Disease Control and Prevention.

FRANCISELLA SPECIES, SUBSPECIES, AND CLADES

The *Francisella* genus currently comprises seven species. *F. tularensis* is split into four subspecies: *F. tularensis* subsp. *tularensis* (type A); *F. tularensis* subsp. *holarctica* (type B); *F. tularensis* subsp. *mediasiatica*, restricted to central Asia and Russia, but never associated with human

diseases; and *F. tularensis* subsp. *novicida*, an aquatic bacterium and rare opportunistic human pathogen. Molecular methods (especially those based on whole genome sequencing) have now allowed the characterization of a large number of *F. tularensis* genotypes, which are divided into clades and subclades. The major clades are A1 (divided into A1a and A1b) and A2 for type A strains, and B4, B6, B12, and B16 for type B strains. These clades vary in geographic distribution, virulence, and resistance to macrolides; clade B12 strains are naturally highly resistant to erythromycin.

EPIDEMIOLOGY

GEOGRAPHIC DISTRIBUTION

Tularemia-endemic areas are mainly distributed in the Northern Hemisphere **(Fig. 170-1)**. Human tularemia cases are described in North America (the United States, Canada, and part of Central America), Asia (Japan, China, Mongolia, Russia, Pakistan, Turkey, Iran, Kazakhstan, Georgia, Armenia, and Azerbaijan), and Europe (almost all countries except Iceland, Ireland, the United Kingdom, Portugal, and the southern Balkan countries). Type A strains are classically restricted to North America, although a few strains (probably imported laboratory strains) have been detected from arthropods in Slovakia. Type B strains are classically found in the whole Northern Hemisphere but have also been detected in southern Australia. In the United States, human tularemia cases predominate in southern and central states (especially, in order of decreasing incidence, Arkansas, Oklahoma, South Dakota, Kansas, Missouri, North Dakota, and Nebraska) and, to a lesser extent, in eastern states (mainly Massachusetts and Martha's Vineyard) and western states (especially California, Oregon, and Montana).

There is a specific, complex, and overlapping geographic distribution of *F. tularensis* clades and subclades (Fig. 170-1). Clade A1 is found throughout North America, while clade A2 is restricted to the U.S. western states. Clade B4 predominates in North America but has also been detected in Scandinavia, Germany, and western China. Clade B6 is spread throughout western Europe (with a predominance of subclade B44), but also in central Europe, Scandinavia, and North America. Clade B12 has been found mainly in eastern Europe, Scandinavia, and Asia (e.g., Russia and China). Finally, clade B16 is currently restricted to Japan, Turkey, Australia, and western China.

RESERVOIRS AND MODES OF TRANSMISSION

F. tularensis can infect a wide range of mammals, birds, amphibians, reptiles, and fish, causing many of these vertebrate species to develop severe and often fatal infections. Because this organism can infect so many animal species, the actual animal reservoir of *F. tularensis* remains unknown. However, small terrestrial and semi-aquatic rodents (including mice, gerbils, beavers, lemmings, and voles) and lagomorphs (hares and rabbits) are the predominant animal sources for human tularemia cases.

Some arthropods are able to transmit *F. tularensis* between animal species, including from animals to humans. Ixodidae ticks are the primary vectors of tularemia and may also represent a reservoir due to transstadial transmission of *F. tularensis*. Mosquitoes (especially *Aedes* species) are vectors of this microorganism in Sweden and Finland. Other blood-sucking arthropods (especially tabanids) may also transmit tularemia in restricted areas. *F. tularensis* survives for weeks or months in contaminated soil or water environments, which possibly represent other natural reservoirs of this bacterium.

The modes of transmission of *F. tularensis* to humans are varied, reflecting the ubiquitous nature of this microbe. A common mode of infection is direct contact with infected animals or, less frequently, through animal bites. Lagomorphs and other game animals as well as small rodents are most frequently involved. Domestic animals, especially cats and dogs, are occasionally involved in transmission to humans or as recipients of the microbe from wild animals. Tularemia can also be acquired through the consumption of contaminated food products (especially those from game animals) or water (often nonpotable water from water wells or spring water). Arthropod-borne tularemia cases mainly occur through tick bites except in Sweden and Finland, where mosquitoes are the primary vectors. Human infections also occur through contact with contaminated soil or water environments or inhalation of contaminated dust.

AT-RISK EXPOSURES AND POPULATIONS

In endemic areas, the people most at risk for tularemia are those frequently exposed to wild animals, arthropod bites (mainly those of ticks), or contaminated hydrotelluric environments.

Occupational Risk Tularemia is recognized as an occupational disease in most endemic countries. The high-risk occupational groups include breeders, farmers, veterinarians, game wardens, forest rangers,

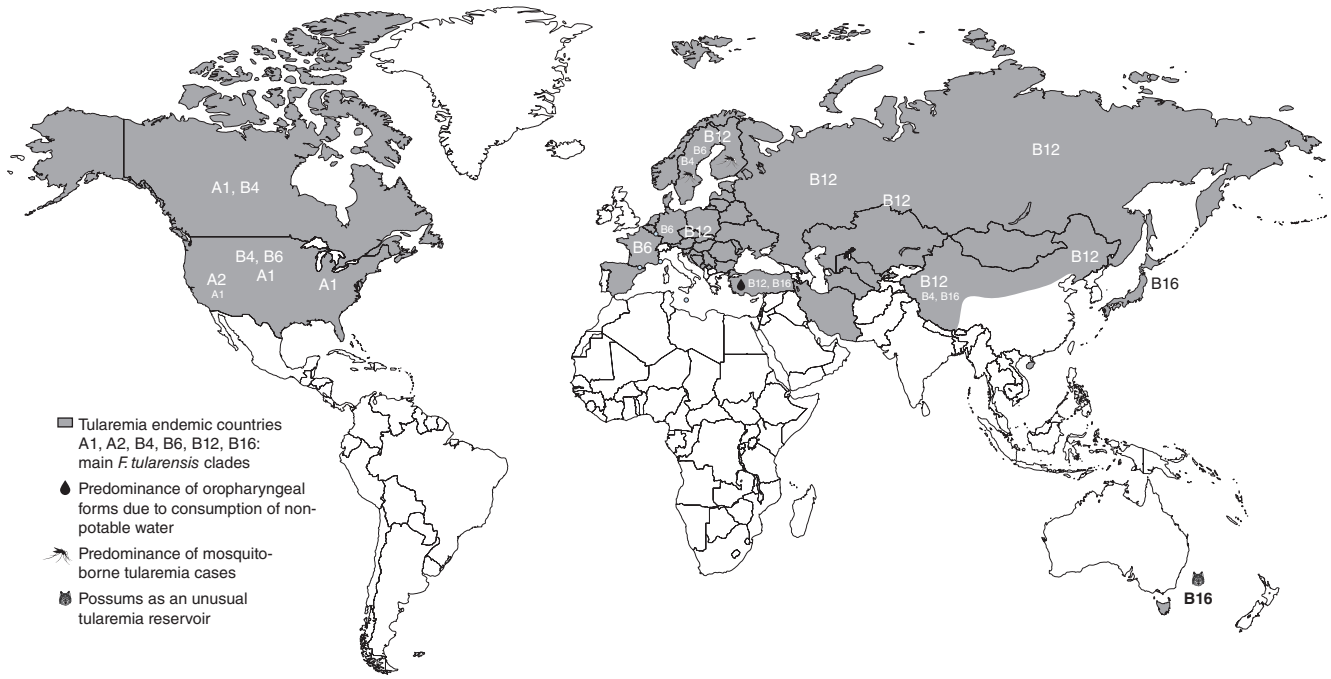

FIGURE 170-1 Global distribution of reported (or strongly suspected) autochthonous human tularemia cases. The major clades detected in specific areas—A1, A2, B4, B6, B12, and B16—are shown. In most countries, the actual endemic areas are poorly defined. The actual distribution of clades and subclades is complex and overlapping. Lagomorphs, small rodents, and ticks are the primary sources of human tularemia cases except in the indicated specific situations.

landscapers, trappers, tanners, slaughterhouse workers, renderers, zoological park employees, butchers who handle game meat, military personnel (especially during the navigation of military obstacle courses), and laboratory personnel handling *F. tularensis* cultures.

Leisure-Associated Risk The leisure activities potentially associated with exposure to *F. tularensis* include hunting, trapping, gardening, mowing the lawn, canyoneering, fishing or swimming in contaminated fresh water, and walking or biking in forests and other areas infested with ticks. Owning pets that may carry *F. tularensis* (especially unusual animals such as prairie dogs) is also a risk factor.

At-Risk Populations and Seasonal Variations The most at-risk population varies according to the geographic area and the predominant mode(s) of contamination. When infections occur through contact with wildlife fauna and tick bites, middle-aged men living in rural areas are most frequently involved. Game-related contamination usually occurs during the hunting (autumn and winter) seasons, while tick-borne tularemia cases are more frequent during the warm season. Infections caused by the consumption of contaminated water occur throughout the year and involve men, women, and children. Mosquito-borne tularemia cases predominate during the warm season in both adults and children in Scandinavia.

NATURAL CYCLES OF *F. TULARENSIS*

The highly variable epidemiologic and clinical aspects of tularemia in different geographic areas suggest several *F. tularensis* natural cycles. These cycles probably vary with the predominant animal reservoirs, arthropod vectors, climatic conditions, and *F. tularensis* species and lineages. However, two cycles have been hypothesized to explain the spatiotemporal maintenance of tularemia. In the *terrestrial* cycle, lagomorphs, terrestrial rodents, and ticks are considered primarily involved. Human infections occur mainly through contact with the terrestrial wildlife fauna and tick bites. This cycle is characterized by sporadic tularemia cases in the most exposed population (often middle-aged men), with a predominance of ulceroglandular and glandular forms. In the *aquatic* cycle, semi-aquatic rodents and the aquatic environment play a significant role. In Turkey, most patients are infected through the consumption of nonpotable water (especially spring water). Water-borne tularemia outbreaks have occurred, involving both adults and children, with a predominance of oropharyngeal forms. In Sweden and Finland, mosquito-borne tularemia cases predominate. These arthropods are likely infected during their larval cycle in contaminated aquatic environments. Tularemia outbreaks can recur and can involve both adults and children, who develop mainly ulceroglandular and glandular forms of disease.

PATHOGENESIS

F. tularensis inoculation can occur through the skin, the conjunctiva, and the oral or respiratory route. After a short incubation period (usually 3–5 days), patients experience a flulike illness with symptoms localized to the site of initial tissue invasion. The organism mainly survives intracellularly and can infect a broad spectrum of eukaryotic cells, including phagocytes and epithelial cells. After phagocytosis by macrophages, the *F. tularensis* pathogenicity island encoding a type VI secretion system allows this bacterium to rapidly exit the phagocytic vacuole and multiply within the cytoplasm. The oxidative response of the infected phagocytic cell is attenuated and delayed, in part because of the specific structure of *F. tularensis* lipopolysaccharide, which is stealth to the innate Toll receptor immune system. Many other virulence factors have been partially characterized. Infected cells eventually undergo apoptosis, which allows released bacteria to initiate new rounds of infection. The organism spreads between cells through the bloodstream, and infected blood cells (e.g., monocytes) participate in the spread of the bacteria in the body. A few bacteria are enough to induce severe infection, resulting in the patient's death within days for the most virulent *F. tularensis* strains. Most frequently, however, the infection is controlled both by the humoral and cellular immune responses.

The earliest infected organs—and thus the earliest clinical manifestations—depend on the route of infection. Infection through the skin results in a local inoculation lesion and development of regional lymphadenopathy within days. Conjunctival inoculation leads to conjunctivitis with local lymphadenopathy. The oral route of infection manifests as pharyngitis with cervical lymphadenopathy, but intestinal involvement may occasionally lead to enteritis and other intraabdominal organ involvement. The inhalation of a contaminated aerosol can result in acute, subacute, or chronic pneumonia. All these localized infections can lead to *F. tularensis* bacteremia (hence the term *tularemia*) and secondary infection of almost all organs.

CLINICAL MANIFESTATIONS

Tularemia can be considered as two separate diseases: a severe, often life-threatening disease observed in North America and caused by the most virulent type A strains; and a disease of mild to moderate severity, with protean clinical manifestations that often resemble those of other infectious diseases; in fact, these other diseases typically are initially suspected before the diagnosis of tularemia is made. The incubation period of tularemia is typically short (3–5 days on average) but can last up to 3 weeks.

SEVERE TYPE A TULAREMIA

The most virulent strains of *F. tularensis* subsp. *tularensis* (genotype A1b) can cause severe systemic disease, usually of acute onset. These infections justify the classification of *F. tularensis* as a Tier 1 select agent in the United States and most other countries. For severe type A tularemia cases, the most frequently reported mode of contamination is the inhalation of an infected aerosol. This event results in the rapid development of acute, life-threatening pneumonia or pleuropneumonia, which is the most severe presentation of the so-called pneumonic form of tularemia. Systemic infections are acquired through other modes of contamination, including ingestion of contaminated food or water and arthropod bites. A severe typhoid-like disease (referred to as the typhoidal form of tularemia) is consistent with a combination of high fever, sepsis, and neurologic symptoms (ranging from confusion to deep coma), but no localized infection (e.g., no skin inoculation lesion and no lymphadenopathy). The acute pneumonic and typhoidal forms of tularemia are usually associated with *F. tularensis* bacteremia, although bloodstream infection may not be detected at hospital admission because of its intermittent and temporary nature.

Severe type A tularemia is not restricted to persons with compromised immunity or underlying disorders and can occur in young, healthy adults. If untreated, the acute pneumonic form rapidly progresses to acute respiratory distress syndrome. Patients with severe type A infections often develop severe sepsis, septic shock, and multiple-organ dysfunction syndrome. Altogether, these severe systemic infections are associated with mortality rates up to 40–60% without appropriate antibiotic therapy. Among patients who are admitted early to an intensive care unit and receive appropriate antibiotics, the death rate is reduced to 3–5%. However, rapid etiologic diagnosis of these nonspecific clinical presentations remains difficult, and a delay in initiating appropriate antibiotic therapy is associated with poorer prognosis.

MORE COMMON PRESENTATIONS OF TULAREMIA

Other than the acute and severe forms of type A infection, the majority of human cases of tularemia are characterized by subacute clinical manifestations of progressive onset and of mild to moderate severity. These less severe forms of disease are almost the only forms observed in Europe and Asia and also are common in North America. Apart from the six classical forms of tularemia (see below), a wide variety of other clinical manifestations can be observed. The predominant clinical presentations vary from one geographic area to another according to the primary sources and modes of transmission of *F. tularensis* to humans.

Prodromal Flulike Illness An unknown proportion of persons infected with *F. tularensis* either do not develop clinical symptoms or have a self-limited febrile illness and do not seek medical attention. In symptomatic patients, early clinical manifestations usually correspond to a flulike illness and may include fever, headache, chills, fatigue, malaise, arthralgia, and myalgia.

Classical Forms of Tularemia Following the prodromal period, tularemia usually evolves into one of six classical clinical forms, which are occasionally combined.

ULCEROGLANDULAR FORM This form is the most common and typical presentation of tularemia worldwide. It occurs after *F. tularensis* inoculation through the skin (e.g., during manipulation of an infected animal or via an arthropod bite). A cutaneous inoculation lesion develops that may be papular or vesicular but that often evolves to a skin ulcer persisting for several weeks before healing. A few days after infection, regional lymphadenopathy develops at locations that vary with the inoculation site (e.g., axillary, epitrochlear, or inguinal). The differential diagnosis of the combination of a skin lesion and regional lymphadenopathy is difficult and includes cat-scratch disease caused by *Bartonella henselae* **(Chap. 172)** as well as several rickettsioses **(Chap. 187)**. However, in patients with the above clinical presentation, tularemia should be considered.

GLANDULAR FORM The glandular form is similar to the ulceroglandular form, but the skin lesion either has not developed or has healed by the time the patient seeks medical attention. This form is a common but clinically less typical presentation. Because many infectious agents may cause regional lymphadenopathy, the diagnosis of tularemia is often delayed.

OCULOGLANDULAR FORM Infection through the conjunctiva usually leads to painful granulomatous unilateral conjunctivitis. Bilateral conjunctivitis due to contamination of both eyes rarely occurs. Within a few days, swollen periauricular lymphadenopathy develops. Thus, tularemia is a rare etiology of Parinaud oculoglandular syndrome. *B. henselae* (the cause of cat-scratch disease) is the most common etiology of this syndrome, but tularemia should be considered as an alternative diagnosis.

OROPHARYNGEAL FORM The oral route of contamination (usually via the hands or through consumption of contaminated water or food) corresponds to painful pharyngitis and the development within days of submandibular or cervical lymphadenopathy. The oropharyngeal form resembles a group A streptococcal infection **(Chap. 148)**, but with swollen cervical lymphadenopathy in most patients and almost no efficacy of β-lactam therapy. This form may also include digestive symptoms of variable severity, including nausea and vomiting, abdominal pain, bloody diarrhea, and occasionally the involvement of other intraabdominal organs.

PNEUMONIC FORM The inhalation of an *F. tularensis*–contaminated aerosol may result in pneumonia or pleuropneumonia. However, the most common presentations of this clinical form consist of subacute lung involvement with low-grade fever and mild pulmonary symptoms (dry cough, moderate dyspnea, and mild chest pain). Some patients suffer from prolonged clinical symptoms, with intermittent fever, fatigue, progressive weight loss, and deterioration in general condition. The diagnosis is usually delayed for weeks or months until chest x-ray or CT reveals hilar or mediastinal lymphadenopathy, often with no or only minor pulmonary lesions. Tuberculosis and lymphoma are usually suspected first. The tularemia diagnosis is usually fortuitous and obtained thanks to histologic and bacteriologic analysis of surgically removed mediastinal or hilar lymph nodes.

TYPHOIDAL FORM In Europe and Asia, a diagnosis of typhoidal tularemia may be considered in patients presenting with sepsis and confusion but without a localized infection (no skin lesion, lymphadenopathy, pharyngitis, or conjunctivitis). However, the prognosis of this form of illness is much better than that of type A infections in North America. Many of these patients experience *F. tularensis* bacteremia. Fatal cases are rare and most often occur in debilitated and elderly patients.

Skin Manifestations Apart from skin inoculation lesions, tularemia patients may present with various other types of skin involvement. Reported manifestations include skin rash, Sweet syndrome, dermatitis, urticaria, acneiform eruption, vasculitis-like eruption, lymphangitis, cellulitis, subcutaneous abscesses, erythema nodosum, erythema multiforme, and livedo reticularis.

Complications Up to 20–30% of symptomatic tularemia patients with common clinical presentations require hospitalization, either in the early stage of the disease—because of severe clinical symptoms—or after several weeks or months of evolution—because of an unfavorable course.

BACTEREMIA, SEPSIS, AND SEPTIC SHOCK These complications are rare among patients with the above classical forms of tularemia and have been reported more frequently in immunocompromised persons, transplant recipients, persons with severe underlying disorders, and the elderly.

LYMPH NODE SUPPURATION, SOFT TISSUE INFECTIONS, AND DEEP ABSCESSES Because of delayed diagnosis, 30–40% of tularemia patients with regional lymphadenopathy experience a progression to lymph node suppuration, which can spontaneously drain through a skin fistula. Soft tissue infections usually occur in the area adjacent to suppurative lymphadenopathy and may consist of cellulitis or subcutaneous abscesses. Periauricular lymphadenopathy may lead to parotid infection. Myositis and rhabdomyolysis have also been reported. Deep abscesses of variable location may occur through the diffusion of a lymph node suppuration into the surrounding tissues or through hematogenous spread of bacteria.

OCULAR COMPLICATIONS Tularemia conjunctivitis rarely evolves to more severe ocular infections. Rare cases of dacryocystitis, keratitis, chorioretinitis, cyclitis, and optic neuritis have been reported.

OTITIS Otitis media is a rare complication likely occurring as a complication of oropharyngeal tularemia or direct inoculation of *F. tularensis* through a tympanic perforation.

MENINGITIS, MENINGOENCEPHALITIS, AND NEUROLOGIC DISEASE Meningitis and meningoencephalitis are hematogenous complications that, although uncommon, can occur as an inaugural and unique clinical manifestation. Their clinical presentation is not specific, and a tularemia diagnosis is usually established by isolation of *F. tularensis* from cerebrospinal fluid. Meningitis has been more commonly reported in the United States than in Europe and Asia. Other rare neurologic complications include cerebral abscesses, polyneuritis cranialis, ataxia, and Guillain-Barré syndrome.

CARDIOVASCULAR INFECTIONS Endocarditis (including prosthetic valve endocarditis), myocarditis, pericarditis, and aortitis are rare complications of tularemia. Therefore, diagnosis may be particularly challenging unless blood cultures allow rapid isolation of *F. tularensis*.

ABDOMINAL INFECTIONS Rare abdominal complications include granulomatous hepatitis, peritonitis, acute renal failure, and liver or spleen abscesses or nodules.

OSTEOARTICULAR INFECTIONS Osteoarticular infections, including osteomyelitis, arthritis, and prosthetic joint infections, are rare hematogenous complications of tularemia.

ADVERSE PREGNANCY OUTCOMES Tularemia is not considered a disease responsible for complications during pregnancy or fetal abnormalities. A single tularemia case in the first trimester of pregnancy, followed by intrauterine fetal death in the third trimester, has been reported.

DIAGNOSIS

A tularemia diagnosis is often missed or delayed. This delay may be related to inadequate knowledge of this disease by some clinicians, lack of specific clinical symptoms, and a high frequency of mild disease with spontaneous recovery. Once clinically suspected, a diagnosis of tularemia usually is readily confirmed by specific laboratory tests.

NONSPECIFIC BIOLOGIC FINDINGS

Routine blood tests usually are not very informative in the diagnosis of tularemia. The leukocyte count can be normal or moderately high, usually with a relative increase in mononuclear cells. Moderate thrombocytopenia is more frequently observed. The erythrocyte sedimentation rate is usually elevated, and the C-reactive protein level may

also be slightly elevated. Levels of liver enzymes, including alkaline phosphatase, aspartate aminotransferase, alanine aminotransferase, and gamma-glutamyl transpeptidase, can be moderately elevated. High levels of creatine phosphokinase are found in patients with rhabdomyolysis.

RADIOLOGIC FINDINGS

Radiologic examinations (e.g., CT, MRI, ultrasonography) may be useful for detecting and specifying the extent of lymphadenopathy and lung or other organ involvement. Although usually not specific to tularemia, radiologic findings may include superficial or deep lymphadenopathies; soft tissue, lymph node, or other organ abscesses; brain tissue involvement; cardiovascular disease; lung or pleural involvement; and osteoarticular lesions. The pneumonic form of tularemia may be associated with variable radiologic findings, including unilateral or bilateral infiltrates, lung consolidation, lung abscess, cavitary lesions, pleural effusion, and hilar or mediastinal enlargement due to lymphadenopathy.

CLINICAL SAMPLES

Blood samples should be collected in blood culture bottles (aerobic and anaerobic) when patients have febrile disease. On the basis of clinical manifestations, biological samples can be obtained for culture and polymerase chain reaction (PCR) testing, including samples of cutaneous biopsies or exudates (especially from the inoculation lesion), conjunctival or pharyngeal exudates, lymph node aspirates or biopsies, various suppurations and abscesses, sputum and other lower respiratory tract secretions, pleural and other serous fluid, cerebrospinal fluid, and organ biopsies.

SEROLOGIC DIAGNOSIS

A serum sample should be collected as early as possible and analyzed for antibodies to *F. tularensis*. Ideally, a second serum sample should be collected at least 2 weeks later. The serologic diagnosis of tularemia is widely used and is sensitive. Antibodies are measured by different techniques, depending on the laboratory. Assays include the microagglutination test, immunofluorescence assays (IFAs), enzyme-linked immunosorbent assays (ELISAs), and Western blots. The IFA and ELISA methods allow separate titration of IgM- and IgG-type antibodies. Significant antibody titers (i.e., titers above the cutoff of the technique used) are usually detected 2–3 weeks after disease onset, with ELISAs allowing the earliest detection. Antibody titers peak 4–6 weeks after disease onset and then decline progressively over the following months. However, in many patients, residual IgG titers and, to a lesser extent, IgM titers persist for several years.

False-negative results may be obtained in the early stage of tularemia or in the rare patients who do not mount a significant antibody response. False-positive results classically arise as a result of antigenic cross-reactions between *F. tularensis* and other bacterial species, including *Brucella* spp. and *Yersinia enterocolitica*. The risk of false-positive results linked to antigenic cross-reactions is high in patients with antibody titers close to the cutoff thresholds. In addition, the long-term persistence of anti–*F. tularensis* antibodies in patients with past infection may also lead to false-positive results. Lack of kinetics between antibody titers in early and (when available) late serum samples may allow the differentiation of recent from past infections.

CULTURE-BASED DIAGNOSIS

F. tularensis is a highly infectious and virulent bacterium. Cultures of this pathogen should be handled in a biosafety level 3 laboratory to prevent the contamination of laboratory personnel. Blood-enriched media (especially chocolate agar supplemented with vitamins) are needed to isolate this fastidious-growth bacterium. Current blood culture systems are adequate for *F. tularensis* isolation within 5 days of incubation. *F. tularensis* may also be isolated from various other clinical samples.

F. tularensis can be presumptively identified by Gram's staining (small gram-negative coccobacilli), a few biochemical tests, agglutination, and matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry. Molecular tests are the gold standard for determination of the involved species, subspecies, and genotype (see below).

MOLECULAR DIAGNOSIS

F. tularensis DNA can be detected in blood or other clinical samples. Available real-time PCR is both rapid and accurate. Whole genome sequencing of a large number of *F. tularensis* strains has allowed the development of molecular tests for the detection and identification of this pathogen at the species, subspecies, or genotype level. The fact that PCR tests usually remain positive despite 1–2 weeks of antibiotic therapy may help establish the diagnosis of tularemia, whereas specific cultures can be negative at that point.

Blood samples may be PCR-positive, especially when collected from patients with *F. tularensis* bacteremia. However, PCR results are more frequently positive for other clinical samples, especially samples of lymph nodes, skin ulcers, and conjunctival and pharyngeal exudates. It is interesting that lymph node tissue surgically removed because of suppuration several weeks after disease onset are PCR-positive in >90% of cases, whereas *F. tularensis* is rarely isolated from these samples.

OPTIMIZED DIAGNOSTIC STRATEGY

Molecular tests are the most useful diagnostic tools for rapid tularemia diagnosis. In the acute phase of the disease, *F. tularensis* DNA can be detected in various biologic samples collected in light of clinical manifestations, including blood, skin inoculation lesions, conjunctival or pharyngeal exudates, sputum or pleural fluid, and cerebrospinal fluid. Real-time PCR can provide a rapid (within 2 h) and accurate diagnosis of acute pneumonic tularemia, especially in the context of bioterrorism. Molecular tests are also useful in patients with late clinical manifestations, especially those with lymph node suppuration. The combination of several molecular tests allows a rapid search for several pathogens responsible for similar clinical manifestations. For example, in patients with a skin inoculation lesion and regional lymphadenopathy, PCR testing of a skin lesion biopsy allows rapid detection of *B. henselae*, *Rickettsia* spp., and *F. tularensis*.

F. tularensis culture remains the most specific diagnostic technique, providing definitive diagnostic confirmation whatever the site of its isolation, although this pathogen is most frequently isolated from blood samples. However, isolation of *F. tularensis* is challenging and classically has <10% sensitivity.

Serologic methods remain useful in patients with common clinical forms of tularemia when no clinical sample is available for culture or PCR. Serologic findings must be interpreted according to the clinical and epidemiologic context. Only seroconversion or a fourfold or greater rise in *F. tularensis* antibody titers between two serum samples collected at least 2 weeks apart is considered a diagnostic confirmation of tularemia. A single antibody titer higher than the cutoff should be interpreted cautiously and may represent a false-positive result.

TREATMENT

Tularemia

ANTIBIOTIC THERAPY

Three antibiotic classes are commonly used for tularemia treatment: the aminoglycosides, the tetracyclines, and the fluoroquinolones. No acquired resistance to these antibiotics has been reported in natural strains of *F. tularensis*. Chloramphenicol is now rarely used because of bone marrow toxicity. The β-lactams are considered ineffective and the macrolides only poorly effective; however, azithromycin is bacteriostatic in vitro against *F. tularensis* (except for B12 genotypes). **Table 170-1** summarizes current treatment recommendations for patients in the United States and Europe.

The aminoglycosides streptomycin and gentamicin remain the gold standard for the treatment of severe tularemia because of their significant and rapid bactericidal activity against *F. tularensis*. Doxycycline or a fluoroquinolone are usually prescribed for treating common clinical forms of mild to moderate severity.

TABLE 170-1 Guidelines for Tularemia Treatment and Postexposure Prophylaxis

REGION, PATIENT GROUP	
United States, Nonpregnant Adults[a]	
First line	Streptomycin, 1 g IM bid, 10 days; *or* Gentamicin,[b] 5 mg/kg IM or IV daily, 10 days
Second line	Doxycycline, 100 mg IV bid, 14–21 days; *or* Chloramphenicol,[b] 15 mg/kg IV qid, 14–21 days; *or* Ciprofloxacin,[b] 400 mg IV bid, 10 days
Prophylaxis	Doxycycline, 100 mg PO bid, 14 days; *or* Ciprofloxacin,[b] 500 mg PO bid, 14 days
United States, Pregnant Women[a]	
First line	Gentamicin,[b] 5 mg/kg IM or IV daily, 10 days; *or* Streptomycin, 1 g IM bid, 10 days
Second line	Doxycycline, 100 mg IV bid, 14–21 days; *or* Ciprofloxacin,[b] 400 mg IV bid, 10 days
Prophylaxis	Ciprofloxacin,[b] 500 mg PO bid, 14 days; *or* Doxycycline, 100 mg PO bid, 14 days
Europe, Nonpregnant Adults and Pregnant Women	
First line	Gentamicin, 5 mg/kg IM or IV daily or bid, 10 days; *or* Streptomycin, 1 g IM bid, 10 days
Second line[c]	Ciprofloxacin, 400 mg IV bid, then 500 mg PO bid, 14 days; *or* Ofloxacin, 400 mg IV bid, then 400 mg PO bid, 14 days; *or* Levofloxacin, 500 mg IV daily, then 500 mg PO daily, 14 days
Third line[c]	Doxycycline, 100 mg IV bid, then 100 mg PO bid, 21 days
Prophylaxis	Ciprofloxacin, 500 mg PO bid, 14 days; *or* Ofloxacin, 400 mg PO bid, 14 days; *or* Levofloxacin, 500 mg PO daily, 14 days; *or* Doxycycline, 100 mg PO bid, 14 days[d]

[a]Persons beginning with IM or IV doxycycline, ciprofloxacin, or chloramphenicol can switch to oral antibiotic administration when clinically indicated. [b]Not a use approved by the U.S. Food and Drug Administration. [c]Persons beginning with IV treatment can switch to oral antibiotic administration when clinically indicated. [d]Second line.

The fluoroquinolones are usually associated with lower rates of treatment failure and relapse than doxycycline.

However, the efficacy of antibiotic treatment varies dramatically with the type and duration of clinical manifestations and with immune status. Antibiotic efficacy is usually poor in curing suppurated lymphadenopathies or other soft tissue or organ abscesses. No standardized treatment has been defined for tularemia complications such as meningitis, endocarditis, and osteoarticular infections. The same holds for infections occurring in immunocompromised patients. The combination of an aminoglycoside with either doxycycline or a fluoroquinolone is often used in these specific situations, although the superiority of dual therapy over monotherapy has not been demonstrated.

For pregnant women in the United States, gentamicin is advocated as first-line treatment and doxycycline or a fluoroquinolone as second-line treatment. All these antibiotics have potential side effects on the mother and the fetus and thus are classically avoided before childbirth—most importantly, during the first trimester of pregnancy. Azithromycin has been used successfully in a few pregnant women with mild disease in western Europe, where tularemia cases are caused only by type B *F. tularensis* strains susceptible to this antibiotic.

SURGICAL TREATMENT

Removal of suppurated lymph nodes in tularemia patients with regional lymphadenopathy is the leading cause of surgical intervention. The combination of surgery and appropriate antibiotic therapy is the most effective treatment of this complication. Several surgeries are sometimes necessary for definite cure. Surgery may also be needed in other clinical situations, including skin or subcutaneous abscesses, cellulitis, deep abscesses, endocarditis, osteoarticular infections, and ocular complications.

PROGNOSIS

The prognosis of patients with tularemia depends on the patient's immune status, the clinical form of disease, and the involved *F. tularensis* strain. Classically, spontaneous mortality rates range from 5 to 15% for type A tularemia and are <1% for type B disease. With receipt of appropriate antibiotic therapy, <2% of type A tularemia patients die. The pneumonic and typhoidal forms have been associated with mortality rates up to 30%. A more recent evaluation of mortality rates in culture-confirmed tularemia cases in the United States highlighted significant variations depending on the involved *F. tularensis* genotype: 24% for A1b, 4% for A1a, 7% for B, and 0% for A2 strains. Therefore, an accurate prognostic evaluation of type A tularemia will require genotyping of the causative *F. tularensis* strain.

PREVENTION

LACK OF HUMAN-TO-HUMAN TRANSMISSION

Human-to-human transmission of *F. tularensis* is considered unlikely. In the literature, such transmission has been reported in only two specific situations: the autopsy of a person who died of tularemia and organ transplantation from a person who died of tularemia. Thus, no isolation measures for tularemia patients are necessary during routine medical care, even those with the pneumonic form of disease.

EXPOSURE PREVENTION

The most effective prophylactic measures against tularemia are those reducing the risk of exposure to *F. tularensis*. Persons manipulating potentially contaminated animals (especially lagomorphs and small rodents) or their carcasses should wear appropriate protective equipment (gloves, glasses, a respiratory mask, and protective clothing). Use of repellants against arthropods (especially ticks) is also essential in tularemia-endemic areas. Water-borne and food-borne tularemia cases can be prevented by consuming potable water and well-cooked food. Hydrotelluric sources of contamination are more challenging to identify and, therefore, to avoid. Finally, laboratory personnel handling *F. tularensis* cultures should work in biosafety level 3 facilities with appropriate safety equipment.

POSTEXPOSURE PROPHYLAXIS

The most at-risk situation is exposure to an *F. tularensis* aerosol. A highly suspected *F. tularensis* aerosol inhalation requires postexposure antibiotic prophylaxis. The need for such treatment is more easily identified for laboratory personnel handling *F. tularensis* cultures. Current recommendations are to treat the exposed person with either doxycycline or a fluoroquinolone for 14 days (Table 170-1). Subsequent medical and possibly serologic monitoring is usually carried out. At least 1 month of surveillance after the end of treatment seems reasonable.

VACCINATION

The live vaccine strain (LVS), a virulence-attenuated type B strain of *F. tularensis*, was widely used before and after World War II to vaccinate highly exposed persons (especially laboratory staff). This vaccine has been abandoned because of its limited efficacy against severe type A pneumonia, unstable colony phenotype, and potentially severe side effects at the inoculation site as well as fear of a potential reversion of LVS to a virulent strain. In recent years, significant efforts have been made to develop new and safer vaccines. *F. tularensis* mutants for metabolic enzymes, virulence factors, or regulatory proteins have been developed. However, no vaccine has currently been authorized by the U.S. Food and Drug Administration or by health protection agencies in other countries.

171 Plague and Other *Yersinia* Infections

Michael B. Prentice

PLAGUE

Plague is a systemic zoonosis caused by *Yersinia pestis*. It predominantly affects small rodents in rural areas of Africa, Asia, and the Americas and is usually transmitted to humans by an arthropod vector (the flea). Less often, infection follows contact with animal tissues or respiratory droplets. Plague is an acute febrile illness that is treatable with antimicrobial agents, but mortality rates among untreated patients are high. Ancient DNA studies have confirmed that both the fourteenth-century Black Death and the sixth-century Plague of Justinian in Europe were due to *Y. pestis* infection. Patients can present with the bubonic, septicemic, or pneumonic form of the disease. Although there is concern about epidemic spread of plague by the respiratory route, this is not the most common route of plague transmission, and established infection-control measures for respiratory plague exist. However, the fatalities associated with plague and the capacity for infection via the respiratory tract mean that *Y. pestis* fits the profile of a potential agent of bioterrorism **(Chap. S3)**. Consequently, measures have been taken to restrict access to the organism, including legislation affecting diagnostic and research procedures in some countries (e.g., the United States).

ETIOLOGY

The genus *Yersinia* comprises gram-negative bacteria of the order *Enterobacterales* (class *Gammaproteobacteria*). Overwhelming taxonomic and paleogenomic evidence shows *Y. pestis* recently evolved from *Yersinia pseudotuberculosis*, an enteric pathogen of mammals spread by the fecal–oral route, and thus has a phenotype distinctly different from that of *Y. pestis*. When grown in vivo or at 37°C, *Y. pestis* forms an amorphous capsule made from a plasmid-specified fimbrial protein, Caf or fraction 1 (F1) antigen, which is an immunodiagnostic marker of infection.

EPIDEMIOLOGY

Human plague generally follows an outbreak in a host rodent population (epizootic). Mass deaths among the rodent primary hosts lead to a search by fleas for new hosts, with consequent incidental infection of other mammals. The precipitating cause for an epizootic may ultimately be related to climate or other environmental factors. The reservoir for *Y. pestis* causing enzootic plague in natural endemic foci between epizootics (i.e., when the organism may be difficult to detect in rodents or fleas) is a topic of ongoing research and may not be the same in all regions. The enzootic/epizootic pattern may be the result of complex dynamic interactions of host rodents that have different plague susceptibilities with different flea vectors; alternatively, an environmental reservoir may be important.

GLOBAL FEATURES

In general, the enzootic areas for plague are lightly populated regions of Africa, Asia, and the Americas **(Fig. 171-1)**. Between January 2013 and December 2018, 2886 cases of plague with a global case–fatality rate of 17% were notified to the World Health Organization (WHO) under the International Health Regulations. More than 97% of these cases were in Africa. The majority of cases in each year were from the island of Madagascar, which in 2017 experienced an urban outbreak of over 2400 clinically suspected cases, with an unusually high proportion of pneumonic plague (78%). A decline in reports from the Democratic Republic of the Congo (DRC) may reflect ongoing conflict in that country affecting surveillance rather than a true decrease. In the past decade, outbreaks of pneumonic plague have been recorded in the DRC, Uganda, Algeria, Madagascar, China, and Peru.

Plague was introduced into North America via the port of San Francisco in 1900 as part of the Third Pandemic, which spread around the world from Hong Kong. The disease is presently enzootic on the western side of the continent from southwestern Canada to Mexico. Most human cases in the United States occur in two regions:

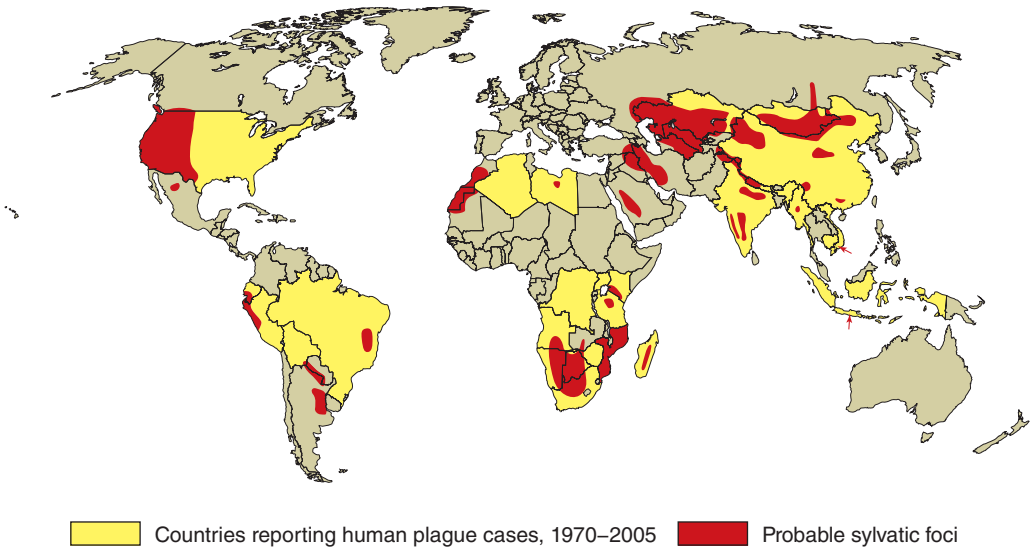

FIGURE 171-1 Approximate global distribution of *Yersinia pestis*. *(Compiled from WHO, CDC, and country sources. From DT Dennis, GL Campbell: Plague and other Yersinia infections, in Harrison's Principles of Internal Medicine, 17th ed, AS Fauci et al [eds]. New York, McGraw-Hill, Chap. 152, 2008.)*

"Four Corners" (the junction point of New Mexico, Arizona, Colorado, and Utah), especially northern New Mexico, northern Arizona, and southern Colorado; and further west in California, southern Oregon, and western Nevada *(www.cdc.gov/plague/maps/)*. From 1970 to 2017, 482 cases of plague were reported in the United States; in recent decades incidence has fallen to an average of 7 cases per year. Most cases occur from May to October—the time of year when people are outdoors and rodents and their fleas are most plentiful. Prior animal contact occurs in at least 50% of cases, and about 60% of these include domestic animals (usually dogs or cats) that brought wild animals or plague-infected fleas home. Infected cats or dogs may transmit plague directly to humans by the respiratory route. A slightly lower percentage of prior animal contacts involve direct handling of living or dead wild small mammals (e.g., rabbits, hares, prairie dogs) or wild carnivores (e.g., wildcats, coyotes, mountain lions). In 2014, an outbreak of nonfatal pneumonic plague in Colorado affected four people exposed to an infected dog, with possible interhuman transmission in one case. Prior to this report, the most recent case of person-to-person transmission in the United States occurred in the Los Angeles pneumonic plague outbreak of 1924.

Plague most often develops in areas with poor sanitary conditions and infestations of rats—in particular, the widely distributed roof rat *Rattus rattus* and the brown rat *Rattus norvegicus* (which serves as a laboratory model of plague). Rat control in warehouses and shipping facilities has been recognized as important in preventing the spread of plague since the early twentieth century and features in the current WHO International Health Regulations. Urban rodents acquire infection from wild rodents, and the proximity of the former to humans increases the risk of transmission. The oriental rat flea *Xenopsylla cheopis* is the most efficient vector for transmission of plague among rats and onward to humans in Asia, Africa, and South America.

Worldwide, bubonic plague is the predominant form reported (80–95% of suspected cases), with mortality rates of 10–20%. The mortality rate is higher (22%) in the small proportion of patients (10–20%) with primary septicemic plague (i.e., systemic *Y. pestis* sepsis with no bubo; see "Clinical Manifestations," below) and is highest with primary pulmonary plague. The latter is generally the least common of the main plague presentations, but, as in the 2017 Madagascar outbreak, it is occasionally predominant. Mortality rates of 50% or more for primary pulmonary plague are reported with delayed antimicrobial treatment in small case series from the older literature. Rare outbreaks of pharyngeal plague following consumption of raw or undercooked camel or goat meat have been reported.

A total of 744 (82%) of the 913 plague cases with clinically documented features (out of 1006 cases reported in total) in the United States from 1900 to 2012 were bubonic disease, 87 (10%) were septicemic disease, and 74 (8%) were pneumonic disease; 6 cases (1%) were pharyngeal. Sixteen percent of cases were fatal in the postantibiotic era from 1942 onward compared with 66% in the period 1900–1941.

PATHOGENESIS

As mentioned earlier, genetic evidence shows *Y. pestis* is a clone derived from the enteric pathogen *Y. pseudotuberculosis* in the recent evolutionary past (7000–50,000 years ago). The change from infection by the fecal–oral route to a two-stage life cycle, with alternate parasitization of arthropod and mammalian hosts, occurred as a result of two plasmid gene acquisitions (*pla* on pPCP1/pPst and *ymt* on pFra/pMT1), and the inactivation of a handful of *Y. pseudotuberculosis* genes, in conjunction with preexisting properties of the *Y. pseudotuberculosis* ancestor, including the presence of a virulence plasmid, pYV, and the capacity to cause septicemia. In the arthropod-parasitizing portion of its life cycle, *Y. pestis* multiplies and forms biofilm-embedded aggregates in the flea midgut after ingestion of a blood meal containing bacteria. In some fleas, biofilm-embedded bacteria eventually fill the proventriculus (a valve connecting the esophagus to the midgut) and block normal blood feeding. Both "blocked" fleas and those containing masses of biofilm-embedded *Y. pestis* without complete blockage inoculate *Y. pestis* into each bite site. The ability of *Y. pestis* to colonize and multiply in the flea requires phospholipase D encoded by the *ymt* gene on the pFra (pMT1) plasmid, and biofilm synthesis requires the chromosomal *hms* locus shared with *Y. pseudotuberculosis*. Three *Y. pseudotuberculosis* genes inhibiting biofilm formation or promoting its degradation are inactivated in *Y. pestis*, together with urease (urease activity otherwise causes acute flea gastrointestinal toxicity). Blockage takes days or weeks to come about after initial infection of the flea and is followed by the flea's death. Many flea vectors (including *X. cheopis*) are also able to transmit plague in an early-phase unblocked state for up to a week after feeding, but 10 fleas in this state are required to infect a mammalian host (mass transmission).

Y. pestis disseminates from the site of inoculation in the mammalian host in a process initially dependent on plasminogen activator Pla, which is encoded by the small pPCP1 (pPst) plasmid. This surface protease activates mammalian plasminogen, degrades complement, and adheres to the extracellular matrix component laminin. Pla is essential for the high-level virulence of *Y. pestis* in mice by subcutaneous or intradermal injection (laboratory proxies for fleabites) and for the development of primary pneumonic plague. When actual fleabite inoculation is used in mouse models, the fimbrial capsule-forming protein (Ca1 or fraction 1; F1 antigen) encoded on pFra increases the efficiency of transmission, and plasminogen activator is required for the formation of buboes.

Paleogenomics (sequencing of DNA extracts from teeth of ancient human remains) shows that *Y. pestis* was a common cause of death in Eurasia in the Bronze age. Remarkably, the *ymt* gene is absent from the pFra (pMT1) plasmid in *Y. pestis* sequences from remains more than 4000 years old, while *pla* is present. This suggests that plague was a common fatal human infection before flea-borne transmission was possible, presumably spread by the pneumonic or gastrointestinal route.

Macrophages, neutrophils, and dendritic cells are all involved in the innate immune response to flea-transmitted *Y. pestis*. The organism is taken up by macrophages but avoids being killed by autophagy and can also survive and replicate in neutrophils. Rapid transport of the bacteria to regional lymph nodes occurs. *Y. pestis* then undergoes extracellular replication with full expression of its antiphagocytic systems: the type III secretion machines and their effectors encoded by pYV as well as the F1 capsule. These factors prevent neutrophil uptake, and the type III secretion effectors also block extrusion of microbicidal DNA by neutrophils and trigger apoptotic cell death. Immune cell targeting follows binding of the N-formylpeptide receptor (FPR1) on phagocytic cells by LcrV, the needle cap protein of the type III secretion system. Overproduction of LcrV also exerts an anti-inflammatory effect, reducing host immune responses. Likewise, *Y. pestis* lipopolysaccharide is modified to minimize stimulation of host Toll-like receptor 4, thereby reducing protective host inflammatory responses during peripheral infection and prolonging host survival with high-grade bacteremia—an effect that probably enhances the pathogen's subsequent transmission by fleabite.

Replication of *Y. pestis* in a regional lymph node results in the local swelling of the lymph node and periglandular region known as a *bubo*. On histology, the node is found to be hemorrhagic or necrotic, with thrombosed blood vessels, and the lymphoid cells and normal architecture are replaced by large numbers of bacteria and fibrin. Periglandular tissues are inflamed and also contain large numbers of bacteria in a serosanguineous, gelatinous exudate.

Continued spread through the lymphatic vessels to contiguous lymph nodes produces second-order primary buboes. Infection is initially contained in the infected regional lymph nodes, although transient bacteremia can be detected. As infection progresses, spread via efferent lymphatics to the thoracic duct produces high-grade bacteremia. Hematogenous spread to the spleen, liver, and secondary buboes follows, with subsequent uncontrolled septicemia leading to death. In some patients, this septicemic phase occurs without obvious prior bubo development or lung disease (septicemic plague). Hematogenous spread to the lungs results in secondary plague pneumonia, with bacteria initially more prominent in the interstitium than in the air spaces (the reverse being the case in primary plague pneumonia). Hematogenous spread to other organs, including the meninges, can occur.

CLINICAL MANIFESTATIONS

Bubonic Plague After an incubation period of 2–6 days, the onset of bubonic plague is sudden and is characterized by fever (>38°C), malaise, myalgia, dizziness, and increasing pain due to progressive lymphadenitis in the regional lymph nodes near the fleabite or other inoculation site. Lymphadenitis manifests as a tense, tender swelling (bubo) that, when palpated, has a boggy consistency with an underlying hard core. Generally, there is one painful and erythematous bubo with surrounding periganglionic edema. The bubo is most commonly inguinal but can also be crural, axillary **(Fig. 171-2)**, cervical, or submaxillary, depending on the site of the bite. Abdominal pain from intraabdominal node involvement can occur without other visible signs. Children are most likely to present with cervical or axillary buboes.

The differential diagnosis includes acute focal lymphadenopathy of other etiologies, such as streptococcal or staphylococcal infection, tularemia, cat-scratch disease, tick typhus, infectious mononucleosis, or lymphatic filariasis. These infections do not progress as rapidly, are not as painful, and are associated with visible cellulitis or ascending lymphangitis—both of which are absent in plague.

Without treatment, *Y. pestis* dissemination occurs and causes serious illness, including pneumonia (secondary pneumonic plague) and meningitis. Secondary pneumonic plague can be the source of person-to-person transmission of respiratory infection by productive cough (droplet infection), with the consequent development of primary plague pneumonia. Appropriate treatment of bubonic plague results in fever resolution within 2–5 days, but buboes may remain enlarged for >1 week after initial treatment and can become fluctuant.

Primary Septicemic Plague A minority (10–25%) of infections with *Y. pestis* present as gram-negative septicemia (hypotension, shock) without preceding lymphadenopathy. Septicemic plague occurs in all age groups, but persons >40 years of age are at elevated risk. Some chronic conditions may predispose to septicemic plague: in 2009 in the United States, a fatal laboratory-acquired infection with an attenuated *Y. pestis* strain manifested as septicemic plague in a 60-year-old researcher with diabetes mellitus and undiagnosed hemochromatosis. These conditions also carry an increased risk of septicemia with other pathogenic *Yersinia* species. The term *septicemic plague* can be confusing since most patients with buboes have detectable bacteremia at some stage, with or without systemic signs of sepsis. In laboratory experiments, however, septicemic disease without histologic changes in lymph nodes is seen in a minority of mice infected via fleabites.

FIGURE 171-2 Plague patient in the southwestern United States with a left axillary bubo and an unusual plague ulcer and eschar at the site of the infective flea bite. *(Reproduced with permission from AS Fauci et al: Harrison's Principles of Internal Medicine, 17th ed. New York: McGraw-Hill; 2008.)*

Pneumonic Plague Primary pneumonic plague results from inhalation of infectious bacteria in droplets expelled from another person or an animal with primary or secondary plague pneumonia. This syndrome has a short incubation period, averaging from a few hours to 2–3 days (range, 1–7 days), and is characterized by a sudden onset of fever, headache, myalgia, weakness, nausea, vomiting, and dizziness. Respiratory signs—cough, dyspnea, chest pain, and sputum production with hemoptysis—typically arise after 24 h. Progression of initial segmental pneumonitis to lobar pneumonia and then to bilateral lung involvement may occur **(Fig. 171-3)**. The possible release of aerosolized *Y. pestis* bacteria in a bioterrorist attack, manifesting as an outbreak of primary pneumonic plague in nonendemic regions or in an urban setting where plague is rarely seen, has been a source of public health concern. Secondary pneumonic plague is a consequence of bacteremia occurring in ~10–15% of patients with bubonic plague. Bilateral alveolar infiltrates are seen on chest x-ray, and diffuse interstitial pneumonitis with scanty sputum production is typical.

Meningitis Meningeal plague is uncommon, occurring in ≤6% of plague cases reported in the United States. Presentation with headache and fever typically occurs >1 week after the onset of bubonic or septicemic plague and may be associated with suboptimal antimicrobial therapy (delayed therapy, penicillin administration, or low-dose tetracycline treatment) and cervical or axillary buboes.

Pharyngitis Symptomatic plague pharyngitis can follow the consumption of contaminated meat from an animal dying of plague or contact with persons or animals with pneumonic plague. This condition can resemble tonsillitis, with peritonsillar abscess and cervical lymphadenopathy. Asymptomatic pharyngeal carriage of *Y. pestis* can also occur in close contacts of patients with pneumonic plague.

LABORATORY DIAGNOSIS

Because of the scarcity of laboratory facilities in regions where human *Y. pestis* infection is most common, and because of the potential significance of *Y. pestis* isolation in a nonendemic area or an area from which human plague has been absent for many years, the WHO recommends an initial presumptive diagnosis followed by reference laboratory confirmation **(Table 171-1)**. In the United States, comprehensive national diagnostic facilities for plague have been in place since 1999 (Laboratory Response Network for Biological Threats; *emergency.cdc.gov/lrn/*) to detect possible use of biological terrorism agents, including *Y. pestis*. Routine diagnostic clinical microbiology laboratories that are included in this network as sentinel-level laboratories use joint protocols from the Centers for Disease Control and Prevention (CDC) and the American Society for Microbiology *(https://asm.org/Articles/Policy/Laboratory-Response-Network-LRN-Sentinel-Level-C)* to identify suspected *Y. pestis* isolates and to refer these specimens to LRN reference laboratories for confirmatory tests. *Y. pestis* is designated a "Tier 1 select agent" under the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 and subsequent executive orders; the provisions of this act, the Patriot Act of 2001, and related executive orders apply to all U.S. laboratories and individuals working with *Y. pestis*. Details of the applicable regulations are available from the CDC (*www.selectagents.gov*).

Yersinia species are gram-negative coccobacilli (short rods with rounded ends) 1–3 μm in length and 0.5–0.8 μm in diameter. *Y. pestis* in particular appears bipolar (with a "closed safety pin" appearance) and pleomorphic when stained with a polychromatic stain (Wayson or Wright-Giemsa; **Fig. 171-4**). Its lack of motility distinguishes *Y. pestis* from other *Yersinia* species, which are motile at 25°C and nonmotile at 37°C. Transport medium (e.g., Cary-Blair medium) preserves the viability of *Y. pestis* if transport is delayed.

The appropriate specimens for diagnosis of bubonic, pneumonic, and septicemic plague are bubo aspirate, bronchoalveolar lavage fluid or sputum, and blood, respectively. Culture of postmortem organ biopsy samples also can be diagnostic. A bubo aspirate is obtained

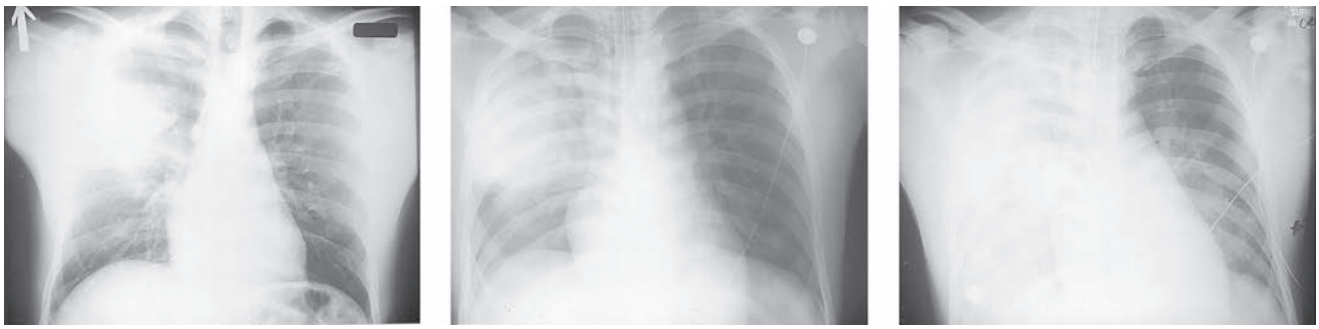

FIGURE 171-3 Sequential chest radiographs of a patient with fatal primary plague pneumonia. ***Left:*** Upright posteroanterior film taken at admission to hospital emergency department on third day of illness, showing segmental consolidation of right upper lobe. ***Center:*** Portable anteroposterior film taken 8 h after admission, showing extension of pneumonia to right middle and right lower lobes. ***Right:*** Portable anteroposterior film taken 13 h after admission (when patient had clinical acute respiratory distress syndrome), showing diffuse infiltration throughout right lung and patchy infiltration of left lower lung. A cavity later developed at the site of initial right-upper-lobe consolidation. *(Reproduced with permission from AS Fauci et al: Harrison's Principles of Internal Medicine, 17th ed. New York: McGraw-Hill; 2008.)*

by injection of 1 mL of sterile normal saline into a bubo under local anesthetic and aspiration of a small amount of (usually blood-stained) fluid. The WHO has provided interim guidance on how to aspirate buboes and collect sputum from patients with suspected pneumonic plague (*www.who.int/csr/disease/plague/collecting-sputum-samples.PDF*). Gram's staining of these specimens may reveal gram-negative rods, which are shown by Wayson or Wright-Giemsa staining to be bipolar. These bacteria may even be visible in direct blood smears in septicemic plague (Fig. 171-4); this finding indicates very high numbers of circulating bacteria and a poor prognosis.

Y. pestis grows on nutrient agar and other standard laboratory media but forms smaller colonies than do other Enterobacteriaceae. Specimens should be inoculated onto nutrient-rich media such as sheep blood agar (SBA), into nutrient-rich broth such as brain-heart infusion broth, and onto selective agar such as MacConkey or eosin methylene blue (EMB) agar. *Yersinia*-specific CIN (cefsulodin, triclosan [Irgasan], novobiocin) agar can be useful for culture of contaminated specimens, such as sputum. Blood should be cultured in a standard blood culture system. The optimal growth temperature is <37°C (25–29°C), with pinpoint colonies only on SBA at 24 h. Slower growth occurs at 37°C. *Y. pestis* is oxidase-negative, catalase-positive, urease-negative, indole-negative, and lactose-negative. Automated biochemical or mass spectrometry identification systems can misidentify *Y. pestis* as *Y. pseudotuberculosis* or other bacterial species.

Reference laboratory tests for definitive identification of isolates include direct immunofluorescence for F1 antigen; specific polymerase chain reaction (PCR) for targets such as F1 antigen, the pesticin gene, and the plasminogen activator gene; and specific bacteriophage lysis. PCR can also be applied to diagnostic specimens, as can direct immunofluorescence for F1 antigen (produced in large amounts by *Y. pestis*) by slide microscopy. An immunochromatographic test strip for F1 antigen detection by monoclonal antibodies in clinical specimens has been devised in Madagascar. This method is effective for both laboratory and near-patient use and is now widely used in endemic countries. A similar test strip for Pla antigen has been developed and could be used to detect wild-type or engineered F1-negative virulent strains. In

TABLE 171-1 World Health Organization Case Definitions of Plague

Suspected Case
Compatible clinical presentation
And
Consistent epidemiologic features, such as exposure to infected animals or humans and/or evidence of fleabites and/or residence in or travel to a known endemic focus within the previous 10 days
Presumptive Case
Meeting the definition of a suspected case
Plus
Putative new or reemerging focus: ≥2 of the following tests positive
• Microscopy: gram-negative coccobacilli in material from bubo, blood, or sputum; bipolar appearance of Wayson or Wright-Giemsa staining
• F1 antigen detected in bubo aspirate, blood, or sputum
• A single anti-F1 serology without evidence of previous *Yersinia pestis* infection or immunization
• PCR detection of *Y. pestis* in bubo aspirate, blood, or sputum
Known endemic focus: ≥1 of the above tests positive
Confirmed Case
Meeting the definition of a suspected case
Plus
• Identification of an isolate from a clinical sample as *Y. pestis* (colonial morphology and 2 of the following 4 tests positive: phage lysis of cultures at 20–25°C and 37°C; F1 antigen detection; PCR; *Y. pestis* biochemical profile)
Or
• A fourfold rise in anti-F1 titer in paired serum samples
Or
• In endemic areas when no other confirmatory test can be performed, a positive rapid diagnostic test with immunochromatography to detect F1 antigen

Abbreviation: PCR, polymerase chain reaction.

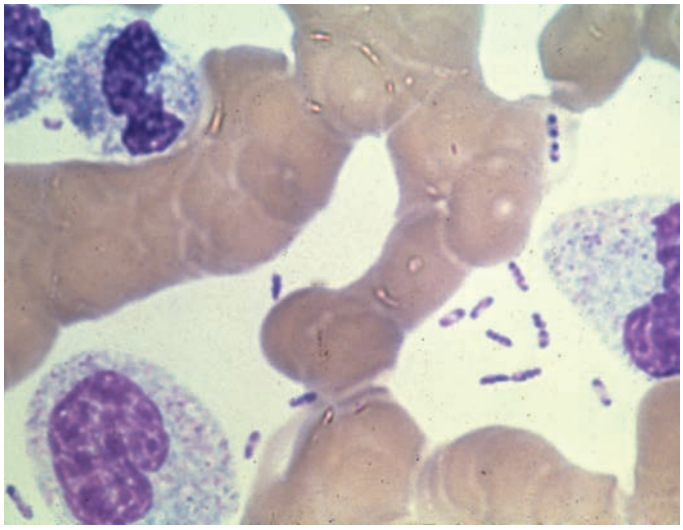

FIGURE 171-4 Peripheral-blood smear from a patient with fatal plague septicemia and shock, showing characteristic bipolar-staining *Yersinia pestis* bacilli (Wright's stain, oil immersion). *(Reproduced with permission from AS Fauci et al: Harrison's Principles of Internal Medicine, 17th ed. New York: McGraw-Hill; 2008.)*

the 2017 Madagascar outbreak, diagnosis by F1-antigen strip or molecular diagnosis from sputum proved more challenging than from bubo aspirates because of the normal respiratory microbiota. Twenty-three percent of pneumonic plague cases had a positive culture, strip, or molecular diagnostic test compared to 45% of bubonic cases. This suggests assays involving multiple real-time PCR targets are required to augment conventional culture with sputum. *Yersinia pestis* is included in the FDA-authorized Biofire® FilmArray® Next Generation Diagnostic System (NGDS) Warrior Panel for use with the FilmArray® 2.0 system (Biomérieux) as a medical diagnostic device suitable for whole blood (EDTA), blood cultures and sputum specimens by U.S. Department of Defense laboratories, and laboratories designated by the Department of Defense. Detailed phylogeographic DNA sequence data based on culture collections have been accumulated to trace plague evolution, and this approach could be adapted in the future to real-time clinical plague epidemiology.

In the absence of other positive laboratory diagnostic tests, a retrospective serologic diagnosis may be made on the basis of rising titers of hemagglutinating antibody to F1 antigen. Enzyme-linked immunosorbent assays (ELISAs) for IgG and IgM antibodies to F1 antigen are also available.

The white blood cell (WBC) count is generally raised (to 10,000–20,000/μL) in plague, with neutrophilic leukocytosis and a left shift (numerous immature neutrophils); in some cases, however, the WBC count is normal or leukopenia develops. WBC counts are occasionally very high, especially in children (>100,000/μL). Levels of fibrinogen degradation products are elevated in a majority of patients, but platelet counts are usually normal or low-normal. However, disseminated intravascular coagulation, with low platelet counts, prolonged prothrombin times, reduced fibrinogen, and elevated fibrinogen degradation product levels, occurs in a significant minority of patients.

TREATMENT

Plague

Guidelines for the treatment of plague are given in Table 171-2. A 10- to 14-day course of antimicrobial therapy (or a course continued until 2 days after fever subsides) is recommended. Streptomycin has historically been the parenteral treatment of choice for plague and is approved for this indication by the FDA. Although not yet approved by the FDA for plague, gentamicin has proved safe and effective in clinical trials in Tanzania and Madagascar and in retrospective reviewed cases in the United States. In view of streptomycin's adverse-reaction profile and limited availability, some experts now recommend gentamicin over streptomycin. The FDA has approved levofloxacin, moxifloxacin, and ciprofloxacin for prophylaxis and treatment of plague (including septicemic and pneumonic plague) under a regulatory approach based on animal studies alone, known as the Animal Rule. Levofloxacin has more efficacy than ciprofloxacin in postexposure prophylaxis of inhalational anthrax in animal models and has also received FDA approval for this indication (Chap. S3); thus it is a suitable agent for prophylaxis against two diseases in possible bioterrorism exposures.

While systemic chloramphenicol therapy is available in the resource-poor countries primarily affected by plague, it is less likely to be available or used in high-income countries because of its adverse-effect profile. Tetracyclines are also effective and can be given by mouth but are not generally recommended for children age <7 years because of tooth discoloration. Doxycycline is the tetracycline of choice; at an oral dosage of 100 mg twice daily, this drug was as effective as intramuscular gentamicin (2.5 mg/kg twice daily) in a trial in Tanzania. There is recent evidence that doxycycline does not cause dental staining in children because it binds calcium less readily than other tetracyclines. Because of reduced efficacy in some non-human primate models of pneumonic plague, CDC recommends doxycycline as a first line agent for bubonic plague and an alternative agent for septicemic and pneumonic plague.

TABLE 171-2 Guidelines for the Treatment of Plague

DRUG	DAILY DOSE	DOSING INTERVAL, h	ROUTE
Gentamicin			
Adult	5 mg/kg[a]	24	IM/IV
Child	4.5-7.5 mg/kg[a]	24	IM/IV
Streptomycin			
Adult	2 g	12	IM
Child	30 mg/kg (maximum 1 g per dose)	12	IM
Levofloxacin			
Adult (child >50 kg)	750 (500-750) mg	24	PO/IV
Child <50 kg and ≥6 months of age	16 mg/kg (maximum, 250 mg/dose)	12	PO/IV
Ciprofloxacin			
Adult	1500 mg	12	PO
	1200 mg	8	IV
Child	30-45 mg/kg (maximum, 500 mg/dose)	8-12	PO
	20-30 mg/kg (maximum, 400 mg/dose)	8-12	IV
Moxifloxacin			
Adult	400 mg (no loading dose)	24	PO/IV
Doxycycline			
Adult and child ≥45 kg	200 mg (200 mg loading dose)	12	PO/IV
Child <45 kg	4.4 mg/kg (maximum, 100 mg/dose), 4.4 mg/kg loading dose	12	PO/IV
Tetracycline			
Adult	2 g	6	PO/IV
Child >8 yr	40–50 mg/kg	6	PO/IV
Chloramphenicol			
Adult	50-100 mg/kg	6	PO/IV
Child >2 yr	50-100 mg/kg (maximum, 4 g)	6	PO/IV

[a]Aminoglycoside dose is adjusted with impaired renal function. No trial data have been published for once-daily gentamicin therapy for plague in adults or children, but this regimen is efficacious in gram-negative sepsis of other etiologies and has been successful in a recent outbreak of pneumonic plague in the Democratic Republic of the Congo. Neonates (up to 1 week of age) should receive gentamicin at 4 mg/kg IV once daily.

JAMA 283:2281, 2000; and *https://www.cdc.gov/plague/healthcare/clinicians.html*. For detailed guidelines on recommended regimens for pneumonic vs bubonic plague, plague meningitis, treatment during pregnancy and lactation, and neonatal infection see CA Nelson et al: Antimicrobial treatment and prophylaxis of plague: Recommendations for naturally acquired infections and bioterrorism response. MMWR Recomm Rep 70(No. RR-3):1, 2021.

Although *Y. pestis* is sensitive to β-lactam drugs in vitro and these drugs have been efficacious against plague in some animal models, the response to penicillins has been poor in some clinical cases; thus β-lactams and macrolides are not generally recommended as first-line therapy. Chloramphenicol, alone or in combination, is recommended for some focal complications of plague (e.g., meningitis, endophthalmitis, myocarditis) because of its tissue penetration properties. Fluoroquinolones, effective in vitro and in animal models, are recommended in guidelines for possible bioterrorism-associated pneumonic plague and are increasingly used in plague therapy.

PREVENTION

In endemic areas, the control of plague in humans is based on reduction of the likelihood of being bitten by infected fleas or exposed to

infected droplets from either humans or animals with plague pneumonia. In the United States, residence and outdoor activity or contact with wild or pet animals in rural areas of western states where epizootics occur are the main risk factors for infection. To assess potential risks to humans in specific areas, surveillance for *Y. pestis* infection among animal plague hosts and vectors is carried out regularly as well as in response to observed animal die-offs. Personal protective measures include avoidance of areas where a plague epizootic has been identified and publicized (e.g., by warning signs or closure of campsites). Sick or dead animals should not be handled by the general public. Hunters, zoologists and pet-owners should wear gloves if handling wild-animal carcasses in endemic areas. General measures to avoid rodent fleabite during outdoor activity are appropriate and include the use of insect repellent, insecticide, and protective clothing. General measures to reduce peridomestic and occupational human contact with rodents are advised and include rodent-proofing of buildings and food-waste stores and removal of potential rodent habitats (e.g., woodpiles and junk heaps). Flea control by insecticide treatment of wild rodents is an effective means of minimizing human contact with plague if an epizootic is identified in an area close to human habitation. Any attempt to reduce rodent numbers must be preceded by flea suppression to reduce the migration of infected fleas to human hosts. An oral F1-V subunit vaccine using raccoon poxvirus (RCN) as a vector (sylvatic plague vaccine) is partially protective against plague when administered to wild prairie dogs in field trials and may in the future provide a means of reducing the risk of human exposure to *Y. pestis*.

Patients in whom pneumonic plague is suspected should be managed in isolation (with negative pressure, if available), with droplet precautions observed until pneumonia is excluded or effective antimicrobial therapy has been given for 48 h. Review of the literature published before the advent of antimicrobial agents suggests that the main infective risk is posed by patients in the final stages of disease who are coughing up sputum with plentiful visible blood and/or pus. Cotton and gauze masks were protective in these circumstances. Current surgical masks capable of barrier protection against droplets, including large respiratory particles, are probably protective, but the differential diagnosis of fever and hemoptysis in plague-endemic areas includes aerosol-transmitted infections such as tuberculosis. In addition, WHO guidance recommends that personal protective equipment for potential aerosol-generating procedures (e.g., collection of respiratory samples from patients with suspected or confirmed plague) should include a fit-tested N95 face mask, a gown, gloves, and a face shield or goggles.

Antimicrobial Prophylaxis Postexposure antimicrobial prophylaxis lasting 7 days is recommended following household, hospital, or other close contact with persons with untreated pneumonic plague. (*Close contact* is defined as contact with a patient at <2 m.) In animal aerosol-infection studies, levofloxacin and ciprofloxacin are associated with higher survival rates than doxycycline **(Table 171-3)**.

Immunization Studies with candidate plague vaccines in animal models show that neutralizing antibody provides protection against exposure but that cell-mediated immunity is critical for protection and clearance of *Y. pestis* from the host. A killed whole-cell vaccine used in humans required multiple doses, caused significant local and systemic reactions, and was not protective against pneumonic plague; this vaccine is not currently available. A live attenuated vaccine based on strain EV76 is still used in countries of the former Soviet Union and China but has significant side effects. Different subunit vaccines devised by governmental agencies in the United States, UK, and China all comprising recombinant F1 (rF1) and various recombinant V (rV) proteins produced in *Escherichia coli*, combined either as a fusion protein or as a mixture, purified, and adsorbed to aluminum hydroxide for injection are close to licensing. This combination protects mice and various nonhuman primates in laboratory models of bubonic and pneumonic plague and has been evaluated in phase 2 clinical trials. Prelicensing field-efficacy studies (phase 3 trials) are difficult to devise because of plague epidemiology. In the United States, the FDA will assess plague vaccines for human use under the Animal Rule, using efficacy data from animal studies and antibodies and other correlates of immunity from human vaccinees *(www.fda.gov/emergencypreparedness/counterterrorism/medicalcountermeasures/mcmregulatoryscience/ucm391604.htm),* and the rF1-V subunit vaccine has orphan drug status. The World Health Organization has produced a target product profile (TPP) for phase 3 trial design and prioritization of the 17 known vaccine candidates. These include protein subunit vaccines, live-attenuated vaccines, and bacterial, viral, and bacteriophage vectors, or outer membrane vesicles, carrying *Y. pestis* antigens. Antigens other than F1 and V are being investigated because of the recovery of F1-negative *Y. pestis* strains from natural sources and the observation that F1 antigen is not required for virulence in primate models of pneumonic plague.

TABLE 171-3 Guidelines for Plague Prophylaxis

DRUG	DAILY DOSE	DOSING INTERVAL, h	ROUTE
Doxycycline			
Adult	200 mg	12 or 24	PO
Child ≥8 y	≥45 kg: adult dose	12	PO
	≤45 kg: 2.2 mg/kg bid (maximum, 200 mg)	12	PO
Tetracycline			
Adult	2 g	6 or 12	PO
Child ≥8 y	40 mg/kg (maximum 500 mg/dose)	6 or 12	PO
Levofloxacin			
Adult and child >50 kg	500-750 mg	24	PO
Child <50 kg and ≥6 months of age	16 mg/kg (maximum, 250 mg/dose)	12	PO
Ciprofloxacin			
Adult	1-1.5 g	12	PO
Child	30 mg/kg (maximum 750 mg dose)	12	PO

YERSINIOSIS

Yersiniosis is a zoonotic infection with an enteropathogenic *Yersinia* species, usually *Y. enterocolitica* or *Y. pseudotuberculosis*. The usual hosts for these organisms are pigs and other wild and domestic animals; humans are usually infected by the oral route, and outbreaks from contaminated food occur. Yersiniosis is most common in childhood and in colder climates. Patients present with abdominal pain and sometimes with diarrhea (which may not occur in up to 50% of cases). *Y. enterocolitica* is more closely associated with terminal ileitis and *Y. pseudotuberculosis* with mesenteric adenitis, but both organisms may cause mesenteric adenitis and symptoms of abdominal pain and tenderness that result in pseudoappendicitis, with the surgical removal of a normal appendix. Diagnosis was historically based on culture of the organism or convalescent serology, but proprietary multiplex PCR systems for gastrointestinal infection diagnosis now include *Y. enterocolitica*. *Y. pseudotuberculosis* and some rarer strains of *Y. enterocolitica* (serogroup O:8) are especially likely to cause systemic infection, which is also more likely in patients with diabetes or iron overload. Systemic sepsis is treatable with antimicrobial agents, but postinfective arthropathy responds poorly to such therapy. Sixteen other *Yersinia* species lacking the virulence plasmid pYV common to *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica* are now recognized. These are, at most, opportunistic pathogens of humans (*Y. aldovae*, *Y. aleksiciae*, *Y. bercovieri*, *Y. entomophaga*, *Y. frederiksenii*, *Y. hibernica*, *Y. intermedia*, *Y. kristensenii*, *Y. massiliensis*, *Y. mollaretii*, *Y. nurmii*, *Y. pekkanenii*, *Y. rohdei*, *Y. similis*, *Y. ruckeri*, *and Y. wautersii*). Whole genome sequencing has recently detected several more probable novel *Yersinia* species. Molecular phylogeny shows that *Y. enterocolitica* is more distantly related to *Y. pseudotuberculosis* than these other

Yersinia species, and the similar virulence plasmid they share has probably been acquired independently by at least one of the two since the species diverged.

EPIDEMIOLOGY

Y. enterocolitica *Y. enterocolitica* is found worldwide and has been isolated from a wide variety of wild and domestic animals and environmental samples, including samples of food and water. In vitro, *Y. enterocolitica* is resistant to predation by the protozoon *Acanthamoeba castellani* and can survive inside it, suggesting a possible mode of environmental persistence. Strains are differentiated by combined biochemical reactions (biovar) and serogroup, and increasingly by whole genome sequence. Most clinical infections are associated with serogroups O:3, O:9, and O:5,27, with a declining number of O:8 infections in North America. Some O:8 infections, previously confined to North America, have been reported from Europe and Japan in recent years, and O:8 infections caused a high percentage of yersiniosis cases in Poland in 2008–2011, with a subsequent decline. Yersiniosis, >99% due to *Y. enterocolitica*, remains the third commonest bacterial food-borne zoonosis reported in Europe, especially prevalent in Germany and Scandinavia. The incidence is highest among children; children <4 years of age are more likely to present with diarrhea than are older children. Abdominal pain with mesenteric adenitis and terminal ileitis is more prominent among older children and adults. Septicemia is more likely in patients with preexisting conditions such as diabetes mellitus, liver disease, any condition involving iron overload (including thalassemia and hemochromatosis), advanced age, malignancy, or HIV/AIDS. As in enteritis of other bacterial etiologies, postinfective complications such as reactive arthritis occur mainly in individuals who are HLA-B27 positive. Erythema nodosum **(Fig. A1-39)** following *Yersinia* infection is not associated with HLA-B27 and is more common among women than among men.

Consumption or preparation of raw pork products (such as chitterlings) and some processed pork products is strongly linked with infection because a high percentage of pigs carry pathogenic *Y. enterocolitica* strains. Outbreaks of *Y. enterocolitica* infection have been associated with consumption of milk (pasteurized, unpasteurized, and chocolate-flavored) and various foods contaminated with spring water. Person-to-person transmission is suspected in a few cases (e.g., in nosocomial and familial outbreaks) but is much less likely with *Y. enterocolitica* than with other causes of gastrointestinal infection, such as *Salmonella*. A multivariate analysis indicates that contact with companion animals is a risk factor for *Y. enterocolitica* infection among children in Sweden, and low-level colonization of dogs and cats with *Y. enterocolitica* has been reported. Transfusion-associated septicemia due to *Y. enterocolitica*, while recognized as a very rare but frequently fatal event for >30 years, has been difficult to eradicate.

Y. pseudotuberculosis *Y. pseudotuberculosis* is much less frequently reported as a cause of human disease than *Y. enterocolitica*, and infection with *Y. pseudotuberculosis* is more likely to present as fever and abdominal pain due to mesenteric lymphadenitis and to be identified from a blood culture isolate. This organism is associated with wild mammals (rodents, rabbits, and deer), birds, and domestic pigs. Although outbreaks are generally rare, several have recently occurred in Finland in association with consumption of lettuce, raw carrots, or unpasteurized milk. Strains have historically been differentiated by combined biochemical reactions (biovar) and serogroup. Multilocus sequence typing shows that some strains previously assigned to *Y. pseudotuberculosis* belong to the closely related but distinct species now called *Yersinia wautersii* (opportunistic pathogenic) and *Yersinia similis* (nonpathogenic).

PATHOGENESIS

The usual route of infection is oral. Studies with both *Y. enterocolitica* and *Y. pseudotuberculosis* in animal models suggest that initial replication in the small intestine is followed by invasion of Peyer's patches of the distal ileum via M cells, with onward spread to mesenteric lymph nodes. The liver and spleen also can be involved after oral infection. The characteristic histologic appearance of enteropathogenic *Yersinia* after invasion of host tissues is as extracellular microabscesses surrounded by an epithelioid granulomatous lesion.

Experiments involving oral infection of mice with tagged *Y. enterocolitica* show that only a very small proportion of bacteria in the gut invade tissues. Individual bacterial clones from an orally inoculated pool give rise to each microabscess in a Peyer's patch, and the host restricts the invasion of previously infected Peyer's patches. A prior model positing progressive bacterial spread from Peyer's patches and mesenteric lymph nodes to the liver and spleen appears to be inaccurate: spread of *Y. pseudotuberculosis* and *Y. enterocolitica* to the liver and spleen of mice occurs independently of regional lymph node colonization and in mice lacking Peyer's patches.

Invasion requires the expression of several nonfimbrial adhesins, such as invasin (Inv) and—in *Y. pseudotuberculosis*—*Yersinia* adhesin A (YadA). Inv interacts directly with β1 integrins, which are expressed on the apical surfaces of M cells but not enterocytes. YadA of *Y. pseudotuberculosis* interacts with extracellular matrix proteins such as collagen and fibronectin to facilitate host cell integrin association and invasion. YadA of *Y. enterocolitica* lacks a crucial N-terminal region and binds collagen and laminin but not fibronectin and does not cause invasion. Inv is chromosomally encoded, whereas YadA is encoded on the virulence plasmid pYV. YadA also helps to confer serum resistance in *Y. enterocolitica* by binding host complement regulators such as factor H and C4-binding protein. Another chromosomal gene, *ail* (attachment and invasion locus), encodes the extracellular protein Ail, which is the main factor conferring serum resistance in *Y. pseudotuberculosis* by binding these complement regulators.

By binding to host cell surfaces, YadA allows targeting of immune effector cells by the pYV plasmid–encoded type III secretion system (injectisome). As a consequence, the host's innate immune response is altered; toxins (*Yersinia* outer proteins, or Yops) are injected into host macrophages, neutrophils, and dendritic cells, affecting signal transduction pathways, resulting in reduced phagocytosis and inhibited production of reactive oxygen species by neutrophils, and triggering apoptosis of macrophages. Other factors functional in invasive disease include yersiniabactin (Ybt), a siderophore produced by some strains of *Y. pseudotuberculosis* and *Y. enterocolitica* as well as other *Enterobacterales*. Ybt allows bacteria to access iron from saturated lactoferrin during infection and reduces production of reactive oxygen species by innate immune effector cells, thereby decreasing bacterial killing. *Y. pseudotuberculosis* and *Y. pestis* make other siderophores apart from Ybt.

CLINICAL MANIFESTATIONS

Self-limiting diarrhea is the most common reported presentation in infection with pathogenic *Y. enterocolitica*, especially in children <4 years of age, who form the single largest group in most case series. Blood may be detected in diarrheal stool. Older children and adults are more likely than younger children to present with abdominal pain, which can be localized to the right iliac fossa—a situation that often leads to laparotomy for presumed appendicitis (pseudoappendicitis). Appendectomy is not indicated for *Yersinia* infection causing pseudoappendicitis. Thickening of the terminal ileum and cecum is seen on endoscopy and ultrasound, with elevated round or oval lesions that may overlie Peyer's patches. Mesenteric lymph nodes are enlarged. Ulcerations of the mucosa are noted on endoscopy. Gastrointestinal complications include granulomatous appendicitis, a chronic inflammatory condition affecting the appendix that is responsible for ≤2% of cases of appendicitis; *Yersinia* is involved in a minority of cases. *Y. enterocolitica* infection can present as acute pharyngitis with or without other gastrointestinal symptoms. Fatal *Y. enterocolitica* pharyngitis has been recorded. Mycotic aneurysm can follow *Y. enterocolitica* bacteremia, as can focal infection (abscess) in many other sites and body compartments (liver, spleen, kidney, bone, meninges, endocardium).

Y. pseudotuberculosis infection is more likely to present as abdominal pain and fever than as diarrhea. A superantigenic toxin—*Y. pseudotuberculosis* mitogen (YPM)—is produced by strains seen in eastern Russia in association with Far Eastern scarlet-like fever, a childhood illness with desquamating rash, arthralgia, and toxic shock. A similar illness is recognized in Japan (Izumi fever) and Korea. Similarities have been noted with Kawasaki disease, the idiopathic acute systematic vasculitis of childhood. There is an epidemiologic link between exposure

of populations to superantigen-positive *Y. pseudotuberculosis* and an elevated incidence of Kawasaki disease.

Y. enterocolitica or *Y. pseudotuberculosis* septicemia presents as a severe illness with fever and leukocytosis, often without localizing features, and is significantly associated with predisposing conditions such as diabetes mellitus, liver disease, and iron overload. Hemochromatosis combines several of these risk factors. Administration of iron chelators like deferoxamine, which provide iron accessible to *Yersinia* (and have an inhibitory effect on neutrophil function), may result in *Yersinia* septicemia in patients with iron overload who presumably have an otherwise mild gastrointestinal infection. HIV/AIDS has been associated with *Y. pseudotuberculosis* septicemia. The unusual phenomenon of transfusion-associated septicemia is linked to the ability of *Y. enterocolitica* to multiply at refrigerator temperature (psychrotrophy). Typically, the transfused unit has been stored for >20 days, and it is believed that small numbers of yersiniae from an apparently healthy donor with subclinical bacteremia are amplified to very high numbers by growth inside the bag at ≤4°C, with consequent septic shock after transfusion. Complete prevention of this very rare event (1 case in several million transfused units in countries such as the United States and France) without unacceptable restriction in the blood supply has not yet been devised.

POSTINFECTIVE PHENOMENA

As in other invasive intestinal infections (salmonellosis, shigellosis), reactive arthritis (articular arthritis of multiple joints developing within 2–4 weeks of a preceding infection) occurs as a result of autoimmune activity initiated by the deposition of bacterial components (not viable bacteria) in joints in combination with the immune response to invading bacteria. The majority of individuals affected by reactive arthritis due to *Yersinia* are HLA-B27 positive. Myocarditis with electrocardiographic ST-segment abnormalities may occur with *Yersinia*-associated reactive arthritis. Most *Yersinia*-associated cases follow *Y. enterocolitica* infection (presumably because it is more common than infection with other species), but *Y. pseudotuberculosis*–associated reactive arthritis is also well documented in Finland, where sporadic and outbreak infections with *Y. pseudotuberculosis* are more common than in other countries. Of infected individuals identified in a recent *Y. pseudotuberculosis* serotype O:3 outbreak in Finland, 12% developed reactive arthritis affecting the small joints of the hands and feet, knees, ankles, and shoulders and lasting >6 months in most cases. Erythema nodosum **(Fig. A1-39)** occurs after *Yersinia* infection (more commonly in women) with no evidence of HLA-B27 linkage.

There is a long-standing association between antithyroid and anti-*Yersinia* antibodies. Antibody evidence of prior *Y. enterocolitica* infection in Graves' disease and increased levels of antithyroid antibody in patients with *Y. enterocolitica* antibodies were first noted in the 1970s. *Y. enterocolitica* contains a thyroid-stimulating hormone (TSH)–binding site that is recognized by antibodies to TSH from Graves' disease patients. Raised titers of antibodies to *Y. enterocolitica* whole cells and Yops have been found in some series of Graves' disease patients but not in others. It remains unclear whether this cross-reactivity is significant in the etiology of Graves' disease.

LABORATORY DIAGNOSIS

Standard laboratory culture methods can be used to isolate enteropathogenic *Yersinia* species from sterile samples, including blood and cerebrospinal fluid. Culture on specific selective media (CIN agar), with or without pre-enrichment in broth or phosphate-buffered saline at either 4°C or 16°C, is the basis of most schema for isolation of yersiniae from stool or other nonsterile samples. Outside known high-incidence areas, specific culture may only be carried out by laboratories on request, or if a multiplex PCR screen detects *Y. enterocolitica*–specific DNA in feces. Several CE-marked, FDA-approved kits for enteric pathogens now offer *Y. enterocolitica* detection (the precise assay targets are not disclosed), and their use has increased detection of *Y. enterocolitica*. A standard for PCR detection of pathogenic *Y. enterocolitica* and *Y. pseudotuberculosis* in food samples is available from the International Organization for Standardization.

Matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometry systems can speciate isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* (but cannot separate *Y. similis* or *Y. pestis* from *Y. pseudotuberculosis*). Virulence plasmid–negative strains of *Y. enterocolitica* can be isolated from cultures of stool from asymptomatic individuals, especially after cold enrichment. These strains usually differ in biotype (typically biovar 1a) from virulence plasmid–possessing strains; although some display apparent pathogenicity in a mouse model and all are pathogenic in an insect model, virulence plasmid–negative strains are not commonly accepted as human pathogens. Because of the frequency with which the virulence plasmid is lost on laboratory subculture, combined biochemical identification (with biotyping according to a standard schema) and serologic identification are usually required to interpret the significance of an isolate of *Y. enterocolitica* from a nonsterile site. Most pathogenic *Y. enterocolitica* strains currently isolated from humans are of serogroup O:3/biovar 4 or serogroup O:9/biovar 2; this pattern holds even in the United States, where serogroup O:8/biovar 1B strains were previously predominant. Whole genome DNA sequencing applying a *Yersinia* genus-wide seven-gene MLST scheme can speciate *Y. enterocolitica*, *Y. pestis*, and *Y. pseudotuberculosis* and differentiate *Y. enterocolitica* biotypes. A core-genome MLST scheme has recently been developed, providing an even more detailed population structure and revealing novel as yet phenotypically undefined *Yersinia* species.

Agglutinating or ELISA antibody titers to specific O-antigen types are used in the retrospective diagnosis of both *Y. enterocolitica* and *Y. pseudotuberculosis* infections. IgA and IgG antibodies persist in patients with reactive arthritis. Serologic cross-reactions between *Y. enterocolitica* serogroup O:9 and *Brucella* are due to the similarity of their lipopolysaccharide structures. Multiple assays are required to cover even the predominant serogroups (*Y. enterocolitica* O:3, O5,27, and O:9; *Y. pseudotuberculosis* O:1a, O:1b, and O:3), and these assays are generally available only in reference laboratories. ELISA and Western blot tests for antibodies to Yops, which are expressed by all pathogenic strains of *Y. enterocolitica* and *Y. pseudotuberculosis*, also are available; most of the positivity in these assays probably relates to previous infection with *Y. enterocolitica*.

TREATMENT

Yersiniosis

Most cases of diarrhea caused by enteropathogenic *Yersinia* are self-limiting. Data from clinical trials do not support antimicrobial treatment for adults or children with *Y. enterocolitica* diarrhea. Systemic infections with bacteremia or focal infections outside the gastrointestinal tract generally require antimicrobial therapy. Infants <3 months of age with documented *Y. enterocolitica* infection may require antimicrobial treatment because of the increased likelihood of bacteremia in this age group. *Y. enterocolitica* strains nearly always express β-lactamases. Because of the relative rarity of systemic *Y. enterocolitica* infection, there are no clinical trial data to guide antimicrobial choice or to suggest the optimal dose and duration of therapy. On the basis of retrospective case series and in vitro sensitivity data, fluoroquinolone therapy is effective for bacteremia in adults; for example, ciprofloxacin is given at a typical dose of 500 mg twice daily by mouth or 400 mg twice daily IV for at least 2 weeks (longer if positive blood cultures persist). A third-generation cephalosporin is an alternative—e.g., cefotaxime (typical dose, 6–8 g/d in 3 or 4 divided doses) or ceftriaxone. In children, third-generation cephalosporins are effective; for example, cefotaxime is given to children ≥1 month of age at a typical dose of 75–100 mg/kg per day in 3 or 4 divided doses, with an increase to 150–200 mg/kg per day in severe cases (maximal daily dose, 8–10 g). Amoxicillin and amoxicillin/clavulanate have shown poor efficacy in case series. Trimethoprim-sulfamethoxazole, gentamicin, and imipenem are all active in vitro. *Y. pseudotuberculosis* strains do not express β-lactamase but are intrinsically resistant to polymyxin. Because human infection with *Y. pseudotuberculosis* is less common than that with *Y. enterocolitica*, less case information is

available; however, studies in mice suggest that ampicillin is ineffective. Drugs similar to those used against *Y. enterocolitica* should be used. The best results have been obtained with a quinolone.

Some trials of treatment for reactive arthritis (with a large proportion of cases due to *Yersinia*) found that 3 months of oral ciprofloxacin therapy did not affect outcome. One trial in which the same therapy was given specifically for *Y. enterocolitica*–reactive arthritis found that, while outcome indeed was not affected, there was a trend toward faster remission of symptoms in the treated group. Follow-up 4–7 years after initial antibiotic treatment of reactive arthritis (predominantly following *Salmonella* and *Yersinia* infections) demonstrated apparent efficacy in the prevention of chronic arthritis in HLA-B27-positive individuals. A trial showing that azithromycin therapy did not affect outcome in reactive arthritis included cases thought to have followed yersiniosis, although no breakdown of cases was provided.

PREVENTION AND CONTROL

Current control measures are similar to those used against other enteric pathogens like *Salmonella* and *Campylobacter*, which colonize the intestine of food animals. The focus is on safe handling and processing of food. No vaccine is effective in preventing intestinal colonization of food animals by enteropathogenic *Yersinia*. Consumption of food made from raw pork (which is popular in Germany and Belgium) should be discouraged at present because it is not possible to eliminate contamination with the enteropathogenic *Yersinia* strains found worldwide in pigs. Exposure of infants to raw pig intestine during domestic preparation of chitterlings is inadvisable. Modification of abattoir technique in Scandinavian countries from the 1990s onward included the removal of pig intestines in a closed plastic bag; levels of carcass contamination with *Y. enterocolitica* were reduced, but such contamination was not eliminated. Experimental pig herds free of pathogenic *Y. enterocolitica* O:3 (and also of *Salmonella*, *Campylobacter*, *Toxoplasma*, and *Trichinella*) have been established by selective breeding in Norway but remain rare. In the food industry, vigilance is required because of the potential for large outbreaks if small numbers of enteropathogenic yersiniae contaminate any ready-to-eat food whose safe preservation is based on refrigeration before consumption.

The rare phenomenon of contamination of blood for transfusion has proved impossible to eradicate. However, leukodepletion is now practiced in most blood transfusion centers, primarily to prevent nonhemolytic febrile transfusion reactions and alloimmunization against HLA antigens. This measure reduces but does not eliminate the risk of *Yersinia* blood contamination.

Notification of yersiniosis is now obligatory in some countries.

172 *Bartonella* Infections, Including Cat-Scratch Disease

Michael Giladi, Moshe Ephros

Bartonella species are fastidious, facultative intracellular, slow-growing, gram-negative bacteria that cause a broad spectrum of diseases in humans. This genus includes >40 distinct species or subspecies, of which at least 16 have been recognized as confirmed or potential human pathogens; *Bartonella bacilliformis*, *Bartonella quintana*, and *Bartonella henselae* are most commonly identified **(Table 172-1)**. Most *Bartonella* species have successfully adapted to survival in specific domestic or wild mammals. Prolonged intraerythrocytic infection in these animals creates a niche where the bacteria are protected from both innate and adaptive immunity and which serves as a reservoir for human infections. *Bartonella* characteristically evades the host immune system by modification of its virulence factors (e.g., lipopolysaccharides or flagella) and by attenuation of the immune response. *B. bacilliformis* and *B. quintana*, which are not zoonotic, are exceptions. Arthropod vectors are often involved. Isolation and characterization of *Bartonella* species are difficult and require special techniques. Clinical presentation generally depends on both the infecting *Bartonella* species and the immune status of the infected individual. *Bartonella* species are susceptible to many antibiotics in vitro; however, clinical responses to therapy and studies in animal models suggest that the minimal inhibitory concentrations of many antimicrobial agents correlate poorly with the drugs' in vivo efficacies in patients with *Bartonella* infections.

CAT-SCRATCH DISEASE

DEFINITION AND ETIOLOGY

Usually a self-limited illness, cat-scratch disease (CSD) has two general clinical presentations. *Typical* CSD, the more common, is characterized by subacute regional lymphadenopathy; *atypical* CSD is the collective designation for numerous extranodal manifestations involving various organs. *B. henselae* is the principal etiologic agent of CSD. Rare cases have been associated with *Afipia felis* and other *Bartonella* species.

EPIDEMIOLOGY

CSD occurs worldwide, favoring warm and humid climates. In temperate climates, incidence peaks during fall and winter. Adults are affected nearly as frequently as children. Intrafamilial clustering is rare, and person-to-person transmission does not occur. Apparently healthy bacteremic cats constitute the major reservoir of *B. henselae*, and cat fleas (*Ctenocephalides felis*) may be responsible for cat-to-cat transmission. CSD usually follows contact with cats (especially kittens), but other animals (e.g., dogs) have been implicated as possible reservoirs in rare instances. In the United States, the estimated annual disease incidence is ~5 cases per 100,000 population. About 5% of patients are hospitalized.

PATHOGENESIS

Although cat fleas are likely responsible for cat-to-cat transmission, the mode of cat-to-human transmission is undetermined. *B. henselae*–infected

TABLE 172-1 *Bartonella* **Species Known or Suspected to Be Human Pathogens**

BARTONELLA SPECIES[a]	DISEASE(S)[b]	RESERVOIR HOST(S)[c]	ARTHROPOD VECTOR
B. henselae	Cat-scratch disease, bacillary angiomatosis, bacillary peliosis, bacteremia, endocarditis	Cats, other felines	Cat fleas (*Ctenocephalides felis*): associated with cat-to-cat, but not with cat-to-human, transmission
B. quintana	Trench fever, chronic bacteremia, bacillary angiomatosis, endocarditis	Humans	Human body lice (*Pediculus humanus corporis*)
B. bacilliformis	Carrión's disease	Humans	Sandflies (*Lutzomyia verrucarum*)
B. elizabethae	Endocarditis	Rats, dogs	Unknown
B. grahamii[d]	Lymphadenopathy	Mice, voles	Fleas
B. vinsonii subsp. *arupensis*	Endocarditis, febrile illness	Mice, dogs	Ticks
B. vinsonii subsp. *berkhoffii*	Endocarditis	Domestic dogs, coyotes, gray foxes	Ticks
B. washoensis	Endocarditis, myocarditis, meningitis	Squirrels, possibly other rodents	Fleas
B. alsatica	Endocarditis, lymphadenitis, vascular graft infection	Rabbits	Fleas
B. koehlerae	Endocarditis	Cats	Unknown
B. clarridgeiae	Possibly cat-scratch disease	Cats	Unknown
B. rochalimae	Bacteremia, fever, splenomegaly	Unknown	Possibly fleas
B. tamiae	Bacteremia, fever, myalgia, rash	Unknown	Unknown
B. melophagi	Various clinical manifestations	Sheep	Sheep keds
B. ancashensis	Verruga peruana	Unknown	Unknown
Candidatus B. mayotimonensis[e]	Endocarditis	Bats	Unknown

[a]Many other *Bartonella* species exist but are not recognized as human pathogens. [b]Animal-associated *Bartonella* species (*B. henselae, B. doshiae, B. schoenbuchensis,* and *B. tribocorum*) were isolated from blood of patients who reported tick bites and chronic symptoms such as fatigue and myalgia. DNA of *B. henselae, B. vinsonii* subsp. *berkhoffii, B. koehlerae*, or *B. melophagi* or co-infection with more than one *Bartonella* species was detected by polymerase chain reaction in blood samples from patients with extensive arthropod and animal exposure who presented with chronic neurologic or neurocognitive syndromes. The causal relationship between bacteremia with these pathogens, tick bites, and clinical manifestations needs to be established. [c]Animals are implicated when existing evidence supports their infection with *Bartonella* species. Data supporting animal-to-human transmission may be lacking. [d]Retinitis may also be associated with *B. grahamii*. [e]*Candidatus* is a taxonomic status for bacteria that cannot be described in sufficient detail to warrant establishment of a novel taxon or cannot be cultured or propagated in culture media. The phylogenetic relatedness of these bacteria has been determined by gene amplification and sequence analysis.

cats' saliva spreads to claws by self-licking, and *B. henselae*–contaminated flea feces can be inoculated by a scratch or a bite. Infection of mucous membranes or conjunctivae via droplets or licking may occur as well. With lymphatic drainage to one or more regional lymph nodes in immunocompetent hosts, a T_H1 response can result in necrotizing granulomatous lymphadenitis. Dendritic cells, along with their associated chemokines, play a role in the host inflammatory response and granuloma formation.

CLINICAL MANIFESTATIONS AND PROGNOSIS

Of patients with CSD, 85–90% have *typical* disease. The primary lesion, a small (0.3- to 1-cm) painless erythematous papule or pustule, develops at the inoculation site within days to 2 weeks in about one-third to two-thirds of patients **(Fig. 172-1*A, B*)**. Lymphadenopathy develops 1–3 weeks or longer after cat contact. The affected lymph node(s) are enlarged and usually painful, sometimes have overlying erythema, and suppurate in ~10% of cases **(Fig. 172-1*C, D*, and *E*)**. Axillary/epitrochlear nodes are most commonly involved, followed by head/neck nodes and inguinal/femoral nodes. Approximately 50% of patients have fever, malaise, and anorexia. A smaller proportion experience weight loss and night sweats mimicking the presentation of lymphoma. Fever is usually low-grade but infrequently rises to ≥39°C. Resolution is slow, requiring weeks (for fever, pain, and accompanying signs and symptoms) to months (for node shrinkage).

Atypical CSD occurs in 10–15% of patients in the absence or presence of lymphadenopathy. Atypical disease includes Parinaud's oculoglandular syndrome (granulomatous conjunctivitis with ipsilateral preauricular lymphadenitis; Fig. 172-1*E*), hepatosplenic disease, neuroretinitis (often presenting as unilateral deterioration of vision; **Fig. 172-1*F***) and other ophthalmologic manifestations, neurologic manifestations (encephalitis, seizures, myelitis, cerebellitis, facial and other cranial or peripheral palsies), fever of unknown origin, pneumonitis, debilitating myalgia, arthritis or arthralgia (affecting mostly women >20 years old), osteomyelitis (including multifocal disease), tendinitis, and dermatologic manifestations (including erythema nodosum **[see Fig. A1-39]**, sometimes accompanying arthropathy). CSD-associated fever of unknown origin is a unique syndrome that may be severe and debilitating, often mimics malignancy, and may present with multiorgan involvement, including hepatosplenic space-occupying lesions, abdominal/mediastinal lymphadenopathy, ocular disease, and multifocal osteomyelitis. Fever may be continuous or relapsing. Other manifestations and syndromes (pleural effusion, idiopathic thrombocytopenic purpura, Henoch-Schönlein purpura, erythema multiforme **[see Fig. A1-24]**, glomerulonephritis, myocarditis) have also been associated with CSD. In elderly patients (>60 years old), lymphadenopathy is more often absent but encephalitis and fever of unknown origin are more common than in younger patients. In immunocompetent individuals, CSD—whether typical or atypical—usually resolves without treatment and without sequelae, although some of the ophthalmologic manifestations may occasionally result in moderate to severe vision loss. Lifelong immunity is the rule.

DIAGNOSIS

Routine laboratory tests usually yield normal or nonspecific results. Histopathology initially shows lymphoid hyperplasia and later demonstrates stellate granulomata with necrosis, coalescing microabscesses, and occasional multinucleated giant cells—findings that, although nonspecific, may narrow the differential diagnosis. Serologic testing (immunofluorescence or enzyme immunoassay) is the most commonly used laboratory diagnostic approach, with variable sensitivity and specificity. CSD serodiagnosis is often based on the presence of IgG alone (i.e., in the absence of IgM), and seroconversion may take a few weeks; these two factors may pose difficulties in the interpretation of serologic results. Other tests are of low sensitivity (culture, Warthin-Starry silver staining), of low specificity (cytology, histopathology), or of limited availability in routine diagnostic laboratories (polymerase chain reaction [PCR], immunohistochemistry). PCR of pus aspirated from lymph nodes or the primary inoculation lesion is highly sensitive and specific and is particularly useful for definitive and rapid diagnosis in seronegative patients. PCR of a lymph node biopsy specimen may be less sensitive, perhaps because of sampling error.

Submental lymphadenitis appeared 10 days later. ***C.*** Axillary lymphadenopathy of 2 weeks' duration. The overlying skin appears normal. ***D.*** Cervical lymphadenopathy of 6 weeks' duration. The overlying skin is red. Thick, odorless pus (12 mL) was aspirated. ***E.*** Preauricular lymphadenopathy. ***F.*** Left-eye neuroretinitis. Note papilledema and stellate macular exudates ("macular star").

APPROACH TO THE PATIENT

Cat-Scratch Disease

A history of cat contact, a primary inoculation lesion, and regional lymphadenopathy—especially axillary/epitrochlear lymphadenopathy—are highly suggestive of CSD. A characteristic clinical course and corroborative laboratory tests make the diagnosis very likely. Conversely, when acute- and convalescent-phase sera are negative (as is the case in 10–20% of CSD patients), when spontaneous regression of lymph node size does not occur, and particularly when constitutional symptoms persist, malignancy must be ruled out. Pyogenic lymphadenitis, mycobacterial infection, brucellosis, syphilis, tularemia, plague, toxoplasmosis, sporotrichosis, and histoplasmosis should also be considered. In clinically suspected CSD in a seronegative individual, fine-needle aspiration may be adequate and PCR can confirm the diagnosis. When data are less supportive of CSD, lymph node biopsy rather than fine-needle aspiration is preferred. In seronegative CSD patients with lymphadenopathy and severe complications (e.g., encephalitis or neuroretinitis), early biopsy is important to establish a specific diagnosis.

TREATMENT

Cat-Scratch Disease

(Table 172-2) Treatment regimens are based on only minimal data. Suppurative nodes should be drained by large-bore needle aspiration and not by incision and drainage to avoid chronic draining tracts. Systemic antibiotics are recommended in immunocompromised patients.

PREVENTION

Avoiding cats (especially kittens) and instituting flea control are options for immunocompromised patients and for patients with valvular heart disease.

TRENCH FEVER AND CHRONIC BACTEREMIA

DEFINITION AND ETIOLOGY

Trench fever, also known as *5-day fever* or *quintan fever*, is a febrile illness caused by *B. quintana*. It was first described as an epidemic in the trenches of World War I; however, recent paleomicrobiological studies have provided evidence that *B. quintana* has been associated with human infection for 4000 years. This infection recently reemerged as chronic bacteremia seen most often in homeless people, also referred to as *urban* or *contemporary trench fever*.

EPIDEMIOLOGY

In addition to epidemics during World Wars I and II, sporadic outbreaks of trench fever have been reported in many regions of the world. The human body louse has been identified as the vector and humans as the only known reservoir. After a hiatus of several decades during which trench fever was almost forgotten, small clusters of cases of *B. quintana* chronic bacteremia were reported sporadically, primarily from the United States and France, in HIV-uninfected homeless people. Alcoholism and louse infestation were identified as risk factors.

CLINICAL MANIFESTATIONS

The typical incubation period is 15–25 days (range, 3–38 days). "Classical" trench fever, as described in 1919, ranges from a mild febrile illness to a recurrent or protracted and debilitating disease. Fever is often periodic, lasting 4–5 days with 5-day (range, 3- to 8-day) intervals between episodes. Other symptoms and signs include headache, back and limb pain, profuse sweating, shivering, myalgia, arthralgia, splenomegaly, a maculopapular rash in occasional cases, and nuchal rigidity in some cases. Untreated, the disease usually lasts 4–6 weeks. Death is rare. The clinical spectrum of *B. quintana* bacteremia in homeless people ranges from asymptomatic infection to a febrile illness with headache, severe leg pain, and thrombocytopenia. Endocarditis sometimes develops.

TABLE 172-2 Antimicrobial Therapy for Disease Caused by *Bartonella* Species in Adults

DISEASE	ANTIMICROBIAL THERAPY
Typical cat-scratch disease	Not routinely indicated; for patients with extensive lymphadenopathy, consider azithromycin (500 mg PO on day 1, then 250 mg PO once a day for 4 days)
Cat-scratch disease neuroretinitis	Value of systemic antibiotics is controversial, particularly when visual acuity is not significantly compromised. For more severe cases, doxycycline (100 mg PO bid) *plus* rifampin (300 mg PO bid) for 4–6 weeks is given. Consider adding systemic glucocorticoids.
Other atypical cat-scratch disease manifestations[a]	As per neuroretinitis. Treatment duration should be individualized.
Trench fever or chronic bacteremia with *B. quintana*	Gentamicin (3 mg/kg IV once a day for 14 days) *plus* doxycycline (200 mg PO once a day or 100 mg PO bid for 6 weeks)
Suspected *Bartonella* endocarditis	Gentamicin[b] (1 mg/kg IV q8h for ≥14 days) *plus* doxycycline (100 mg PO/IV bid for 6 weeks[c]) *plus* ceftriaxone (2 g IV once a day for 6 weeks)
Confirmed *Bartonella* endocarditis	As for suspected *Bartonella* endocarditis *minus* ceftriaxone
Bacillary angiomatosis	Erythromycin[d] (500 mg PO qid for 3 months) *or* Doxycycline (100 mg PO bid for 3 months)
Bacillary peliosis	Erythromycin[d] (500 mg PO qid for 4 months) *or* Doxycycline (100 mg PO bid for 4 months)
Carrión's disease	
Oroya fever	Chloramphenicol (500 mg PO/IV qid for 14 days) *plus* another antibiotic (β-lactam preferred) *or* Ciprofloxacin (500 mg PO bid for 10 days) +/– ceftriaxone (1–2 g IV once a day for 10 days)
Verruga peruana	Azithromycin (500 mg PO once a day for 7 days) *or* Ciprofloxacin (500 mg PO bid for 7–10 days) *or* Rifampin (10 mg/kg PO once a day, to a maximum of 600 mg, for 14 days) *or* Streptomycin (15–20 mg/kg IM once a day for 10 days)

[a]Data on treatment efficacy for encephalitis and hepatosplenic cat-scratch disease are lacking. Therapy similar to that given for neuroretinitis is reasonable. [b]Some experts recommend gentamicin at 3 mg/kg IV once a day. If gentamicin is contraindicated, rifampin (300 mg PO bid) can be added to doxycycline for documented *Bartonella* endocarditis. [c]Some experts recommend extending oral doxycycline therapy for 3–6 months. [d]Other macrolides are probably effective and may be substituted for erythromycin or doxycycline.

Source: Recommendations are modified from JM Rolain et al: Antimicrob Agents Chemother 48:1921, 2004.

DIAGNOSIS

Definitive diagnosis requires isolation of *B. quintana* by blood culture. Some patients have positive blood cultures for several weeks. Patients with acute trench fever typically develop significant titers of antibody to *Bartonella*, whereas those with chronic *B. quintana* bacteremia may be seronegative. Patients with high titers of IgG antibodies should be evaluated for endocarditis. In epidemics, trench fever should be differentiated from epidemic louse-borne typhus and relapsing fever, which occur under similar conditions and share many features.

TREATMENT

B. quintana Bacteremia

(Table 172-2) In a small, randomized, placebo-controlled trial involving homeless people with *B. quintana* bacteremia, therapy with gentamicin and doxycycline was superior to administration

of placebo in eradicating bacteremia. Treatment of bacteremia is important, even in clinically mild cases, to prevent endocarditis. Optimal therapy for trench fever without documented bacteremia is uncertain.

BARTONELLA ENDOCARDITIS

DEFINITION AND ETIOLOGY

Coxiella burnetii **(Chap. 187)** and *Bartonella* species are the most common pathogens in culture-negative endocarditis **(Chap. 128)**. In France, for example, *Bartonella* species were identified as the etiologic agents in 28% of 348 cases of culture-negative endocarditis. Prevalence, however, varies by geographic location and epidemiologic setting. In addition to *B. quintana* and *B. henselae* (the most common *Bartonella* species implicated in endocarditis, the former more commonly than the latter), other *Bartonella* species have reportedly caused rare cases (Table 172-1).

EPIDEMIOLOGY

Bartonella endocarditis has been reported worldwide. Most patients are adults; more are male than female. Risk factors associated with *B. quintana* endocarditis include homelessness, alcoholism, and body louse infestation; however, individuals with no risk factors have had *Bartonella* endocarditis diagnosed as well. *B. henselae* endocarditis is associated with exposure to cats. Most cases involve native rather than prosthetic valves; the aortic valve accounts for ~60% of cases. Patients with *B. henselae* endocarditis usually have preexisting valvulopathy, whereas *B. quintana* often infects normal valves.

CLINICAL MANIFESTATIONS

Clinical manifestations are usually characteristic of subacute endocarditis of any etiology. However, a substantial number of patients have a prolonged, minimally febrile or even afebrile indolent illness, with mild nonspecific symptoms lasting weeks or months before the diagnosis is made. Initial echocardiography may not show vegetations. Acute, aggressive disease is rare.

DIAGNOSIS

Blood cultures, even with use of special techniques (lysis centrifugation or EDTA-containing tubes), are positive in only ~25% of cases—mostly those caused by *B. quintana* and only rarely those caused by *B. henselae*. Prolonged incubation of cultures (up to 6 weeks) is required. Serologic tests—either immunofluorescence or enzyme immunoassay—usually demonstrate high-titer (≥1:800) IgG antibodies to *Bartonella*. Because of cross-antigenicity, routine serology does not distinguish between *B. quintana* and *B. henselae* and may also be low-titer cross-reactive with other pathogens, such as *C. burnetii* and *Chlamydia* species. Identification of *Bartonella* to the species level is usually accomplished by application of PCR and DNA sequencing methods to valve tissue.

TREATMENT

Bartonella Endocarditis

(Table 172-2) For patients with culture-negative endocarditis suspected to be due to *Bartonella* species, empirical treatment consists of gentamicin, doxycycline, and ceftriaxone; the major role of ceftriaxone in this regimen is to adequately treat other potential causes of culture-negative endocarditis, including members of the HACEK group **(Chap. 158)**. Once a diagnosis of *Bartonella* endocarditis has been established, ceftriaxone is discontinued. Aminoglycosides, the only antibiotics known to be bactericidal against *Bartonella*, should be included in the regimen for ≥2 weeks. Indications for valvular surgery are the same as in subacute endocarditis due to other pathogens; however, the proportion of patients who undergo surgery (~60%) is high, probably as a consequence of delayed diagnosis.

BACILLARY ANGIOMATOSIS AND PELIOSIS

DEFINITION AND ETIOLOGY

Bacillary angiomatosis (sometimes called *bacillary epithelioid angiomatosis* or *epithelioid angiomatosis*) is a disease of severely immunocompromised patients, is caused by *B. henselae* or *B. quintana*, and is characterized by neovascular proliferative lesions involving various organs. Both species cause cutaneous lesions; hepatosplenic lesions are caused only by *B. henselae*, whereas subcutaneous and lytic bone lesions are more frequently associated with *B. quintana*. Bacillary peliosis is a closely related angioproliferative disorder caused by *B. henselae* and involving primarily the liver (peliosis hepatis) but also the spleen and lymph nodes. Bacillary peliosis is characterized by blood-filled cystic structures whose size ranges from microscopic to several millimeters.

EPIDEMIOLOGY

Bacillary angiomatosis and bacillary peliosis occur primarily in HIV-infected persons **(Chap. 202)** with CD4+ T-cell counts of <100/μL but also affect other immunosuppressed patients and, in rare instances, immunocompetent patients. The incidence has decreased since the introduction of effective antiretroviral therapy and the routine use of rifabutin and macrolides to prevent *Mycobacterium avium* complex infection in AIDS patients. Contact with cats or cat fleas increases the risk of *B. henselae* infection. Risk factors for *B. quintana* infection are low income, homelessness, and body louse infestation.

CLINICAL MANIFESTATIONS

Bacillary angiomatosis presents most commonly as one or more cutaneous lesions that are not painful and may be tan, red, or purple in color. Subcutaneous, often tender nodules, superficial ulcerated plaques **(Fig. 172-2)**, and verrucous growths are also seen. Nodular forms resemble those seen in fungal or mycobacterial infections. Painful osseous lesions, most often involving long bones, may underlie cutaneous lesions and occasionally develop in their absence. Other organs are rarely involved. Patients usually have constitutional symptoms, including fever, chills, malaise, headache, anorexia, weight loss, and night sweats. In patients with advanced immunodeficiency, *B. henselae* and *B. quintana* are important causes of fever of unknown origin. In osseous disease, lytic lesions are generally seen on radiography, and technetium scan shows focal uptake. The differential diagnosis of cutaneous bacillary angiomatosis includes Kaposi's sarcoma, pyogenic granuloma, subcutaneous tumors, and verruga peruana. In bacillary peliosis, hypodense hepatic areas are usually evident on imaging.

PATHOLOGY

Bacillary angiomatosis consists of lobular proliferations of small blood vessels lined by enlarged endothelial cells interspersed with mixed infiltrates of neutrophils and lymphocytes, with predominance of the former. Histologic examination of organs with bacillary peliosis reveals small blood-filled cystic lesions partially lined by endothelial cells that can be several millimeters in size. Peliotic lesions are surrounded by fibromyxoid stroma containing inflammatory cells, dilated capillaries, and clumps of granular material. Warthin-Starry silver staining of bacillary angiomatosis and peliosis lesions reveals clusters of bacilli. Cultures are usually negative.

DIAGNOSIS

Bacillary angiomatosis and bacillary peliosis are diagnosed by histologic examination. Blood cultures may be positive.

TREATMENT

Bacillary Angiomatosis and Peliosis

(Table 172-2) Prolonged therapy with a macrolide or doxycycline is recommended for both bacillary angiomatosis and bacillary peliosis.

FIGURE 172-2 Lesions of cutaneous bacillary angiomatosis (BA) in three severely immunocompromised AIDS patients. Left panel shows a 1.5-cm ulcerated, bleeding BA lesion with an erythematous base; middle panel shows numerous small, 2-mm, scattered angiomatous BA lesions; right panel shows a 2.0-cm friable BA lesion on the thigh. *(Photos courtesy of Timothy Berger, MD; Jordan Tappero, MD, MPH; and Jane Koehler, MA, MD.)*

PREVENTION

Reasonable strategies for HIV-infected persons consist of control of cat-flea infestation and avoidance of cat scratches (for prevention of *B. henselae*) and avoidance and treatment of body louse infestation (for prevention of *B. quintana*). Primary prophylaxis is not recommended, but suppressive therapy with a macrolide or doxycycline is indicated in HIV-infected patients with bacillary angiomatosis or bacillary peliosis until CD4+ T-cell counts are >200/μL. Relapse may necessitate lifelong suppressive therapy in individual cases.

CARRIÓN'S DISEASE (OROYA FEVER AND VERRUGA PERUANA)

DEFINITION AND ETIOLOGY

Carrión's disease is a biphasic disease caused by *B. bacilliformis*. Oroya fever is the initial, bacteremic, systemic form, and verruga peruana is its late-onset, eruptive manifestation.

EPIDEMIOLOGY AND PREVENTION

Infection is endemic to the geographically restricted Andes valleys of Peru, Ecuador, and Colombia (~500–3200 m above sea level). Sporadic epidemics occur. The disease is transmitted by the phlebotomine sandfly *Lutzomyia verrucarum*. Maternal-fetal transmission as well as transmission by blood transfusion have been reported. Humans are the only known reservoir of *B. bacilliformis*. Sandfly control measures (e.g., insecticides) and personal protection measures (e.g., repellents, screening, bed nets) may decrease the risk of infection.

PATHOGENESIS

After inoculation by the sandfly, bacteria invade the blood vessel endothelium and proliferate; the reticuloendothelial system and various organs may also be involved. Upon reentry into blood vessels, *B. bacilliformis* invades, replicates, and ultimately destroys erythrocytes, with consequent massive hemolysis and sudden, severe anemia. Microvascular thrombosis results in end-organ ischemia. Survivors sometimes develop cutaneous hemangiomatous lesions characterized by various inflammatory cells, endothelial proliferation, and the presence of *B. bacilliformis* (verruga peruana).

CLINICAL MANIFESTATIONS

The incubation period is 3 weeks (range, 2–14 weeks). Oroya fever may present as a nonspecific bacteremic febrile illness without anemia or as an acute, severe hemolytic anemia with hepatomegaly and jaundice of rapid onset leading to vascular collapse and clouded sensorium. Myalgia, arthralgia, lymphadenopathy, and abdominal pain may develop. Temperature is elevated but not extremely so; high fever may suggest intercurrent infection. Subclinical asymptomatic infection also occurs. In verruga peruana, red, hemangioma-like, cutaneous vascular lesions of various sizes appear either weeks to months after systemic illness or with no previous suggestive history. These lesions persist for months up to 1 year. Mucosal and internal lesions may also develop.

DIAGNOSIS AND APPROACH TO THE PATIENT

Systemic illness (with or without anemia) or the development of cutaneous lesions in a person who has been to an endemic area raises the possibility of *B. bacilliformis* infection. Severe anemia with exuberant reticulocytosis—and sometimes thrombocytopenia—can occur. In systemic illness, Giemsa-stained blood films may show typical intraerythrocytic bacilli. Blood and bone marrow cultures may be positive, but growth is slow (1–6 weeks) and requires lower incubation temperature. Serologic assays may be helpful. Diagnosis of verruga peruana is largely clinical, although biopsy may be required to confirm the diagnosis. Several PCR assays have been described; however, their role in diagnosis remains to be clinically validated. Differential diagnosis includes coendemic systemic febrile illnesses (e.g., typhoid fever, malaria, brucellosis) and diseases producing cutaneous vascular lesions (e.g., hemangiomata, bacillary angiomatosis, Kaposi's sarcoma).

TREATMENT

Carrión's Disease

(Table 172-2) Antibiotic therapy for systemic *B. bacilliformis* infection usually results in rapid defervescence. Additional antibiotic treatment of intercurrent infection (particularly salmonellosis) is often required. Blood transfusion may be necessary. Treatment of verruga peruana usually is not always required. Patients with numerous lesions, especially lesions that have been present for only a short period, may respond well to antibiotic therapy.

COMPLICATIONS AND PROGNOSIS

Mortality rates associated with Oroya fever have been reported to be as high as 40% without treatment but are considerably lower (~10%) with treatment. Complications such as bacterial superinfection and neurologic and cardiac manifestations occur frequently. Generalized massive edema (anasarca) and petechiae are associated with poor outcome. Permanent immunity usually develops.

173 Donovanosis

Nigel O'Farrell

Donovanosis is a chronic, progressive bacterial infection that usually involves the genital region. The condition is generally regarded as a sexually transmitted infection of low infectivity. This infection has been known by many other names, the most common being *granuloma inguinale*.

ETIOLOGY

The causative organism has been reclassified as *Klebsiella granulomatis comb nov* on the basis of phylogenetic analysis, although there is ongoing debate about this decision. Some authorities consider the original nomenclature (*Calymmatobacterium granulomatis*) to be more appropriate in light of analysis of 16S rRNA gene sequences.

Donovanosis was first described in Calcutta in 1882, and the causative organism was recognized by Charles Donovan in Madras in 1905. He identified the characteristic Donovan bodies, measuring 1.5 × 0.7 μm, in macrophages and the stratum malpighii. The organism was not reproducibly cultured until the mid-1990s, when its isolation in peripheral-blood monocytes and human epithelial cell lines was reported.

EPIDEMIOLOGY

Donovanosis has an unusual geographic distribution that has included Papua New Guinea, parts of southern Africa, India, the Caribbean, French Guyana, Brazil, and Aboriginal communities in Australia. In Australia, donovanosis has been almost entirely eliminated through a sustained program backed by strong political commitment and resources at the primary health care level. In South Africa, donovanosis is also very close to elimination. Although few cases are now reported in the United States, donovanosis was once prevalent in this country, with 5000–10,000 cases recorded in 1947. The largest epidemic recorded was in Dutch South Guinea, where 10,000 cases were identified in a population of 15,000 (the Marind-anim) between 1922 and 1952.

Donovanosis is associated with poor hygiene and is more common in lower socioeconomic groups than in those who are better off and in men than in women. Infection in sexual partners of index cases occurs to a limited extent. Donovanosis is a risk factor for HIV infection **(Chap. 202)**.

Globally, the incidence of donovanosis has decreased significantly in recent times. This decline probably reflects a greater focus on effective management of genital ulcers because of their role in facilitating HIV transmission.

CLINICAL FEATURES

A lesion starts as a papule or subcutaneous nodule that later ulcerates after trauma. The incubation period is uncertain, but experimental infections in humans indicate a duration of ~50 days. Four types of lesions have been described: (1) the classic ulcerogranulomatous lesion **(Fig. 173-1)**, a beefy red ulcer that bleeds readily when touched; (2) a hypertrophic or verrucous ulcer with a raised irregular edge; (3) a necrotic, offensive-smelling ulcer causing tissue destruction; and (4) a sclerotic or cicatricial lesion with fibrous and scar tissue.

The genitals are affected in 90% of patients and the inguinal region in 10%. The most common sites of infection are the prepuce, coronal sulcus, frenum, and glans in men and the labia minora and fourchette in women. Cervical lesions may mimic cervical carcinoma. In men, lesions are associated with lack of circumcision. Lymphadenitis is uncommon. Extragenital lesions occur in 6% of cases and may involve the lip, gums, cheek, palate, pharynx, larynx, and chest. Hematogenous spread with involvement of liver and bone has been reported. During pregnancy, lesions tend to develop more quickly and respond more slowly to treatment. Polyarthritis and osteomyelitis are rare complications. In newborn infants, donovanosis may present with ear infection. Cases in children have been attributed to sitting on the laps of infected adults. As the incidence of donovanosis has decreased, the number of unusual case reports has appeared to be increasing.

Complications include neoplastic changes, pseudoelephantiasis, and stenosis of the urethra, vagina, or anus.

FIGURE 173-1 Ulcerogranulomatous penile lesion of donovanosis, with some hypertrophic features.

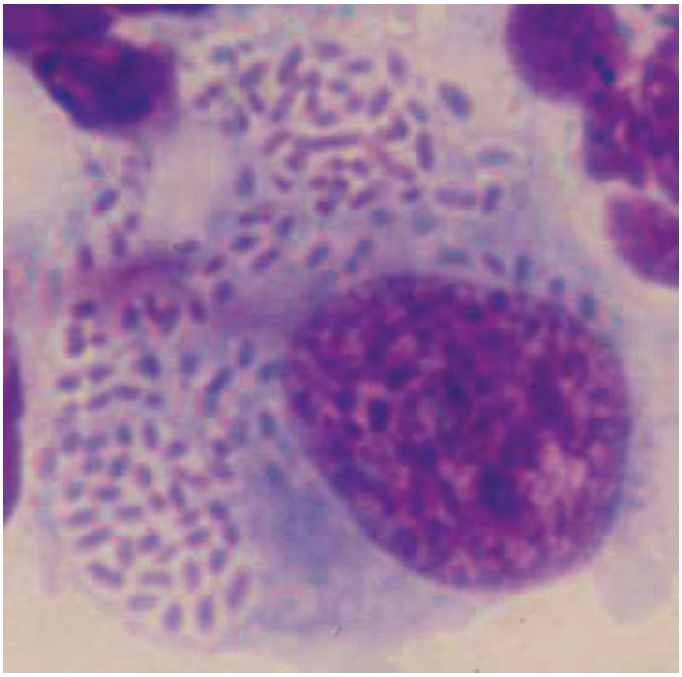

FIGURE 173-2 Pund cell stained by rapid Giemsa (RapiDiff) technique. Numerous Donovan bodies are visible.

DIAGNOSIS

A clinical diagnosis of donovanosis made by an experienced practitioner on the basis of the lesion's appearance usually has a high positive predictive value. The diagnosis is confirmed by microscopic identification of Donovan bodies **(Fig. 173-2)** in tissue smears. Preparation of a good-quality smear is important. If donovanosis is suspected on clinical grounds, the smear for Donovan bodies should be taken before swab samples are collected to be tested for other causes of genital ulceration so that enough material can be collected from the ulcer. A swab should be rolled firmly over an ulcer previously cleaned with a dry swab to remove debris. Smears can be examined in a clinical setting by direct microscopy with a rapid Giemsa or Wright's stain. Alternatively, a piece of granulation tissue crushed and spread between two slides can be used. Donovan bodies can be seen in large, mononuclear (Pund) cells as gram-negative intracytoplasmic cysts filled with deeply staining bodies that may have a safety-pin appearance. These cysts eventually rupture and release the infective organisms. Histologic changes include chronic inflammation with infiltration of plasma cells and neutrophils. Epithelial changes include ulceration, microabscesses, and elongation of rete ridges.

A diagnostic polymerase chain reaction (PCR) test was based on the observation that two unique base changes in the *phoE* gene eliminate Hae111 restriction sites, enabling differentiation of *K. granulomatis comb nov* from related *Klebsiella* species. PCR analysis with a colorimetric detection system can now be used in routine diagnostic laboratories. A genital ulcer multiplex PCR that includes *K. granulomatis* has been developed. Serologic tests are only poorly specific and are not currently used.

The differential diagnosis of donovanosis includes primary syphilitic chancres, secondary syphilis (condylomata lata), chancroid, lymphogranuloma venereum, genital herpes, neoplasm, and amebiasis. Mixed infections are common. Histologic appearances should be distinguished from those of rhinoscleroma, leishmaniasis, and histoplasmosis.

TREATMENT

Donovanosis

Many patients with donovanosis present quite late with extensive ulceration. They may be embarrassed and have low self-esteem related to their disease. Reassurance that they have a treatable condition is important, as are the administration of antibiotics and the monitoring of patients for an adequate interval (see below). Epidemiologic treatment of sexual partners and advice about how to improve genital hygiene are recommended.

The recommended drug regimens for donovanosis are shown in **Table 173-1**. Gentamicin can be added if the response is slow. Ceftriaxone, chloramphenicol, and norfloxacin also are effective. Patients treated for 14 days should be monitored until lesions have healed completely. Those treated with azithromycin probably do not need such rigorous follow-up.

Surgery may be indicated for very advanced lesions.

TABLE 173-1 Effective Antibiotics for the Treatment of Donovanosis

ANTIBIOTIC	ORAL DOSE
Azithromycin	1 g on day 1, then 500 mg daily for 7 days or 1 g weekly for 4 weeks
Trimethoprim-sulfamethoxazole	960 mg bid for 14 days
Doxycycline	100 mg bid for 14 days
Erythromycin	500 mg qid for 14 days (in pregnant women)
Tetracycline	500 mg qid for 14 days

CONTROL AND PREVENTION

Donovanosis is probably the cause of genital ulceration that is most readily recognizable clinically. Donovanosis is now limited to a few specific locations, and its global eradication is a distinct possibility.

Section 7 Miscellaneous Bacterial Infections

174 Nocardiosis

Gregory A. Filice

Nocardiosis can occur after infection with bacteria in the genus *Nocardia*, saprophytic aerobic actinomycetes that commonly reside in soil worldwide and contribute to the decay of organic matter. Nocardiae are relatively inactive in standard biochemical tests, and speciation with traditional biochemical methods is difficult. In the last 20 years, molecular phylogenetic techniques have identified more than 100 *Nocardia* species, more than 50 of which are implicated in human disease.

In the past, the majority of isolates associated with pneumonia and systemic disease were identified biochemically as *Nocardia asteroides*, but the lineage of the type strain was muddled, and most human isolates in fact belong to other species. Nine species or species complexes are commonly associated with human disease **(Table 174-1)**. Most systemic disease involves *N. cyriacigeorgica*, *N. farcinica*, *N. pseudobrasiliensis*, and species in the *N. transvalensis* and *N. nova* complexes.

TABLE 174-1 *Nocardia* Species Most Commonly Associated with Human Disease and Their In Vitro Susceptibility Patterns

SPECIES	SUSCEPTIBLE TO[a]	RESISTANT TO[b]
N. abscessus	Amikacin, amoxicillin/clavulanate, ampicillin, ceftriaxone, gentamicin, linezolid, minocycline, tigecycline, tobramycin, TMP-SMX	Ciprofloxacin, clarithromycin (v), imipenem (v), moxifloxacin
N. brevicatena/paucivorans complex (*N. brevicatena*, *N. paucivorans*, *N. carnea*, others)	Amikacin, ampicillin, ceftriaxone, ciprofloxacin (v), clarithromycin (v), gentamicin, imipenem, linezolid, minocycline (v), moxifloxacin, tigecycline, tobramycin, TMP-SMX	Amoxicillin/clavulanate (v)
N. nova complex (*N. nova*, *N. veterana*, *N. africana*, *N. kruczakiae*, *N. elegans*, others)	Amikacin, ampicillin (v), ceftriaxone (v), clarithromycin, gentamicin (v), imipenem, linezolid, tigecycline (v), TMP-SMX	Amoxicillin/clavulanate, ciprofloxacin, minocycline, moxifloxacin, tobramycin
N. transvalensis complex (*N. blacklockiae*, *N. wallacei*, others)	Ceftriaxone (v), ciprofloxacin (v), linezolid, moxifloxacin, TMP-SMX (v)	Amikacin (v), amoxicillin/clavulanate (v), ampicillin, clarithromycin, gentamicin, imipenem, minocycline (v), tobramycin
N. farcinica	Amikacin, amoxicillin/clavulanate (v), linezolid, moxifloxacin (v), TMP-SMX	Ampicillin, ceftriaxone, ciprofloxacin (v), clarithromycin, gentamicin, imipenem (v), minocycline, tigecycline (v), tobramycin
N. cyriacigeorgica	Amikacin, ceftriaxone, gentamicin, linezolid, tigecycline, tobramycin, TMP-SMX	Amoxicillin/clavulanate, ampicillin, ciprofloxacin, clarithromycin, imipenem (v), minocycline, moxifloxacin
N. brasiliensis	Amikacin, amoxicillin/clavulanate, linezolid, tigecycline, tobramycin, TMP-SMX	Ampicillin, ceftriaxone (v), ciprofloxacin, clarithromycin, imipenem, minocycline (v), moxifloxacin
N. pseudobrasiliensis	Amikacin (v), ciprofloxacin, clarithromycin, linezolid, tobramycin, TMP-SMX (v)	Amoxicillin/clavulanate, ampicillin, ceftriaxone, imipenem, minocycline
N. otitidiscaviarum complex	Amikacin, gentamicin (v), linezolid, tobramycin (v), TMP-SMX	Amoxicillin/clavulanate, ampicillin, ceftriaxone, ciprofloxacin, clarithromycin, imipenem, minocycline (v), moxifloxacin (v)

[a]From 85 to 100% of isolates are susceptible unless the drug name is followed by (v), in which case 50–84% are susceptible. [b]From 0 to 15% of isolates are susceptible unless the drug name is followed by (v), in which case 16–49% are susceptible.

Abbreviations: TMP-SMX, trimethoprim-sulfamethoxazole; v, variable.

Source: Adapted from multiple sources.

N. brasiliensis is usually associated with disease limited to the skin. *N. asteroides* sensu stricto is rarely associated with human disease. However, most clinical laboratories cannot speciate isolates accurately and may identify them simply as *N. asteroides* or *Nocardia* species.

EPIDEMIOLOGY

Pulmonary and/or systemic nocardiosis occurs worldwide. The annual incidence, estimated on three continents (North America, Europe, and Australia), is ~0.375 case per 100,000 persons and may be increasing. There is some geographic variation in species frequencies; for example, *N. asiatica*, *N. beijingensis*, *and N. terpenica* infections appear to be more commonly involved in cases from eastern Asia. However, exact species prevalences are difficult to determine precisely since nocardial infections are not reportable and most publications consist of case reports or case series.

Mycetoma is an indolent, slowly progressive disease of skin and underlying tissues with nodular swellings and draining sinuses. Actinomycetoma refers to cases of mycetoma associated with actinomycetes as opposed to fungi or other bacterial orders, and nocardia strains commonly associated with actinomycetoma include *N. brasiliensis*, *N. otitidiscaviarum*, and *N. transvalensis* complex. Mycetoma occurs mainly in tropical and subtropical regions. Most cases are reported from Sudan, Mexico, and India. The most important risk factors are lower socioeconomic status and frequent contact with soil or vegetable matter; accordingly, many patients are laborers or women who perform outdoor chores like gathering wood.

Pulmonary and/or systemic nocardiosis is more common among adults than among children and more common among males than among females. Nearly all cases are sporadic, but outbreaks have been associated with contamination of the hospital environment, cosmetic procedures, and parenteral illicit drug use. Person-to-person spread is not well documented. There is no known seasonality. In regions of the world where tuberculosis is relatively common, nocardiosis is diagnosed in 1–5% of patients in whom pulmonary tuberculosis is suspected, and tuberculosis and nocardiosis can occur in the same patient.

The majority of cases of pulmonary or disseminated disease occur in people with a host defense defect. Most have deficient cell-mediated immunity, especially that associated with lymphoma, transplantation, glucocorticoid therapy, or AIDS. In transplant recipients, nocardiosis has been associated with high-dose prednisone, elevated calcineurin inhibitor concentrations, and cytomegalovirus disease. The incidence is ~140-fold greater among patients with AIDS and ~340-fold greater among bone marrow transplant recipients than in general populations. In AIDS, nocardiosis usually affects persons with <250 CD4+ T lymphocytes/μL. Nocardiosis has also been associated with pulmonary alveolar proteinosis, tuberculosis and other mycobacterial diseases, chronic granulomatous disease, interleukin 12 deficiency, and autoantibodies to granulocyte-macrophage colony-stimulating factor (GM-CSF). Any child with nocardiosis and no known cause of immunosuppression should undergo tests to determine the adequacy of the phagocytic respiratory burst. Cases have been associated with newer immunomodulating drugs, especially with tumor necrosis factor and calcineurin inhibitors. *Nocardia* is frequently isolated from and may persist in respiratory secretions of patients with cystic fibrosis and may be associated with deterioration of lung function, but this association has not been convincingly established.

PATHOLOGY AND PATHOGENESIS

Pneumonia and disseminated disease are both thought to follow inhalation of fragmented bacterial mycelia. The characteristic histologic feature of nocardiosis is an abscess with extensive neutrophil infiltration and prominent necrosis. Granulation tissue usually surrounds the lesions, but extensive fibrosis or encapsulation is uncommon.

Actinomycetoma is characterized by suppurative inflammation with sinus tract formation. Granules—microcolonies composed of dense masses of bacterial filaments extending radially from a central core—are occasionally observed in histologic preparations. The granules are frequently found in discharges from lesions of actinomycetoma but almost never in discharges from lesions in other forms of nocardiosis.

Nocardiae have evolved a number of properties that enable them to survive within phagocytes, including neutralization of oxidants, prevention of phagosome–lysosome fusion, and prevention of phagosome acidification. Neutrophils phagocytose the organisms and limit their growth but do not kill them efficiently. Cell-mediated immunity is important for definitive control and elimination of nocardiae. Antibodies to GM-CSF have been found in the majority of patients with alveolar proteinosis and appear to be central to the pathogenesis of this disease. Nocardiae stimulate the production of GM-CSF in phagocytes in vitro, and nocardial infection has been observed in several patients with autoantibodies to GM-CSF, most of whom had not had

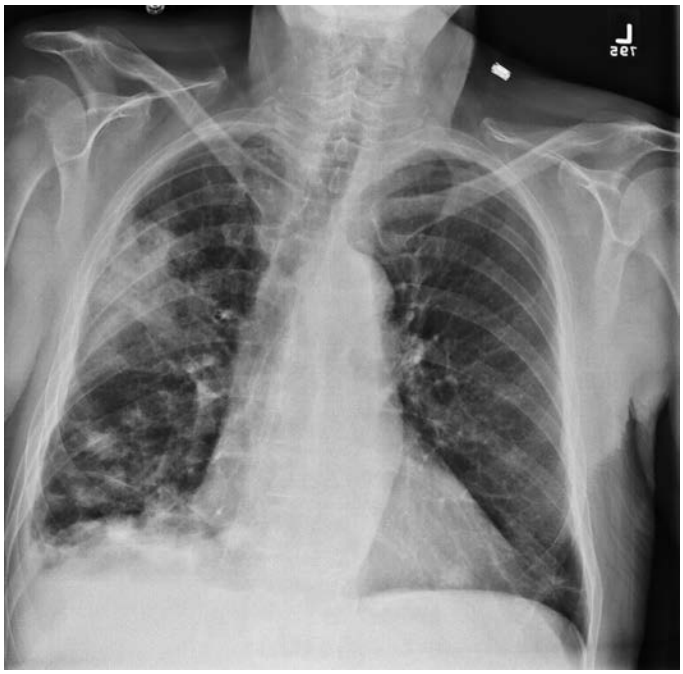

FIGURE 174-1 Nocardial pneumonia. A dense infiltrate with a possible cavity and several nodules are apparent in the right lung.

pulmonary alveolar proteinosis. The relationships between pulmonary alveolar proteinosis, nocardiosis, and antibodies to GM-CSF remain incompletely defined.

CLINICAL MANIFESTATIONS

Respiratory Tract Disease Pneumonia, the most common form of nocardial disease in the respiratory tract, is typically subacute; symptoms have usually been present for days or weeks at presentation. The onset is occasionally more acute in immunosuppressed patients. Cough is prominent and produces small amounts of thick, purulent sputum that is not malodorous. Fever, anorexia, weight loss, and malaise are common; dyspnea, pleuritic pain, and hemoptysis are less common. Remissions and exacerbations over several weeks are frequent. Roentgenographic patterns vary, but some are highly suggestive of nocardial pneumonia. Infiltrates vary in size and are typically dense. Single or multiple nodules are common **(Figs. 174-1 and 174-2)**, sometimes suggesting tumors or metastases. Infiltrates and nodules tend to cavitate (Fig. 174-2). Empyema is present in one-quarter of cases.

Nocardiosis may spread directly from the lungs to adjacent tissues. Pericarditis, mediastinitis, and superior vena cava syndrome have all been reported. Nocardial laryngitis, tracheitis, bronchitis, and sinusitis are much less common than pneumonia. In the major airways, disease often presents as a nodular or granulomatous mass. Nocardiae are sometimes isolated from respiratory secretions of persons without apparent nocardial disease, usually individuals who have underlying lung or airway abnormalities.

Extrapulmonary Disease In half of all cases of pulmonary nocardiosis, disease appears outside the lungs. In one-fifth of cases of disseminated disease, lung disease is not apparent. The most common site of dissemination is the brain. Other common sites include the skin and supporting structures, kidneys, bones, muscles, and eyes, but almost any organ can be involved. Peritonitis has been reported in patients undergoing peritoneal dialysis. Nocardiae have been recovered from blood in a few cases of pneumonia, disseminated disease, or central venous catheter infection. Nocardial endocarditis occurs rarely and can affect either native or prosthetic valves.

The typical manifestation of extrapulmonary dissemination is a subacute abscess. A minority of abscesses outside the lungs or central nervous system (CNS) form fistulas and discharge small amounts of pus. In CNS infections, brain abscesses are usually supratentorial, are often multiloculated, and may be single or multiple **(Fig. 174-3)**. Cases in the posterior fossa and spinal cord have been reported, but they are less common. Brain abscesses tend to burrow into the ventricles or extend out into the subarachnoid space. The symptoms and signs are somewhat more indolent than those of other types of bacterial brain abscess. Meningitis is uncommon and is usually due to spread from a nearby brain abscess. Nocardiae are not easily recovered from cerebrospinal fluid (CSF).

Disease following Transcutaneous Inoculation Disease that follows transcutaneous nocardial inoculation usually takes one of three forms: cellulitis, lymphocutaneous syndrome, or actinomycetoma.

Cellulitis generally begins 1–3 weeks after a recognized breach of the skin, often with soil contamination. Subacute cellulitis, with pain, swelling, erythema, and warmth, develops over days to weeks. The lesions are usually firm and not fluctuant. Disease may progress to involve underlying muscles, tendons, bones, or joints. Dissemination is

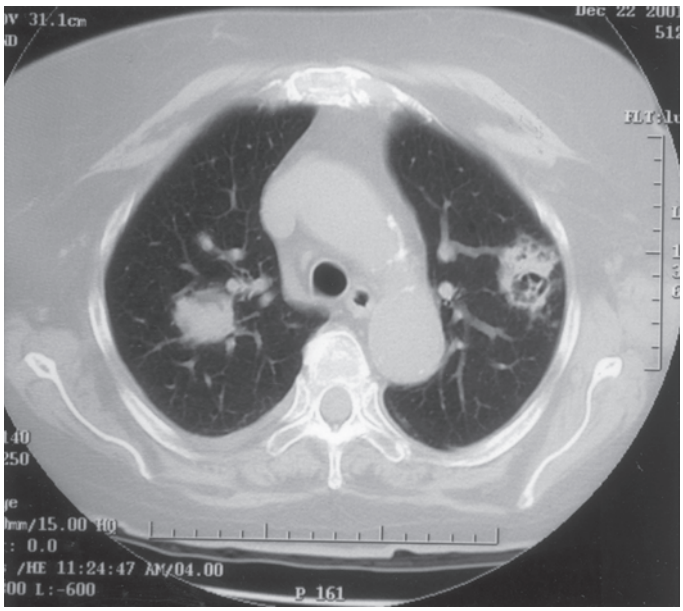

FIGURE 174-2 Nocardial pneumonia. A computed tomography scan shows bilateral nodules, with cavitation in the nodule in the left lung.

FIGURE 174-3 Nocardial abscesses in the right occipital lobe.

rare. *N. brasiliensis* and species in the *N. otitidiscaviarum* complex are most common in cellulitis cases.

Lymphocutaneous disease usually begins as a pyodermatous nodule at the site of inoculation, with central ulceration and purulent or honey-colored drainage. Subcutaneous nodules often appear along lymphatics that drain the primary lesion. Most cases of nocardial lymphocutaneous syndrome are associated with *N. brasiliensis*. Similar disease occurs with other pathogens, most notably *Sporothrix schenckii* **(Chap. 219)** and *Mycobacterium marinum* **(Chap. 180)**.

Actinomycetoma usually begins with a nodular swelling, sometimes at a site of local trauma. Lesions **(Fig. 174-4*A*)** typically develop on the feet or hands but may involve the posterior part of the neck, the upper back, the head, and other sites. The nodule eventually breaks down, and a fistula appears, typically followed by others. The fistulas tend to come and go, with new ones forming as old ones disappear. The discharge is serous or purulent, may be bloody, and often contains 0.1- to 2-mm white granules consisting of masses of mycelia **(Figs. 174-4*C* and 174-4*D*)**. The lesions spread slowly along fascial planes to involve adjacent areas of skin, subcutaneous tissue, and bone. Over months or years, there may be extensive deformation of the affected part. Lesions involving soft tissues are only mildly painful; those affecting bones or joints are more so **(Fig. 174-4*B*)**. Systemic symptoms are absent or minimal, but mycetoma cases are often associated with prolonged, severe disability. Infection rarely disseminates from actinomycetoma, but lesions on the head, neck, and trunk can invade locally to involve deep organs.

Eye Infections Nocardia species are uncommon causes of subacute keratitis, usually following eye trauma. Nocardial endophthalmitis can develop after eye surgery. In one series, nocardiae accounted for more than half of culture-proved cases of endophthalmitis after cataract surgery. Endophthalmitis can also occur during disseminated disease. Nocardial infection of lachrymal glands has been reported.

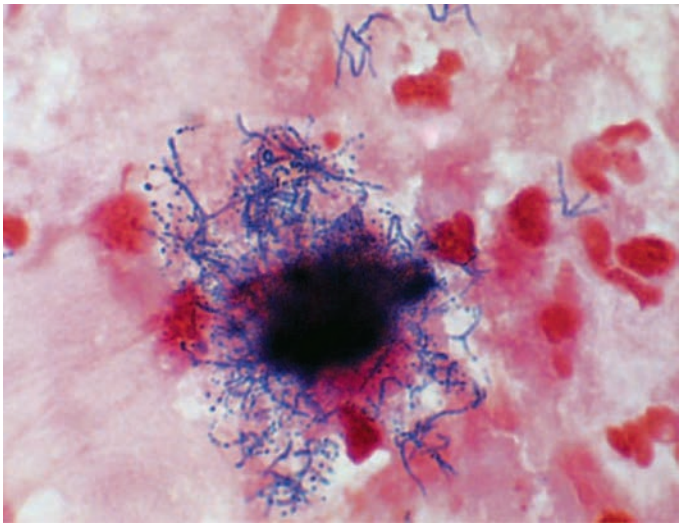

FIGURE 174-5 Gram-stained sputum from a patient with nocardial pneumonia. *(Image provided by Charles Cartwright and Susan Nelson, Hennepin County Medical Center, Minneapolis, MN.)*

DIAGNOSIS

The first step in diagnosis is examination of sputum or pus for crooked, branching, beaded, gram-positive filaments 1 μm wide and up to 50 μm long **(Fig. 174-5)**. Most nocardiae are acid-fast in direct smears if a weak acid is used for decolorization (e.g., in the modified Kinyoun, Ziehl-Neelsen, and Fite-Faraco methods). The organisms often take up silver stains. Recovery from specimens containing a mixed flora can be improved with selective media (colistin–nalidixic acid agar, modified Thayer-Martin agar, or buffered charcoal–yeast extract agar).

Reprinted from R Arenas, M Ameen: Lancet Infect Dis 10:66, 2010, with permission from Elsevier.)*

Nocardiae grow well on most fungal and mycobacterial media, but procedures used for decontamination of specimens for mycobacterial culture can kill nocardiae and should not be used when nocardiae are suspected.

Nocardiae grow relatively slowly; colonies may take up to 2 weeks to appear and may not develop their characteristic appearance—white, yellow, or orange, with aerial mycelia and delicate, dichotomously branched substrate mycelia—for up to 4 weeks. Several blood culture systems support nocardial growth, although nocardiae may not be detected for up to 2 weeks. The growth of nocardiae is so different from that of more common pathogens that the laboratory should be alerted when nocardiosis is suspected in order to maximize the likelihood of isolation.

In nocardial pneumonia, sputum smears are often negative. Unless the diagnosis can be made in smear-negative cases by sampling lesions in more accessible sites, bronchoscopy or lung aspiration is usually necessary. To evaluate the possibility of dissemination in patients with nocardial pneumonia, a careful history should be obtained and a thorough physical examination performed. Suggestive symptoms or signs should be pursued with further diagnostic tests. MRI or CT with contrast of the brain should be done when feasible in cases of pulmonary or disseminated disease. When clinically indicated, CSF or urine should be concentrated and then cultured. Actinomycetoma, eumycetoma (cases involving fungi; **Chap. 219**), and botryomycosis (cases involving cocci or bacilli, often *Staphylococcus aureus*) are difficult to distinguish clinically but are readily distinguished with microbiologic testing or biopsy. Granules should be sought in any discharge. Suspect particles should be washed in saline, examined microscopically, and cultured. Granules in actinomycetoma cases are usually white, pale yellow, pink, or red. Viewed microscopically, they consist of tight masses of fine filaments (0.5–1 μm wide) radiating outward from a central core (Fig. 174-5). Granules from eumycetoma cases are white, yellow, brown, black, or green; under the microscope, they appear as masses of broader filaments (2–5 μm wide) encased in a matrix. Granules of botryomycosis consist of loose masses of cocci or bacilli. Organisms can also be seen in wound discharge or histologic specimens. The most reliable way to differentiate among the various organisms associated with mycetoma is by culture.

Isolation of nocardiae from sputum or blood occasionally represents colonization, transient infection, or contamination. In typical cases of respiratory tract colonization, Gram-stained specimens are negative and cultures are only intermittently positive. A positive sputum culture in an immunosuppressed patient usually reflects disease. When nocardiae are isolated from sputum of an immunocompetent patient without apparent nocardial disease, the patient should be observed carefully without treatment. A patient with a host-defense defect that increases the risk of nocardiosis should usually receive antimicrobial treatment.

Nocardia DNA has been detected in respiratory tract samples from patients with proven or suspected pulmonary nocardiosis, other chronic lung diseases, and healthy controls. The sensitivity and specificity of DNA testing has not been well defined.

Species are definitively determined by molecular techniques. Matrix-assisted laser desorption/ionization/time-of-flight (MALDI-TOF) mass spectrometry is accurate in 75% or more cases when compared with genetic testing. MALDI-TOF is much more practical for clinical laboratories and is becoming common in laboratories in high-resource countries.

Because nocardiosis is uncommon, data on the relation between susceptibility test results for specific drugs and clinical outcomes in patients treated with these drugs are meager. Careful clinical monitoring is essential, and consultation with clinicians who have experience with nocardiosis is often needed. Susceptibility to antimicrobial agents in vitro is best determined with a Clinical Laboratory Standards Institute (CLSI)–approved broth dilution test. Susceptibility testing with E-test or BACTEC radiometric methods is less definitive. Nocardial growth is slower than the growth of most clinically important bacteria, and nocardiae tend to clump in suspension so that susceptibility-test end points are difficult to read; thus experience is necessary for reliable reading of results. If an isolate can be accurately speciated, its susceptibility to antimicrobial drugs can be predicted with reasonable accuracy.

Speciation by molecular methods or MALDI-TOF is not practical in many resource-poor countries. As a result, therapy for nocardiosis is often initiated without definitive speciation or knowledge of susceptibility results. For mild or moderate cases, therapy with drugs known to be effective against most isolates is usually adequate. For severe cases or cases that do not respond promptly to antimicrobial therapy, isolates should be sent to a laboratory experienced with *Nocardia* for identification and susceptibility testing whenever possible.

TREATMENT

Nocardiosis

Trimethoprim-sulfamethoxazole (TMZ-SMX) is the drug of choice for most cases **(Tables** 174-1 and **174-2)**. Reported rates of TMP-SMX susceptibility have varied widely, and controversy has ensued about the reliability of sulfonamides for therapy. However, clinical responses to appropriate sulfonamide treatment around the world are usually satisfactory. At the outset, 10–20 mg/kg of TMP and 50–100 mg/kg of SMX are given each day in two divided doses. Later, daily doses can be decreased to as little as 5 mg/kg and 25 mg/kg, respectively. In persons with sulfonamide allergies, desensitization usually allows continuation of therapy with these effective and inexpensive drugs.

Clinical experience with other oral drugs is limited. Minocycline (100–200 mg twice a day) is often effective; other tetracyclines are usually less effective. Linezolid is the most consistently active antimicrobial agent, but adverse effects become common and limiting in many patients after 2–3 weeks. Amoxicillin (875 mg) combined with clavulanate (125 mg), given twice a day, has been effective in *N. brasiliensis* cases and some *N. farcinica* cases. Among the quinolones, moxifloxacin and gemifloxacin appear to be most active.

Amikacin, the best-established parenteral drug except in cases involving the *N. transvalensis* complex, is given in doses of 5–7.5 mg/kg every 12 h or 15 mg/kg every 24 h. Serum drug levels should be monitored during prolonged therapy in patients with diminished renal function and in the elderly. Ceftriaxone and imipenem are usually effective except as indicated in Table 174-1. Tigecycline appears to be active in vitro against some species, but little clinical experience has been reported.

Patients with severe disease are initially treated with a combination including TMP-SMX, amikacin, and ceftriaxone or imipenem. Clinical improvement is usually noticeable after 1–2 weeks of therapy but may take longer, especially with CNS disease. After definite

TABLE 174-2 Treatment Duration for Nocardiosis

DISEASE	DURATION
Pulmonary or systemic	
Intact host defenses	6–12 months
Deficient host defenses	12 months[a]
CNS disease	12 months[b]
Cellulitis, lymphocutaneous syndrome	2 months
Osteomyelitis, arthritis, laryngitis, sinusitis	4 months
Actinomycetoma	6–12 months after clinical cure
Keratitis	Topical: until apparent cure Systemic: until 2–4 months after apparent cure

[a]In some patients with AIDS and CD4+ T lymphocyte counts of <200/μL or with chronic granulomatous disease, therapy for pulmonary or systemic disease must be continued indefinitely. [b]If all apparent central nervous system (CNS) disease has been excised, the duration of therapy may be reduced to 6 months.

clinical improvement, therapy can be continued with a single oral drug, usually TMP-SMX. Some experts use two or more drugs for the entire course of therapy, but whether multiple drugs are better than a single agent is not known, and additional drugs increase the risk of toxicity. In patients with nocardiosis who need immunosuppressive therapy for an underlying disease or prevention of transplant rejection, immunosuppressive therapy should be continued.

Use of SMX and TMP in high-risk populations to prevent *Pneumocystis* disease or urinary tract infections appears to reduce but not eliminate the risk of nocardiosis. The incidence of nocardiosis is low enough that prophylaxis solely to prevent this disease is not recommended.

Surgical management of nocardial disease is similar to that of other bacterial diseases. Brain abscesses should be aspirated, drained, or excised if the diagnosis is unclear, if an abscess is large and accessible, or if an abscess fails to respond to chemotherapy. Small or inaccessible brain abscesses should be treated medically; clinical improvement should be noticeable within 1–2 weeks. Brain imaging should be repeated to document the resolution of lesions, although abatement on images often lags behind clinical improvement.

Antimicrobial therapy usually suffices for nocardial actinomycetoma. In deep or extensive cases, drainage or excision of heavily involved tissue may facilitate healing, but structure and function should be preserved whenever possible. Keratitis is treated with a topical sulfonamide or amikacin drops plus a sulfonamide or an alternative drug given by mouth.

Nocardial infections tend to relapse (particularly in patients with chronic granulomatous disease), and long courses of antimicrobial therapy are necessary (Table 174-2). If disease is unusually extensive or if the response to therapy is slow, the recommendations in Table 174-2 should be exceeded.

With appropriate treatment, the mortality rate for pulmonary or disseminated nocardiosis outside the CNS should be <5%. CNS disease carries a higher mortality rate. Patients should be followed carefully for at least 6 months after therapy has ended. Actinomycetoma often responds better to therapy than mycetoma associated with fungi, but relapses occur in a minority of patients, and disability often persists.

175 Actinomycosis

Thomas A. Russo

Actinomycosis is uncommon, and most physicians' personal experience with its clinical presentations is limited. Laboratory identification of the etiologic agents from the order Actinomycetales is not routine. Thus, actinomycosis remains a diagnostic challenge, even for a skilled clinician. However, this infection is usually curable with medical therapy alone. Therefore, an awareness of the full spectrum of clinical syndromes can expedite diagnosis and treatment and minimize unnecessary surgical interventions, morbidity, and mortality.

Classical actinomycosis is an indolent, slowly progressive infection caused by anaerobic or microaerophilic bacteria, primarily of the genus *Actinomyces*, that colonize the mouth, colon, and vagina. Mucosal disruption may lead to infection at virtually any site in the body. In vivo growth of actinomycetes usually results in the formation of characteristic clumps called *grains* or *sulfur granules*. The clinical presentations of actinomycosis are myriad. Common in the preantibiotic era, actinomycosis has diminished in incidence, as has its timely recognition. Actinomycosis has been called the most misdiagnosed disease, and it has been said that no disease is so often missed by experienced diagnosticians.

Three "classic" clinical presentations that should prompt consideration of this unique infection are (1) the combination of chronicity, progression across tissue boundaries, and mass-like features (mimicking malignancy, with which it is often confused); (2) the development of a sinus tract, which may spontaneously resolve and recur; and (3) a refractory or relapsing infection after a short course of therapy, since cure of established actinomycosis requires prolonged treatment.

ETIOLOGIC AGENTS

Actinomycosis is most commonly caused by *A. israelii, A. naeslundii, A. odontolyticus, A. viscosus, A. meyeri, A. graevenitzii*, and *A. gerencseriae*. Infections due to *A. neuii* have been increasingly recognized. Most if not all actinomycotic infections are polymicrobial. *Aggregatibacter (Actinobacillus) actinomycetemcomitans, Eikenella corrodens*, Enterobacteriaceae, and species of *Fusobacterium, Bacteroides, Capnocytophaga, Staphylococcus*, and *Streptococcus* are commonly isolated with actinomycetes in various combinations, depending on the site of infection. Their contribution to the pathogenesis of actinomycosis is uncertain.

Comparative 16S rRNA gene sequencing has led to the identification of an ever-expanding list of *Actinomyces* species and a reclassification of some species to other genera. At present, 53 species and 2 subspecies have been recognized (*https://www.bacterio.net/genus/actinomyces*), with at least 25 species implicated as causes of human disease. *A. europaeus, A. neuii, A. radingae, A. turicensis, A. cardiffensis, A. urogenitalis, A. hongkongensis, A. georgiae, A. massiliensis, A. timonensis,* and *A. funkei* as well as two former *Actinomyces* species—*Trueperella* (*Arcanobacterium*) *pyogenes* and *Trueperella* (*Arcanobacterium*) *bernardiae*—and *Propionibacterium propionicum* are additional causes of human actinomycosis, albeit not always with a "classic" presentation.

EPIDEMIOLOGY

Actinomycosis has no geographic boundaries and occurs throughout life, with a peak incidence in the middle decades. Males have a threefold higher incidence than females, possibly because of poorer dental hygiene and/or more frequent trauma. Improved dental hygiene and the initiation of antimicrobial treatment before actinomycosis fully develops have probably contributed to a decrease in incidence since the advent of antibiotics. Individuals who do not seek or have access to health care, those who have an intrauterine contraceptive device (IUCD) in place for a prolonged period (see "Pelvic Disease," below), and those who receive bisphosphonate treatment (see "Oral–Cervicofacial Disease," below) are probably at higher risk.

PATHOGENESIS AND PATHOLOGY

The etiologic agents of actinomycosis are members of the normal oral flora and are often cultured from the bronchi, the gastrointestinal tract, and the female genital tract. The critical step in the development of actinomycosis is disruption of the mucosal barrier. Local infection may ensue. Once established, actinomycosis spreads contiguously in a slow, progressive manner, ignoring tissue planes. Although acute inflammation may initially develop at the infection site, the hallmark of actinomycosis is the characteristic chronic, indolent phase manifested by lesions that usually appear as single or multiple indurations. Central necrosis consisting of neutrophils and sulfur granules develops and is virtually diagnostic. The fibrotic walls of the mass are typically described as "wooden." The responsible bacterial and/or host factors have not been identified. Over time, sinus tracts to the skin, adjacent organs, or bone may develop. In rare instances, distant hematogenous seeding may occur; lymphatic spread and associated lymphadenopathy are uncommon. As mentioned above, these unique features of actinomycosis mimic malignancy, with which it is often confused.

Foreign bodies appear to facilitate infection. This association most frequently involves IUCDs. Reports have described an association of actinomycosis with HIV infection; transplantation; common variable immunodeficiency; chronic granulomatous disease; treatment with anti–tumor necrosis factor α agents, glucocorticoids, or bisphosphonates; and radio- or chemotherapy. Ulcerative mucosal infections (e.g., by herpes simplex virus or cytomegalovirus) may facilitate disease development.

CLINICAL MANIFESTATIONS

Oral–Cervicofacial Disease Actinomycosis occurs most frequently at an oral, cervical, or facial site, usually as a soft tissue swelling, abscess, mass, or ulcerative lesion that is often mistaken for a neoplasm. Dental diseases or procedures are common precipitating factors. The angle of the jaw is generally involved, but a diagnosis of actinomycosis should be considered with any mass lesion or relapsing infection in the head and neck. Radiation therapy and especially bisphosphonate treatment have been recognized as contributing to an increasing incidence of actinomycotic infection of the mandible and maxilla **(Fig. 175-1)**. Canaliculitis (commonly due to *P. propionicum*), otitis, sinusitis, and laryngeal disease also can develop. Pain, fever, and leukocytosis are variably reported. Contiguous extension to the cranium, cervical spine, or thorax is a potential sequela.

Thoracic Disease Thoracic actinomycosis, which may be facilitated by aspirated foreign material, usually follows an indolent progressive course, with involvement of the pulmonary parenchyma and/or the pleural space. Chest pain, fever, and weight loss are common. A cough, when present, is variably productive. The usual radiographic finding is either a mass lesion or pneumonia. On CT, central areas of low attenuation and ring-like rim enhancement may be seen; cavitary disease may develop. More than 50% of cases include pleural thickening, effusion, or empyema **(Fig. 175-2)**. Rarely, pulmonary nodules or endobronchial lesions occur. Lesions suggestive of actinomycosis include those that cross fissures or pleura; extend into the mediastinum, contiguous bone, or chest wall (*empyema necessitatis*); or are associated with a sinus tract. In the absence of these findings, thoracic actinomycosis is usually mistaken for a neoplasm or pneumonia due to more usual causes.

Mediastinal infection is uncommon, usually arising from thoracic extension but rarely from perforation of the esophagus, trauma, or extension of head and neck or abdominal disease. The structures within the mediastinum and the heart can be involved in various combinations; consequently, the possible presentations are diverse. Primary endocarditis (in which *A. neuii* has been increasingly described), esophageal infection, and isolated disease of the breast occur.

Abdominal Disease Abdominal actinomycosis poses a great diagnostic challenge. Months or years usually pass from the inciting event (e.g., appendicitis, diverticulitis, peptic ulcer disease, spillage of gallstones or bile during cholecystectomy, foreign-body perforation, bowel surgery, or ascension from IUCD-associated pelvic disease) to clinical recognition. Because of the flow of peritoneal fluid and/or the direct extension of primary disease, virtually any abdominal

B. Hsiao, Division of Infectious Diseases, Department of Medicine, State University of New York at Buffalo.)*

organ, region, or space can be involved. The disease usually presents as an abscess, a mass, or a mixed lesion that is often fixed to underlying tissue and mistaken for a tumor. On CT, enhancement is most often heterogeneous and adjacent bowel is thickened. Sinus tracts to the abdominal wall, to the perianal region, or between the bowel and other organs may develop and mimic inflammatory bowel disease **(Chap. 326)**. Recurrent disease or a wound or fistula that fails to heal suggests actinomycosis.

Hepatic infection usually presents as one or more abscesses or masses **(Fig. 175-3)**. Isolated disease presumably develops via hematogenous seeding from cryptic foci. Imaging and percutaneous techniques have resulted in improved diagnosis and treatment.

All levels of the urogenital tract can be infected. Renal disease usually presents as pyelonephritis and/or renal and perinephric abscess. Bladder involvement, usually due to extension of pelvic disease, may result in ureteral obstruction or fistulas to bowel, skin, or uterus. *Actinomyces* can be detected in urine with appropriate stains and cultures.

Pelvic Disease Actinomycotic involvement of the pelvis occurs most commonly in association with an IUCD but can also be associated with other foreign bodies, such as surgical mesh. When an IUCD is in place or has been used but removed, pelvic symptoms should prompt consideration of actinomycosis. The risk, although not quantified, appears small. The disease rarely develops when the IUCD has been in place for <1 year, but the risk increases with time. Symptoms are typically indolent; fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge are the most common. The earliest stage of disease—often endometritis—commonly progresses to pelvic masses or a tuboovarian abscess **(Fig. 175-4)**. Unfortunately, because the diagnosis is often delayed, a "frozen pelvis" mimicking malignancy or endometriosis can develop by the time of recognition, which may lead to unnecessary surgery. Cancer antigen 125 levels may be elevated, further contributing to misdiagnosis. In contrast to malignancy and tuberculosis, pelvic actinomycosis only uncommonly includes ascites and lymphadenopathy. An endometrial biopsy may enable diagnosis in a minimally invasive fashion.

Actinomyces-like organisms (ALOs), which are identified in Papanicolaou-stained specimens in (on average) 7% of women using an IUCD, have a low positive predictive value for diagnosis. The detection of ALOs in an asymptomatic patient warrants education and close follow-up but not removal of the IUCD unless a suitable contraceptive alternative is agreed on. In the presence of symptoms that cannot be accounted for, it seems prudent to remove the IUCD and—if advanced disease is excluded—to initiate a 14-day course of empirical treatment for possible early endometritis.

Central Nervous System Disease Actinomycosis of the central nervous system (CNS) is rare. Single or multiple brain abscesses are most common. Individuals with hereditary hemorrhagic telangiectasia are at increased risk for brain abscess with *Actinomyces* as the potential etiologic agent. An abscess usually appears on CT as a ring-enhancing lesion with a thick wall that may be irregular or nodular. Magnetic resonance perfusion and spectroscopy findings have also been described, as have primary meningitis, epidural or subdural space infection, and cavernous sinus syndrome.

FIGURE 175-4 Computed tomogram showing pelvic actinomycosis associated with an intrauterine contraceptive device. The device is encased by endometrial fibrosis (*solid arrow*); also visible are paraendometrial fibrosis (*open triangular arrowhead*) and an area of suppuration (*open arrow*).

Musculoskeletal and Soft Tissue Infection Actinomycotic infection of bones and joints is usually due to adjacent soft tissue infection but may be associated with trauma, injections, surgery (e.g., prostheses), osteoradionecrosis and bisphosphonate osteonecrosis (limited to mandibular and maxillary bones), or hematogenous spread. Because of slow disease progression, new bone formation and bone destruction can be seen concomitantly. Infection of soft tissue is uncommon and is usually a result of trauma. Actinomycetoma is a slowly progressive infection of the skin and subcutaneous tissue that is usually seen in warm climates. Despite the name being suggestive of *Actinomyces* as a causative agent, it is most commonly caused by *Nocardia* or *Actinomadura* species **(Chap. 174)**.

Disseminated Disease Hematogenous dissemination of disease from any location rarely results in multiple-organ involvement.

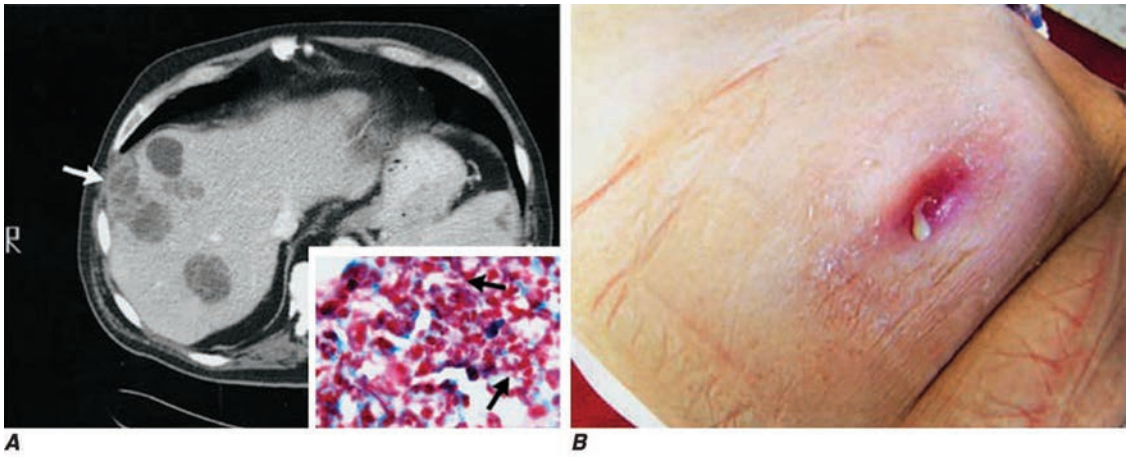

FIGURE 175-3 Hepatic–splenic actinomycosis. *A.* Computed tomogram showing multiple hepatic abscesses and a small splenic lesion due to *Actinomyces israelii*. *Arrow* indicates extension outside the liver. *Inset:* Gram's stain of abscess fluid demonstrating beaded filamentous gram-positive rods. ***B.*** Subsequent formation of a sinus tract. *(Reprinted with permission from Saad M: Actinomyces hepatic abscess with cutaneous fistula. A. meyeri is most commonly involved. The lungs and liver are most often affected, with the presentation of multiple nodules mimicking disseminated malignancy. The clinical presentation may be surprisingly indolent given the extent of disease.

DIAGNOSIS

The diagnosis of actinomycosis is rarely considered. All too often, actinomycosis is first mentioned by the pathologist after extensive surgery. Since medical therapy alone is frequently sufficient for cure, the challenge for the clinician is to consider the possibility of actinomycosis, to diagnose it in the least invasive fashion, and to avoid unnecessary surgery. The clinical and radiographic presentations that suggest actinomycosis are discussed above. Of note, hypermetabolism has been demonstrated by ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) in actinomycotic disease. Aspirations and biopsies (with or without CT or ultrasound guidance) are being used successfully to obtain clinical material for diagnosis, although surgery may be required. The microscopic identification of sulfur granules (an in vivo matrix of bacteria, calcium phosphate, and host material) in pus or tissues, which increases with the examination of additional histopathologic sections and the use of positively charged slides to optimize adhesion, is the most common means of diagnosis. Occasionally, these granules are identified grossly from draining sinus tracts or pus. Although sulfur granules are a defining characteristic of actinomycosis, granules also are found in mycetoma **(Chaps. 174 and 219)** and botryomycosis (a chronic suppurative bacterial infection of soft tissue or, in rare cases, visceral tissue that produces clumps of bacteria resembling granules). These entities can easily be differentiated from actinomycosis with appropriate histopathologic and microbiologic studies. Microbiologic identification of actinomycetes is often precluded by prior antimicrobial therapy or failure to perform appropriate microbiologic cultures. For optimal yield, the avoidance of even a single dose of antibiotics is mandatory. Although some species can grow aerobically, isolation is maximized under anaerobic conditions, usually requiring 5–7 days but potentially up to 2–4 weeks. The use of 16S rRNA gene amplification and sequencing by clinical microbiology laboratories is increasing and is enhancing diagnostic sensitivity and specificity. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) holds similar promise, but databases are still being optimized. Because actinomycetes are components of the normal oral and genital-tract flora, their identification in the absence of sulfur granules in sputum, bronchial washings, and cervicovaginal secretions is of little significance.

TREATMENT

Actinomycosis

Decisions about treatment are based on the collective clinical experience of the past 70 years. Actinomycosis requires prolonged treatment with high doses of antimicrobial agents; suitable antimicrobial agents and those deemed unreliable are listed in **Table 175-1**. The need for intensive treatment is presumably due to the drugs' poor penetration of the thick-walled masses common in this infection and/or the sulfur granules themselves, which may represent a biofilm. Although therapy must be individualized, the IV administration of 18–24 million units of penicillin daily for 2–6 weeks, followed by oral therapy with penicillin or amoxicillin (total duration, 6–12 months), is a reasonable guideline for serious infections and bulky disease. For penicillin-allergic patients, tetracyclines, ceftriaxone, or carbapenems are reasonable alternatives. Less extensive disease, particularly that involving the oral–cervicofacial region or the isolation of *Actinomyces* in the absence of tissue changes associated with actinomycosis, may be cured with a shorter course. For home IV therapy, the ease of once-a-day dosing makes ceftriaxone appealing in certain circumstances; however, a greater body of literature supporting its efficacy would be desirable. The availability of portable infusion pumps for home therapy allows for both the appropriate dosing and practical administration of IV penicillin. For infections in critical sites (e.g., CNS), this approach remains the safest until more information is available on other agents. The pharmacokinetic properties, availability of oral and parenteral formulations, and potential efficacy of azithromycin also make this agent appealing. Unfortunately, few in vitro and no clinical data exist on its use to treat actinomycosis. If therapy is extended beyond the resolution of measurable disease, the risk of relapse—a clinical hallmark of this infection—will be minimized; CT and MRI are generally the most sensitive and objective techniques by which to accomplish this goal. A similar approach is reasonable for immunocompromised patients, although refractory disease has been described in HIV-infected individuals. While the role played by "companion" microbes in actinomycosis is unclear, many isolates are pathogens in their own right, and a regimen covering these organisms during the initial treatment course is reasonable. Isolation of *Actinomyces* from blood cultures in the absence of defined infection may represent contamination or transient bacteremia from a mucosal site of colonization, in which case treatment may not be necessary.

Combined medical–surgical therapy is still advocated in some reports. However, an increasing body of literature now supports an initial attempt at cure with medical therapy alone, even in extensive disease. CT and MRI should be used to monitor the response to therapy. In most cases, either surgery can be avoided or a less extensive procedure can be used. This approach is particularly valuable in sparing critical organs, such as the bladder or the reproductive organs in women of childbearing age. For a well-defined abscess, percutaneous drainage in combination with medical therapy is a reasonable approach. When a critical location is involved (e.g., the epidural space, the CNS), when there is significant hemoptysis, or

TABLE 175-1 Appropriate and Inappropriate Antibiotic Therapy for Actinomycosis[a]

CATEGORY	AGENT
Extensive successful clinical experience[b]	Penicillin: 3–4 million units IV q4h[c,d] Amoxicillin: 500 mg PO q6h Erythromycin: 500–1000 mg IV q6h or 500 mg PO q6h[c] Tetracycline: 500 mg PO q6h Doxycycline: 100 mg IV or PO q12h Minocycline: 100 mg IV or PO q12h Clindamycin: 900 mg IV q8h or 300–450 mg PO q6h[c]
Anecdotal successful clinical experience	Ceftriaxone[d] Ceftizoxime Imipenem-cilastatin Piperacillin-tazobactam
Agents predicted to be efficacious on the basis of in vitro activity	Vancomycin Linezolid Quinupristin-dalfopristin Rifampin Ertapenem[d] Tigecycline[d] Azithromycin[d]
Agents that should be avoided	Metronidazole Aminoglycosides Oxacillin, dicloxacillin Cephalexin Fluoroquinolones

[a]Additional coverage for concomitant "companion" bacteria may be required. [b]Controlled evaluations have not been performed. Dose and duration require individualization depending on the host, site, and extent of infection. As a general rule, a maximal parenteral antimicrobial dose for 2–6 weeks followed by oral therapy, for a total duration of 6–12 months, is required for serious infections and bulky disease, whereas a shorter course may suffice for less extensive disease, particularly in the oral–cervicofacial region. Monitoring the impact of therapy with CT or MRI is advisable when appropriate. [c]Recent in vitro data have demonstrated resistance in up to 33% of isolates. [d]This agent can be considered for at-home parenteral therapy; penicillin requires a continuous infusion pump.

when suitable medical therapy fails, surgical intervention may be appropriate. In the absence of optimal data, the combination of a prolonged course of antimicrobial therapy and resection—at least of necrotic bone for bisphosphonate-related osteonecrosis of the jaw (BRONJ)—is a reasonable approach.

176 Whipple's Disease

Thomas A. Russo, Seth R. Glassman

Whipple's disease (WD), described by George Whipple in 1907, is a chronic infection caused by *Tropheryma whipplei*. Most commonly, years pass from the onset of symptoms to the recognition of the disease because of its rarity, its various manifestations mimicking other conditions, and the need to perform nonroutine diagnostic tests. The long-held belief that WD is an infection was supported by observations on its responsiveness to antimicrobial therapy in the 1950s and the identification of bacilli via electron microscopy in small-bowel biopsy specimens in the 1960s. This hypothesis was finally confirmed by amplification and sequencing of a partial 16S rRNA polymerase chain reaction (PCR)–generated amplicon from duodenal tissue in 1991. The subsequent successful cultivation of *T. whipplei* enabled whole-genome sequencing and the development of additional diagnostic tests. The development of PCR-based diagnostics has broadened our understanding of both the epidemiology of and the clinical syndromes attributable to *T. whipplei*. Exposure to *T. whipplei*, which appears to be much more common than has been appreciated, can be followed by asymptomatic carriage, acute disease, or chronic infection. Chronic infection—WD—is a rare development after exposure. "Classic" WD is manifested by some combination of arthralgias/arthritis, weight loss, chronic diarrhea, abdominal pain, and fever. Variable involvement at other sites also occurs; neurologic and cardiac disease are most common. Acute infection and chronic organ disease in the absence of intestinal involvement (see "Isolated Infection," below) are described with increasing frequency. Since untreated WD is often fatal and delayed diagnosis may lead to irreparable organ damage (e.g., in the central nervous system [CNS]), knowledge of the clinical scenarios in which Whipple's should be considered and of an appropriate diagnostic strategy is mandatory.

ETIOLOGIC AGENT

T. whipplei is a weakly staining gram-positive bacillus. Genomic sequence data have revealed that the organism has a small (<1-megabase) chromosome, with many biosynthetic pathways absent or incomplete. This finding is consistent with a host-dependent intracellular pathogen or a pathogen that requires a nutritionally rich extracellular environment. It is one of the slowest growing human pathogens, with a doubling time of 18 days. A genotyping scheme based on a variable region has disclosed >100 genotypes to date. All genotypes appear to be capable of causing similar clinical syndromes.

EPIDEMIOLOGY

WD is rare but has been increasingly recognized since the advent of PCR-based diagnostic tools. Prevalence had been previously estimated at 1–3 cases per 1 million population, although a recent U.S. epidemiologic survey places the number closer to 10 cases per million. Seroprevalence studies indicate that ~50% of Western Europeans and ~75% of Africans from rural Senegal have been exposed to *T. whipplei*. Higher prevalence may be attributable to differences in sanitation. Humans are the only known host. In most studies, males more commonly develop WD; WD is more common in Caucasians and increases with age. To date, no clear animal or environmental reservoir has been demonstrated. However, the organism has been identified by PCR in sewage water and human feces. Workers with direct exposure to sewage are more likely to be asymptomatically colonized than controls, a pattern suggesting fecal–oral spread. Fecal PCR detection rates of 38% among family members of carriers or patients with infection support oral–oral or fecal–oral spread, although a common environmental exposure cannot be excluded. Further, the development of acute *T. whipplei* pneumonia in children raises the possibility of droplet or airborne transmission.

PATHOGENESIS AND PATHOLOGY

Rates of asymptomatic carriage of *T. whipplei* are far higher than rates of chronic infection (<0.01% of those exposed). Both decreased host pathogen-specific inflammatory response and pathogen-driven modulation of host inflammatory response likely play a role in establishing chronic infection. The human leukocyte antigen (HLA) alleles DRB1*13 and DQB1*06, which stimulate humoral rather than cell-mediated immune responses, are associated with an increased risk of infection. However, only a minority of infected patients possess these haplotypes, suggesting a role for other host factors. IRF4, a transcription factor involved with the immune response, could be such a factor as evidenced by four related family members with WD who possessed IFR4 haploinsufficiency due to a loss-of-function mutation; the distribution of WD in this extended family was consistent with an autosomal dominant trait with incomplete penetrance.

Flow cytometry performed in WD patients demonstrates B-cell subset abnormalities when compared to matched controls. Chronic infection is associated with an impaired T_H1 response, enhanced production of anti-inflammatory cytokines, increased activity of regulatory T cells, M2 polarization of macrophages with diminished antimicrobial activity and impaired phagosome–lysosome fusion and ensuing apoptosis, and blunted development of *T. whipplei*–specific T cells. Therapies that blunt cell-mediated host immune responses (e.g. systemic glucocorticoids or anti–tumor necrosis factor α [TNF-α] agents) may accelerate progression of chronic disease. Impaired cell-mediated immunity may play a role in establishing chronic carriage of *T. whipplei* as is evidenced by higher rates of detection in the secretions of HIV-infected persons.

T. whipplei has a tropism for myeloid cells, which it invades and in which it can avoid being killed. Infiltration of infected tissue by large numbers of foamy macrophages containing periodic acid–Schiff (PAS)–staining inclusions (representing ingested bacteria) is a characteristic and most common finding. With gastrointestinal disease progression, villus atrophy, lymphangiectasia, crypt hyperplasia, and apoptosis of surface epithelial cells are observed in the small intestine, with resultant diarrhea due to decreased absorption and increased leak of water and solutes. Occasionally, involvement of lymphatic or hepatic tissue may manifest as noncaseating granulomas that can mimic sarcoid or granulomatous vasculitis.

CLINICAL MANIFESTATIONS

Asymptomatic Colonization/Carriage Studies using primarily PCR have detected *T. whipplei* sequence in stool, saliva, duodenal tissue, and (rarely) blood in the absence of symptoms. Although prevalence rates are still being defined, in Western European countries, detection in saliva (0.2%) is less common than that in stool (1–11%) and appears to occur only with concomitant fecal carriage. The prevalence of fecal carriage is elevated among individuals with exposure to waste water or sewage (12–26%) and among children living in tropical Africa and Asia (20–48%). A duration of carriage of 7 years for the same strain has been described in a sewer worker. Evolution of the carrier state into chronic disease is uncommon. Bacterial loads are lighter in asymptomatic carriage than in active disease.

Acute Infection *T. whipplei* has been implicated as a cause of acute gastroenteritis in children. It was also detected via PCR in the blood of 4.6% of febrile patients (75% of whom were <15 years of age) from two rural villages in Senegal as opposed to 0.25% of healthy controls. Further, *T. whipplei* has been implicated as a cause of acute pneumonia. These data suggest that primary acquisition may result in symptomatic pulmonary or intestinal infection or a febrile syndrome, which perhaps are more common than is generally appreciated.

Chronic Infection • **"CLASSIC" WD** So-called classic WD was the initial clinical syndrome recognized, with consequent identification of *T. whipplei*. This chronic infection is defined by involvement of the duodenum and/or jejunum that develops over years. In most individuals, the initial phase of disease manifests primarily as intermittent, often symmetrical, occasionally chronic, and rarely destructive migratory oligo- or polyarthralgias/seronegative arthritis involving the knees, wrists, ankles, and metacarpal-interphalangeal joints most commonly. Less frequently, spondylitis, sacroiliitis, discitis, tenosynovitis, bursitis, and prosthetic hip infection also have been described. Intermittent fever, myalgias, and skin nodules may accompany joint symptoms. Tests for rheumatoid factor and antinuclear antibody are usually negative. This initial stage is often confused with a variety of rheumatologic disorders and, on average, lasts 6–8 years before gastrointestinal symptoms commence. Treatment of presumed inflammatory arthritis with immunosuppressive agents (e.g., glucocorticoids, anti-TNF-α, anakinra) can accelerate progression of the disease process; thus, screening for WD prior to initiation of immunosuppressant therapy may be appropriate, depending on the clinical scenario. Alternatively, antimicrobial therapy for another indication may reduce symptoms, and this situation should also prompt consideration of WD. The intestinal symptoms that develop in the majority of cases are characterized by diarrhea with accompanying weight loss and may be associated with fever and abdominal pain. Occult gastrointestinal blood loss, vitamin deficiencies, hepatosplenomegaly (10–15%), and ascites (10%) are less common. Anemia and hypereosinophilia may be detected. The most common finding on abdominal CT is mesenteric and/or retroperitoneal lymphadenopathy (usually raising concern about lymphoma). The endoscopic or video-capsule observation of pale, yellow, or shaggy mucosa with erythema or ulceration past the first portion of the duodenum suggests WD **(Fig. 176-1)**. When endoscopy with duodenal biopsy is nondiagnostic, a video-capsule study may assist in identifying more distal lesions for subsequent biopsy. ^{18}F-Fluorodeoxyglucose positron emission tomography (FDG-PET) studies in patients with WD suggest the entire small bowel can be involved. Diagnostic misdirection can be caused by co-infection with *Giardia lamblia*, which is occasionally identified. The intestinal phase can also be confused with Crohn's or celiac disease. In addition to rheumatologic and intestinal disease, neurologic (6–63%), cardiac (17–55%), pulmonary (10–50%), lymphatic (10–55%), ocular (5–10%), dermal (5–30%), and less commonly other sites are variably involved in classic WD.

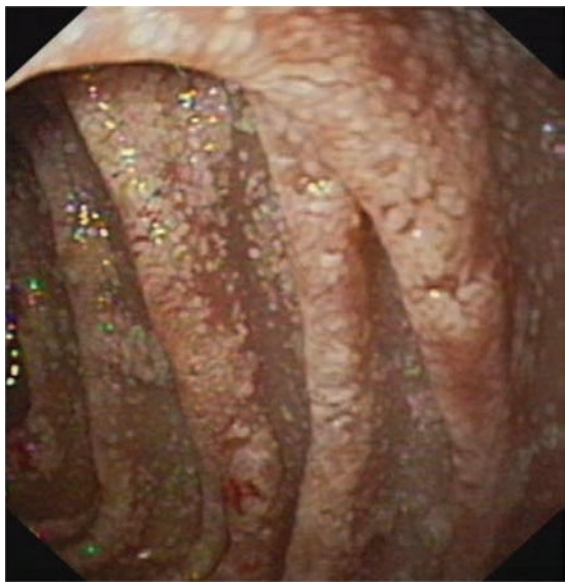

FIGURE 176-1 Endoscopic view of the jejunal mucosa demonstrating a thickened, granular mucosa and "white spots" due to dilated lacteals. *(Reprinted with permission from J Bureš et al: Whipple's disease: Our own experience and review of the literature. Gastroenterol Res Pract, 2013.)*

Neurologic Disease CNS disease, defined by PCR-based detection of *T. whipplei* in cerebrospinal fluid (CSF), develops in ~50% of patients, many of whom are asymptomatic. A variety of neurologic manifestations have been reported and portend a poor prognosis. The most common are cognitive changes including memory impairment progressing to dementia, personality and mood alterations, hypothalamic involvement (e.g., polyuria/polydipsia, sleep-cycle disorders), and supranuclear ophthalmoplegia. In addition, neuro-ophthalmologic manifestations of WD include supranuclear gaze palsy (usually vertical), oculomasticatory and oculofacial myorhythmia (highly suggestive of Whipple's), nystagmus, and retrobulbar neuritis. Focal neurologic presentations (dependent on lesion location), seizures, ataxia, meningitis, encephalitis, rhombo- or limbic encephalitis, hydrocephalus, myelopathy, myoclonus, choreiform movements, and distal polyneuropathy also have been described. Neurologic sequelae occur with CNS disease, and the mortality risk is significant.

MRI results may be normal. Identified lesions (solitary or multifocal) are usually T2 and fluid-attenuated inversion recovery (FLAIR) hyperintense and may enhance with gadolinium. All sites can be involved, and the nature of lesions is variable (e.g., nodular, infiltrative, tumor-like). Although imaging findings are myriad and are not diagnostic, the median temporal lobe, midbrain, hypothalamus, and thalamus are commonly affected. FDG-PET may reveal increased uptake. CSF analysis may be normal; when abnormal, leukocytosis (generally lymphocyte-predominant) and an elevated protein concentration are common. A low CSF glucose level has been reported.

Cardiac Disease Endocarditis is increasingly recognized in WD (85% of cases in males), causes 2.6–6.3% of culture-negative endocarditis cases, and may be complicated by congestive heart failure (40% of cases), embolic events, arrhythmias, mycotic aneurysm, or rarely hypotension. Fever is often absent, and the Duke clinical criteria are rarely met. Vegetations are identified by echocardiography in 50–75% of cases. All valves, alone or in combination, can be affected; most commonly involved are the aortic and mitral valves. Preexisting valvular disease is found in only a minority of cases, although infection of bioprosthetic

valves has been described. Mural, myocardial, or pericardial disease also occurs alone or in combination with valvular involvement. Constrictive pericarditis develops infrequently. Diagnosis of cardiac disease is rarely made prior to surgical intervention.

Pulmonary Disease Some combination of interstitial disease, nodules, parenchymal infiltrate, and pleural effusion is observed. An association with pulmonary hypertension has also been reported. The clinical significance of *T. whipplei* sequence identified in bronchoalveolar lavage fluid (BALF) from asymptomatic HIV-infected individuals or in a case of interstitial lung disease is unresolved but suggests caution in diagnosing "isolated" pneumonia on the basis of sequence alone. Notably, while the bacterium seems to exist in the airways of HIV-infected persons at higher rates, its presence is not clearly associated with increased inflammation or a discernible decrease in lung function.

Lymphatic Disease Mesenteric and retroperitoneal lymphadenopathy are common with intestinal disease, and mediastinal adenopathy may be associated with pulmonary infection. Peripheral adenopathy is less common.

Ocular Disease (Non–Neuro-Ophthalmologic) Uveitis is the most common form of ocular disease, usually presenting as a change in vision or "floaters." Anterior (anterior chamber), intermediate (vitreous), and posterior (retina/choroid) uveitis can occur alone or in combination. Treatment with glucocorticoids alone can worsen uveitis and unmask extraocular disease. Likewise, use of local or systemic glucocorticoids after ocular surgery can precipitate ocular infection, likely as a result of asymptomatic or subclinical disease. Keratitis, crystalline keratopathy, and optic neuritis also have been reported. Patients may be misdiagnosed with sarcoid or Behçet's disease prior to the recognition of Whipple's.

Dermatologic Disease Skin hyperpigmentation (melanoderma), particularly in light-exposed areas in the absence of adrenal dysfunction, is suggestive of WD. A variety of other cutaneous manifestations have been described, including erythematous macular lesions, nonthrombocytopenic purpura, subcutaneous nodules, and hyperkeratosis.

Miscellaneous Sites Thyroid, renal, testicular, epididymal, gallbladder, skeletal muscle, and bone marrow involvement have all been described. In fact, almost any organ can be involved in classic WD, with varying frequency, variable combinations, and myriad signs and symptoms. As a result, WD should be considered in the setting of a chronic multisystemic process. Despite its rarity, the combination of rheumatologic and intestinal disease with weight loss, with or without neurologic and cardiac involvement, warrants heightened suspicion.

ISOLATED INFECTION This entity has been defined as infection in the absence of intestinal symptoms, although an occasional small-bowel biopsy may be PAS-positive or more commonly PCR-positive in this setting. "Isolated infection" is something of a misnomer since multiple nonintestinal sites of *T. whipplei* infection are not uncommon. Infection at the same nonintestinal sites (single or multiple) that are variably involved in classic WD may also present as "isolated infection." Further, intestinal disease can subsequently develop. Endocarditis, neurologic disease, uveitis, rheumatologic manifestations, and pulmonary involvement are most commonly described. Signs and symptoms are similar to those described for *T. whipplei* infection of these sites in classic WD. With enhanced PCR-based diagnostic capabilities, *T. whipplei* infection without concomitant intestinal involvement (of which endocarditis is the best example) will probably be diagnosed increasingly often.

REINFECTION/RELAPSING DISEASE/IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS) It has been suggested that, if an underlying host immune defect places an individual at risk for chronic infection, then that person may be at risk for reinfection due to occupational exposure or contact with family members who are asymptomatically colonized. One case of apparent reinfection that was due to a different genotype supports this contention.

Optimal treatment regimens and durations are still being defined. However, it is clear, especially in the setting of occult or overt CNS disease, that treatment with oral tetracycline or trimethoprim-sulfamethoxazole (TMP-SMX) alone may result in disease relapse. Relapses or perhaps reinfections occurring years to decades after initial therapy have been described.

As in patients treated for HIV or mycobacterial disease, IRIS has been described in up to 17% of patients treated for *T. whipplei* infection. Prior immunosuppressive therapy increases the likelihood of IRIS, in which inflammation recurs after an initial clinical response to treatment and loss of PCR detection of *T. whipplei*. Manifestations include the development of fever, arthritis, skin lesions, subcutaneous nodules, pleuritis, uveitis, and orbital and periorbital inflammation; some cases have been fatal.

DIAGNOSIS

Considering *T. whipplei* infection and ensuring that the appropriate tests are performed are the critical steps in making the diagnosis, which otherwise will likely be missed. Serology is of little value since patients with active infection usually mount a poor IgM/IgG response to *T. whipplei* and a positive result most likely reflects prior exposure and clearance. The clinical presentation will in part dictate which clinical specimens are most likely to enable the diagnosis. In the presence (and perhaps the absence) of gastrointestinal symptoms, postbulbar duodenal biopsies should be performed, although a normal macroscopic appearance is common. As a general rule, diagnostic yield is greater for tissue specimens than for body fluids. Biopsy of normal-appearing skin may detect *T. whipplei* in the setting of classic WD and serve as a minimally invasive means to establish the diagnosis. It is prudent to collect CSF even in the absence of CNS symptoms; asymptomatic disease is common, the CNS is the most common site for relapse, and thus the information gained by CSF examination could influence the design and duration of the treatment regimen.

The diagnosis of classic WD was originally based on histologic findings in intestinal biopsy specimens. Although this diagnostic procedure remains important, it is not optimally sensitive. Infiltration of the lamina propria with macrophages containing PAS-positive inclusions that are resistant to diastase is observed. However, PAS is nonspecific, also yielding positive results with mycobacteria (which can be differentiated with Ziehl-Neelsen stain and culture), *Rhodococcus equi*, *Bacillus cereus*, *Corynebacterium* species, and *Histoplasma* species. *T. whipplei* can be detected by silver stain, Brown-Brenn (weakly positive), or acridine orange and is not stained by calcofluor. Staining of other tissues or fluids (e.g., ocular aspirations) for PAS-positive inclusions in macrophages can be performed to support the diagnosis. The sensitivity of identification of PAS-positive inclusions in WD may be decreased by anti-TNF-α therapy. Electron microscopy can be used to identify the trilaminar cell wall of *T. whipplei*. When available, immunohistochemistry has greater specificity and sensitivity than PAS staining and can be performed on archived fixed tissue. Alternatively, the use of fluorescence in situ hybridization (FISH) has been reported as a complementary diagnostic tool with various tissue samples.

The development and implementation of specific PCR-based diagnostics have significantly increased the sensitivity and specificity of *T. whipplei* identification. PCR can be applied to affected tissues (with greater sensitivity for non-formalin-fixed than for formalin-fixed tissue) in support of histologic findings and to various body fluids (e.g., CSF; aqueous or vitreous humor; joint, pericardial, or pleural fluid; BALF; blood; urine). It is important to note that the interpretation of a PCR-based diagnostic approach must take into account limitations such as false-positive results due to sample contamination, false-negative results due to low organism load, poor sample quality, inadequate DNA extraction, and variability in performance of various PCR assays. As with all diagnostic tests, consideration of pretest probability is critical for interpretation and a negative result does not exclude WD. Urine PCR for T. *whipplei* infection may hold promise for the noninvasive diagnosis of classic and isolated WD. In a recent study of 12 cases, urine PCR was positive in 9 (75%) of 12 cases prior to treatment compared to 0 (0%) of 110 controls, including 11 controls that were presumed carriers in which feces PCR was positive, although there was no evidence of disease. In addition, urine PCR is a potential tool to evaluate success of WD therapy. Saliva and fecal PCR is inappropriate

as the sole diagnostic tool for WD due to a low positive predictive value, which more commonly identifies colonization, not disease; a positive result requires confirmation from appropriate end-organ tissue or body fluid.

T. whipplei has been successfully cultured from blood, CSF, synovial fluid, BALF, valve tissue, duodenal tissue, skeletal muscle, and lymph nodes, but culture is not practical since it takes months to obtain a positive result.

Affected anatomic sites in WD patients may demonstrate uptake on FDG-PET, which in turn could guide tissue sampling for use in specific tests.

TREATMENT

Whipple's Disease

Data on treatment are emerging, but the optimal regimen and duration for chronic infection, which may depend on the sites involved (e.g., CNS and heart valve), are unclear. Appropriate treatment usually results in a rapid—and at times remarkable—clinical response (e.g., in CNS disease), but eradication requires prolonged treatment. Maintenance of a durable response has been more challenging because of both relapse and host predisposition to reinfection.

Rates of relapse, particularly of CNS disease, were unacceptable with oral tetracycline or TMP-SMX monotherapy. Sequence data now indicate that TMP is not active against *T. whipplei* (given the absence of dihydrofolate reductase in *T. whipplei*) and that resistance to SMX and sulfadiazine can occur. However, a randomized controlled trial in 40 patients, who received either ceftriaxone (2 g IV q24h) or meropenem (1 g IV q8h) for 2 weeks followed by oral TMP-SMX (160/800 mg) twice a day for 1 year, demonstrated outstanding efficacy. The only case in which therapy failed—an asymptomatic CNS infection that was not eradicated by either regimen—was subsequently cured with oral minocycline and chloroquine (250 mg/d after a loading dose). A follow-up trial reported similar efficacy with a regimen of ceftriaxone (2 g IV q24h) for 2 weeks followed by oral TMP-SMX for 3 months. One issue in these trials was that the doses—and perhaps the duration of ceftriaxone and meropenem treatment as well—were not optimal for CNS infection. By contrast, in a small retrospective series, outcome was better in patients treated with oral doxycycline (100 mg twice a day) plus hydroxychloroquine (200 mg three times a day; to raise phagosome pH and increase drug activity in vitro) than in patients initially treated with TMP-SMX.

Until more data become available, it seems prudent—at least in asymptomatic/symptomatic CNS disease (which is present in many cases of WD)—first to administer CNS-optimized doses of IV ceftriaxone (2 g q12h) or meropenem (2 g q8h) for 2–4 weeks and then to treat with oral doxycycline, or minocycline plus hydroxychloroquine for at least 1 year, if tolerated. Although TMP-SMX has been frequently used as the oral alternative with reported success, a number of relapses or reinfections with TMP-SMX treatment have been reported, thereby suggesting caution for its use in patients with infection in critical locations such as the CNS and the heart. Although data on the use of PCR to guide therapy do not exist, it seems reasonable that continued *T. whipplei* detection by PCR, especially in the CSF and perhaps urine, should dictate at least continuation of therapy or perhaps consideration of an alternative regimen when in conjunction with a poor clinical response.

As molecular diagnostics become more available, *T. whipplei* may be increasingly recognized as a cause of endocarditis, and thus, timely recognition may result in cure with medical management alone. Surgery may be needed in the setting of endocarditis with significant valve dysfunction or myocardial abscess. Current European guidelines for the treatment of endocarditis caused by *T. whipplei* recommend oral doxycycline plus hydroxychloroquine for ≥18 months or, alternatively, ceftriaxone (2 g q24h IV) or penicillin (2 million units q4h IV) plus streptomycin (1 g q24h IV) for 2–4 weeks followed by oral TMP-SMX (800 mg q12h); a small study from Spain reported that treatment durations of 12–13 months with these regimens or variations were efficacious.

Data on isolated infection and certain site-specific treatment issues are even more limited. Anecdotal reports describe successful treatment of uveitis with oral TMP-SMX with or without rifampin, whereas treatment with tetracycline alone has resulted in relapse. Although a role for adjunctive intraocular therapy has been reported, the data are unclear on this point. There is a single case report of clearance of infection in a chronically relapsing patient by the addition of interferon gamma to antimicrobials. The supplementation to antimicrobials may be a consideration to address refractory disease or potential issues with antibiotic resistance.

Although data on the treatment of foreign body–associated infection are virtually nonexistent, medical treatment for a prosthetic hip infection was apparently successful; however, follow-up was limited.

The occurrence of a Jarisch-Herxheimer reaction within 24 h of treatment initiation has been described, with rapid resolution. The addition of glucocorticoids may be beneficial in the management of IRIS, and thalidomide has been used in steroid-refractory cases.

Importantly, although data are lacking, due to the inherent risk of relapse or reinfection, lifelong suppressive therapy with doxycycline after completion of the initial treatment regimen has been advocated. Regardless of the therapeutic approach chosen, an effort to ensure compliance and close follow-up for potential relapse or reinfection, which can occur many years after an apparent cure, will maximize the chances for a good outcome.

177 Infections Due to Mixed Anaerobic Organisms

Neeraj K. Surana, Dennis L. Kasper

Anaerobes comprise the predominant class of bacteria of the normal human microbiota that reside on mucous membranes and predominate in many infectious processes, particularly those arising from mucosal surfaces. These organisms generally cause disease subsequent to the breakdown of mucosal barriers and the leakage of the microbiota

into normally sterile sites. Infections resulting from contamination by the microbiota are usually polymicrobial and involve both aerobic and anaerobic bacteria. However, the difficulties encountered in handling specimens in which anaerobes may be important and the technical challenges entailed in cultivating and identifying these organisms in clinical microbiology laboratories continue to leave the anaerobic etiology of an infectious process unproven in many cases. Therefore, an understanding of the types of infections in which anaerobes can play a role is crucial in selecting appropriate microbiologic tools to identify the organisms in clinical specimens and in choosing the most appropriate treatment, including antibiotics and surgical drainage or debridement of the infected site. This chapter focuses on infections caused by anaerobic bacteria other than *Clostridium* species, which are covered elsewhere **(Chaps. 134 and 154)**.

HISTORICAL PERSPECTIVE

Anaerobic organisms were first identified by Antonie van Leeuwenhoek in 1680—nearly a century before oxygen itself was discovered. Leeuwenhoek set up culture medium (crushed pepper powder and clean rainwater) in two glass tubes—one open to ambient air and the other sealed closed—that he incubated for several days. Although he did not expect to observe anything in the sealed tube, he was surprised to find "animalcules" in both tubes. He noted that these bacteria in the sealed tube were "bigger than the biggest sort" in the tube left open to air. It was not until the mid- to late nineteenth century that Leeuwenhoek's findings were confirmed by Pasteur and others. However, these principles described by Leeuwenhoek underlie the basic pathogenesis of anaerobic infections: development of an anaerobic environment in a closed space is due to consumption of oxygen by aerobic organisms and results in the outgrowth of anaerobic organisms.

DIFFERENCES BETWEEN ANAEROBIC AND AEROBIC ORGANISMS

Anaerobic bacteria can be categorized as *obligate anaerobes* (killed in the presence of ≥0.5% oxygen), *aerotolerant organisms* (can tolerate the presence of oxygen but cannot use it for growth), and *facultative anaerobes* (can grow in the presence or absence of oxygen). Most clinically relevant anaerobes, such as *Bacteroides fragilis, Prevotella melaninogenica,* and *Fusobacterium nucleatum*, are relatively aerotolerant. These organisms contrast with *obligate aerobes*, which require high concentrations of oxygen for growth, and *microaerophilic organisms*, which are damaged by atmospheric concentrations of oxygen (~21%) but require low concentrations of oxygen (typically 2–10%) for growth. Given that molecular oxygen can reduce to superoxide (O_2^-) and hydrogen peroxide (H_2O_2), which are damaging to cells, the ability to tolerate the presence of oxygen is due, in part, to the expression of superoxide dismutase and catalase. The variation in anaerobic organisms tolerating anywhere from <0.5 to 8% O_2 may reflect the amount of these enzymes that is produced.

Furthermore, aerobic and anaerobic organisms differ in their energy metabolism. Cellular respiration requires establishment of an electrochemical gradient across the membrane, resulting in an electric potential (often related to a proton gradient) across the membrane. In aerobic respiration, electrons are shuttled through an electron transport chain, with oxygen as the final electron acceptor. Anaerobic organisms can metabolize energy by either anaerobic respiration or fermentation. Given that the final electron acceptor in anaerobic respiration (e.g., sulfate, nitrate, carbon dioxide, or fumarate) is not as highly oxidizing as oxygen, this pathway is less efficient than aerobic respiration and produces less ATP per glucose molecule. In contrast, fermentation does not use an electrochemical gradient. Rather, it releases energy from an organic molecule (e.g., pyruvate and its derivatives) via substrate-level phosphorylation and is therefore a less efficient process than either aerobic or anaerobic respiration; for comparison, fermentation results in ~5% of the energy released by aerobic respiration. For these reasons, facultative anaerobes will preferentially utilize oxygen if it is available; in oxygen-limiting situations, organisms will use anaerobic respiration rather than fermentative processes, if possible.

ANAEROBES OF THE HUMAN MICROBIOTA

Most human mucocutaneous surfaces harbor a rich indigenous normal microbiota composed of aerobic and anaerobic bacteria. These surfaces are dominated by anaerobic bacteria, which often account for 99.0–99.9% of the cultivable microbiota and range in concentration from 10^3/mL in the nose to 10^{12}/mL in gingival scrapings and the colon **(Table 177-1)**. It is interesting that anaerobes inhabit many areas of the body that are exposed to air: skin, nose, mouth, and throat. Anaerobes are thought to reside in the portions of these sites that either are relatively well protected from oxygen (e.g., gingival crevices) or have a local anaerobic environment conferred by neighboring aerobic organisms (e.g., tooth surfaces). The ability to cultivate these organisms is improving, and—with strict attention to anaerobic conditions—more than 80% of the microscopic counts in fecal samples can be cultured. However, culture-independent approaches (e.g., sequencing of the 16S rDNA gene) show that the overwhelmingly diverse low-abundance bacterial species present in the microbiota remain uncultivated. Several projects, including the Human Microbiome Project (funded by the U.S. National Institutes of Health) and MetaHIT (financed by the European Commission), have characterized the normal microbiota of healthy individuals and have demonstrated the presence of >10,000 different bacterial species in the collective human microbiota. The human gut alone harbors >1000 bacterial species, with 100–200 species present in any given individual.

The major reservoir of anaerobic bacteria is the lower gastrointestinal tract, but these organisms are also present in considerable numbers in the oral cavity, skin, and female genital tract (Table 177-1). In the oral cavity, the ratio of anaerobic to aerobic bacteria ranges from 1:1 on the surface of a tooth to 1000:1 in the gingival crevices. *Prevotella* and *Porphyromonas* species make up much of the indigenous oral anaerobic microbiota. *Fusobacterium* and *Bacteroides* (non–*B. fragilis* group) species are present in lower numbers. Anaerobic bacteria are not found in appreciable numbers in the normal stomach and proximal small intestine. In the distal ileum, the microbiota begins to resemble that of the

TABLE 177-1 The Anaerobic Human Microbiota: An Overview

ANATOMIC SITE	TOTAL BACTERIA[a]	ANAEROBIC/ AEROBIC RATIO	POTENTIAL PATHOGEN(S)
Nose	10^3–10^4	2:1	*Peptostreptococcus* spp., *Prevotella* spp.
Oral cavity			
Saliva	10^8–10^9	10:1	*Fusobacterium nucleatum, Prevotella melaninogenica, Prevotella oralis* group, *Bacteroides ureolyticus* group, *Peptostreptococcus* spp.
Tooth surface	10^{10}–10^{11}	1:1	
Gingival crevices	10^{11}–10^{12}	10^3:1	
Gastrointestinal tract			
Stomach	10^0–10^3	1:10	*Lactobacillus* spp.
Duodenum	10^1–10^5	1:1	*Lactobacillus* spp., *Streptococcus* spp.
Jejunum	10^3–10^6	1:1	*Streptococcus* spp., *Lactobacillus* spp., *Peptostreptococcus* spp.
Ileum	10^4–10^9	10:1	*Bacteroides* spp., *Streptococcus* spp., *Enterococcus* spp.
Cecum and colon	10^{11}–10^{12}	10^3:1	*Bacteroides* spp. (principally members of the *B. fragilis* group), *Prevotella* spp., *Clostridium* spp.
Female genital tract	10^7–10^9	10:1	*Peptostreptococcus* spp., *Bacteroides* spp., *Prevotella bivia*
Skin	10^4–10^6	100:1	*Cutibacterium acnes*

[a]Per gram or milliliter.

colon, where the ratio of anaerobes to aerobic species is high (~1000:1). The predominant anaerobes in the human intestine belong to the phyla Bacteroidetes and Firmicutes and include a number of *Prevotella* and *Bacteroides* species (e.g., members of the *B. fragilis* group, such as *B. fragilis, B. thetaiotaomicron, B. ovatus, B. vulgatus, B. uniformis*, and *Parabacteroides distasonis*) as well as various *Clostridium, Peptostreptococcus, Blautia*, and *Fusobacterium* species. In the female genital tract, there are ~10^9 organisms/mL of secretions, with an anaerobe-to-aerobe ratio of ~10:1. The predominant anaerobes in the female genital tract are *Prevotella, Bacteroides, Fusobacterium, Clostridium*, and the anaerobic *Lactobacillus* species. The skin microbiota contains anaerobes as well; *Cutibacterium acnes* (which was previously *Propionibacterium acnes* and will be considered as one of the *Propionibacterium* species for the remainder of this chapter) is the predominant species, and other species of propionibacteria and peptostreptococci are present in lower numbers.

ANAEROBES AND HUMAN HEALTH

Commensal anaerobes have been implicated as crucial mediators of physiologic, metabolic, and immunologic functions in the mammalian host. The intestinal microbiota is essential for fermenting dietary carbohydrates into forms that are more usable by the host, among which polysaccharides are the most abundant biological source of energy. Of the organisms found within the intestines, *Bacteroides* species express the widest array of polysaccharide-degrading enzymes, providing important nutrients for both the host and other commensal organisms. For example, *B. thetaiotaomicron* expresses 172 glycosyl hydrolases. The anaerobic intestinal microbiota is also responsible for the production of secreted products that promote human health (e.g., vitamin K and bile acids useful in fat absorption and cholesterol regulation).

One of the most important roles that anaerobes serve as components of the normal colonic microbiota is the promotion of resistance to colonization. The presence of commensal bacteria effectively interferes with colonization by potentially pathogenic bacterial species through the depletion of oxygen and nutrients, the production of enzymes and toxic end products, and the modulation of the host's intestinal innate immune response. For example, the normal intestinal microbiota plays an important role in protection against enteric infections, including those due to *Salmonella enterica* serotype Typhimurium and *Clostridium difficile*.

The anaerobic intestinal microbiota also has immunomodulatory properties that help regulate the immune system. The first example of this role was demonstrated with *B. fragilis*, which can balance the effector functions of T cells in the peripheral immune system and induce colonic regulatory T cells via expression of polysaccharide A (PSA). Moreover, *B. fragilis* expresses a glycosphingolipid that regulates the number of colonic invariant natural killer T cells. There are now numerous examples of commensal anaerobes that can modulate different aspects of the intestinal and extraintestinal immune system—everything from specific effector T cells to dendritic cells to antimicrobial peptides.

Clearly, the gut microbiota confers many benefits, and its dysregulation may play a role in the pathogenesis of diseases characterized by inflammation and aberrant immune responses, such as inflammatory bowel disease, rheumatoid arthritis, multiple sclerosis, asthma, and type 1 diabetes. Furthermore, the gut microbiota has been associated with obesity and metabolic syndrome. A more complete discussion of the intersection between the microbiota and human health is covered elsewhere **(Chap. 471)**.

ETIOLOGY

There are >10,000 species of bacteria—the overwhelming majority of which are anaerobes—in the human microbiota, with each individual colonized by hundreds of species. Anaerobic infections occur when the harmonious relationship between the host and the host's microbiota is disrupted. Any site in the body is susceptible to infection with these indigenous organisms if they are introduced into otherwise sterile tissue, either through disruption of mucosal surfaces (e.g., intestinal perforation, ischemia, surgery) or via direct inoculation of organisms into tissue (e.g., bite wounds, trauma). Because the sites that are colonized by anaerobes contain many species of bacteria, the resulting infections are often polymicrobial, involving multiple species of anaerobes in combination with synergistically acting facultative and/or microaerophilic organisms.

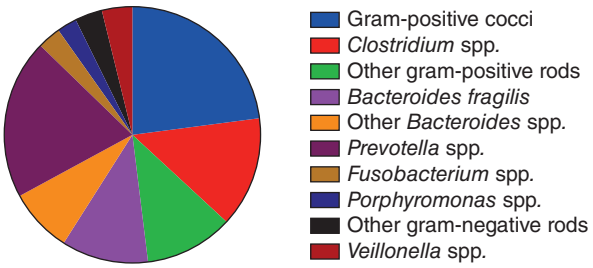

FIGURE 177-1 Distribution of anaerobic organisms isolated from clinical materials. *(Data combined from Y Park et al: Clinical features and prognostic factors of anaerobic infections: A 7-year retrospective study. Korean J Intern Med 24:13, 2009; and Japanese Association for Anaerobic Infections Research: Anaerobic infections (general): Epidemiology of anaerobic infections. J Infect Chemother 17[Suppl 1]:4, 2011.)*

Despite the complex array of bacteria in the normal microbiota, relatively few genera are isolated commonly from human infections **(Fig. 177-1)**. While the specific organisms identified vary with the site and source of infection, the etiologic agents typically reflect the neighboring microbiota. For example, organisms normally found in the oro- and nasopharyngeal microbiota (e.g., *P. melaninogenica*, *Fusobacterium necrophorum*, *F. nucleatum*, *Peptostreptococcus* species, *Porphyromonas gingivalis*, *Porphyromonas asaccharolytica*, and *Actinomyces* species) can cause disease in contiguous areas, including odontogenic infections, peripharyngeal space infections, chronic sinusitis, and pleuropulmonary infections. In female genital tract infections, organisms normally colonizing the vagina (e.g., *Prevotella bivia* and *Prevotella disiens*) are the most common isolates. *Escherichia coli* and *B. fragilis*, both of which are components of the intestinal microbiota, are the most commonly identified isolates from intraabdominal abscesses. Indeed, the *B. fragilis* group, which encompasses 25 species and includes *B. thetaiotaomicron, B. vulgatus, B. uniformis*, and *B. ovatus*, contains the anaerobic organisms among the most frequently isolated from clinical infections.

It is useful to think about anaerobic infectious etiologies with regard not only to their anatomic location but also to their microbiologic features. While many anaerobic gram-negative bacilli cause disease (e.g., *Prevotella*, *Bacteroides*, *Fusobacterium*, and *Porphyromonas* species), *Veillonella* species, which are part of the oral and intestinal microbiota, are among the few anaerobic gram-negative cocci that have been implicated in human disease. Similarly, the peptostreptococci (e.g., *P. micros, P. asaccharolyticus*, and *P. anaerobius*) and *Finegoldia magnus* (which was previously *Peptostreptococcus magnus* and will be considered as part of the peptostreptococci for the remainder of this chapter) are the chief anaerobic gram-positive cocci that have pathogenic potential. *Clostridium* species are the primary anaerobic spore-forming gram-positive rods that produce human disease **(Chap. 154)**. Uncommonly, anaerobic gram-positive non-spore-forming bacilli cause infection; *C. acnes*, a component of the skin microbiota and a cause of foreign-body infections, and *Actinomyces* species are relevant examples.

PATHOGENESIS

First and foremost, anaerobic infections require an anaerobic environment with a lowered oxidation-reduction potential. In some circumstances, this environment can occur directly—e.g., in tissue ischemia, trauma, surgery, or a perforated viscus. In many other situations, the infection is polymicrobial, and the facultative organisms maintain a lowered oxidation-reduction potential in the local microenvironment that allows for the propagation of obligate anaerobes. Once the proper anaerobic environment is established, the organisms must still contend with the host's immune defenses. Similar to aerobic organisms, anaerobes express an array of virulence factors that help evade host defenses,

they can form abscesses as a protective measure, and they can act synergistically with other bacteria to better persist in the host.

Virulence factors associated with anaerobes typically confer the ability to evade host defenses, adhere to cell surfaces, produce toxins and/or enzymes, or display surface structures such as capsular polysaccharides and lipopolysaccharide that contribute to pathogenic potential. The ability of an organism to adhere to host tissues is often critical to the establishment of infection. Some oral species adhere to the epithelium in the oral cavity. *P. gingivalis*, a common isolate in periodontal disease, has fimbriae that facilitate attachment. In supragingival plaque, many oral anaerobes are able to attach directly to aerobic bacteria (e.g., *Streptococcus* species) that are adherent to the tooth's surface. *F. nucleatum* is a notable example of these secondary colonizers: it expresses receptors to which almost all oral bacteria can bind and serves as an important bridge between the primary colonizers and subsequent layers of bacteria. *B. fragilis* synthesizes pili, fimbriae, and hemagglutinins that aid in attachment to host cell surfaces in the intestine.

Anaerobic bacteria produce a number of exoproteins that can enhance the organisms' virulence. *P. gingivalis* produces a collagenase that enhances tissue destruction. Exotoxins produced by clostridial species, including botulinum toxins, tetanus toxin, *C. difficile* toxins A and B, and five toxins produced by *Clostridium perfringens*, are among the most virulent bacterial toxins in mouse lethality assays. Anaerobic gram-negative bacteria, such as *B. fragilis, P. gingivalis*, and *Prevotella intermedia*, possess lipid A molecules (endotoxins) that are 100–1000 times less biologically potent than endotoxins associated with aerobic gram-negative bacteria; these differences may relate to variations in acylation status, length of fatty acids, and number of phosphate groups. This relative biologic inactivity may account for the lower frequency of disseminated intravascular coagulation and purpura in anaerobic gram-negative bacteremia than in facultative and aerobic gram-negative bacillary bacteremia. An exception is the lipopolysaccharide from *Fusobacterium*, which may account for the severity of Lemierre syndrome (see "Complications of Anaerobic Head and Neck Infections," below).

The most extensively studied virulence factor of the nonsporulating anaerobes is the capsular polysaccharide complex of *B. fragilis*. This organism is unique among anaerobes in its potential for virulence during growth at normally sterile sites. Although it constitutes only 0.5–1% of the normal colonic microbiota, *B. fragilis* is the anaerobe most commonly isolated from intraabdominal infections and bacteremia. In an animal model of intraabdominal sepsis, the capsular polysaccharide was identified as the major virulence factor of *B. fragilis*; this polymer plays a specific, central role in the induction of abscesses. A series of detailed biologic and molecular studies of this virulence factor showed that *B. fragilis* produces at least eight distinct capsular polysaccharides, far more than the number reported for any other encapsulated bacterium. *B. fragilis* can exhibit distinct surface polysaccharides either alone or in combination by regulating the expression of these different capsules in an on–off manner through a reversible inversion of DNA segments within the promoters for operons containing the genes required for polysaccharide synthesis. Structural analysis of two of these polysaccharides, PSA and polysaccharide B (PSB), revealed that each polymer consists of repeating units with positively charged free amino groups and negatively charged groups. This structural feature is rare among bacterial polysaccharides, and the ability of PSA—and, to a lesser extent, PSB—to induce abscesses in animals depends on this zwitterionic charge motif. Intraabdominal abscess induction is related to the capacity of PSA to stimulate macrophages to release cytokines and chemokines—in particular, interleukin (IL) 8, IL-17, and tumor necrosis factor α (TNF-α)—from resident peritoneal cells through a Toll-like receptor 2–dependent mechanism. The release of cytokines and chemokines results in the chemotaxis of polymorphonuclear neutrophils (PMNs) into the peritoneum, where they adhere to mesothelial cells induced by TNF-α to upregulate their expression of intercellular adhesion molecule 1 (ICAM-1). PMNs adherent to ICAM-1-expressing cells probably represent the nidus for an abscess. PSA also activates T cells to produce certain cytokines, including IL-17 and interferon γ, that are necessary for abscess formation.

These virulence factors not only promote persistence of the anaerobe that produces them but also aid in the survival of bystander organisms and result in bacterial synergies. Clinically, these synergies are evidenced by the fact that anaerobic infections typically involve three to six different organisms. Examples of this synergistic pathogenesis include creation of a favorable environment for growth (e.g., establishment and maintenance of an anaerobic environment by facultative organisms), inhibition of host defenses (e.g., production of short-chain fatty acids and succinic acid that inhibit the ability of phagocytes to clear facultative organisms), provision of necessary growth factors for other organisms (e.g., oral diphtheroids that produce vitamin K, which is needed by *P. melaninogenica*), and creation of tissue damage that promotes spread of the infection. In these ways, facultative and obligate anaerobes synergistically potentiate abscess formation.

APPROACH TO THE PATIENT

Infections Due to Anaerobic Bacteria

The physician must consider several points when approaching the patient with a possible infection due to anaerobic bacteria.

1. The organisms colonizing mucosal sites are commensals, very few of which typically cause disease. When these organisms do cause disease, it often occurs in proximity to the mucosal site they colonize.
2. For anaerobes to cause tissue infection, they must spread beyond the normal mucosal barriers.
3. Conditions favoring the propagation of anaerobic bacteria, particularly a lowered oxidation-reduction potential, are necessary. These conditions exist at sites of trauma, tissue destruction, compromised vascular supply, and necrosis.
4. Frequently, a complex array of infecting microbes can be found, occasionally with >10 different species isolated from a suppurative site.
5. Anaerobic organisms tend to be found in abscess cavities or in necrotic tissue. The failure of an abscess to yield organisms on routine culture is a clue that the abscess is likely to contain anaerobic bacteria. Often smears of this "sterile pus" are found to be teeming with bacteria when Gram's stain is applied. Although some facultative organisms (e.g., *Staphylococcus aureus*) are also capable of causing abscesses, abscesses in organs or deeper body tissues should call anaerobic infection to mind.
6. Gas is found in many anaerobic infections of deep tissues but is not diagnostic because it can be produced by aerobic bacteria as well.
7. Although a putrid-smelling infection site or discharge is considered diagnostic for anaerobic infection, this manifestation usually develops late in the course and is present in only 30–50% of cases.
8. Some species (the best example being the *B. fragilis* group) require specific therapy. However, many synergistic infections can be cured with antibiotics directed at some but not all of the organisms involved. Antibiotic therapy, combined with debridement and drainage, disrupts the interdependent relationship among the bacteria, and some species that are resistant to the antibiotic do not survive without the co-infecting organisms.
9. Manifestations of severe sepsis and disseminated intravascular coagulation are unusual in patients with purely anaerobic infection.

EPIDEMIOLOGY

Difficulties in the performance of appropriate cultures, contamination of cultures by components of the normal microbiota, and the lack of readily available, reliable culture techniques have made it challenging to obtain accurate data on the incidence or prevalence of anaerobic infections. However, anaerobic infections are encountered frequently, with anaerobes comprising 7–8% and 13–15% of bacteria isolated from inpatients and outpatients, respectively. Bacteremia and soft

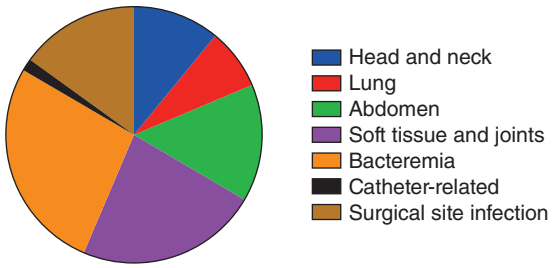

FIGURE 177-2 Distribution of types of infection from which anaerobic organisms were cultured at a single hospital over a 7-year period. Head and neck infections included sinusitis, otitis media, and retropharyngeal abscess; abdominal infections included liver abscess, biliary tract infection, bowel obstruction, and intraabdominal abscess; catheter-related infections included those related to peritoneal dialysis catheters and ventriculoperitoneal shunts. *(Data from Y Park et al: Clinical features and prognostic factors of anaerobic infections: A 7-year retrospective study. Korean J Intern Med 24:13, 2009.)*

tissue infections are the most common types of anaerobic infection **(Fig. 177-2)**. Typically, anaerobic bacteria account for <1% of all cases of bacteremia.

CLINICAL MANIFESTATIONS

Although anaerobes can cause infection anywhere in the body, certain clinical findings and characteristics are commonly found. These include abscess formation, putrid purulence (due to volatile fatty acid by-products), septic thrombophlebitis, tissue necrosis, and failure to respond clinically to broad-spectrum antibiotics that lack activity against anaerobes.

Anaerobic Infections of the Mouth, Head, and Neck

Anaerobic bacteria are commonly involved in infections of the mouth, head, and neck **(Chap. 35)**. The predominant isolates are components of the normal microbiota of the upper airways—mainly *Prevotella* species, *P. asaccharolytica*, *Fusobacterium* species, peptostreptococci, and microaerophilic streptococci.

OROFACIAL INFECTIONS The most common oral infections are odontogenic and include dental caries and periodontal disease (gingivitis and periodontitis). While dental caries usually manifest with pain, sensitivity, and discoloration of the tooth, periodontal disease involves inflammation of the gums and underlying tissue. In its more severe forms, periodontitis can result in difficulty chewing, loose teeth, and occasionally tooth loss. Severe orofacial infections typically develop as a consequence of dental infection, and the infection can spread from the tooth to different anatomic areas that provide the least resistance, resulting in periapical, periodontal, or pericoronal infections. If the dental surface is completely breached, an endodontic infection (pulpitis) can occur. In late stages of pulpitis, the tooth is generally very sensitive to heat, but cold stimuli may provide relief. Left untreated, pulpitis can progress to invade the alveolar bone and develop into a periapical abscess. The abscesses, particularly those involving the second and third molars, can occasionally extend into the submandibular, sublingual, and submental spaces (*Ludwig's angina*). This infection results in marked local swelling of tissues, with pain, trismus, and superior and posterior displacement of the tongue. Submandibular swelling of the neck and obstruction by the tongue can impair swallowing and cause respiratory obstruction. In some cases, tracheotomy is lifesaving.

Microbiologically, dental caries begin with the binding of *Streptococcus mutans* and *Streptococcus sanguis* to the tooth surface, with subsequent further colonization by anaerobes. In contrast, periodontitis is typically associated with *P. gingivalis, Tannerella forsythensis, Aggregatibacter actinomycetemcomitans*, and *Treponema denticola*. *Fusobacterium*, *Actinomyces*, *Peptostreptococcus*, and *Bacteroides* species (other than *B. fragilis*) are the organisms most commonly isolated from periapical abscesses.

ACUTE NECROTIZING ULCERATIVE GINGIVITIS Gingivitis may become a necrotizing infection (*trench mouth*, *Vincent's stomatitis*). The onset of disease is usually sudden and is associated with painful bleeding gums, foul breath, and a bad taste. The gingival mucosa, especially the papillae between the teeth, becomes ulcerated and may be covered by a yellowish-white or gray "pseudomembrane," which is removable with gentle pressure. Patients may become systemically ill, developing fever, malaise, cervical lymphadenopathy, and leukocytosis. The infection can sometimes extend into the pharynx, resulting in an extremely sore throat, foul breath, and tonsillar pillars that are swollen, red, ulcerated, and covered by a pseudomembrane. *Prevotella*, *Treponema*, and *Fusobacterium* species have been implicated.

In some cases, acute necrotizing gingivitis can rapidly progress to noma (*cancrum oris*), a gangrenous infection that destroys the soft and hard tissues related to the oral cavity. Noma occurs most frequently in young children (1–4 years of age) who have immune dysfunction related to malnutrition and endemic infections (particularly measles). This infection occurs worldwide but is most common in sub-Saharan Africa, where the incidence is 1–7 cases per 1000 children. Although the pathogenesis is not fully understood, infections with *F. necrophorum* and *P. intermedia* are thought to be key drivers of this disease. Without treatment, the mortality rate is 70–90%.

PERIPHARYNGEAL SPACE INFECTIONS These infections arise from the spread of organisms from the upper airways to potential spaces formed by the fascial planes of the head and neck. The etiology is typically polymicrobial and represents the normal microbiota of the mucosa of the originating site.

Peritonsillar abscess (*quinsy*) is the most common peripharyngeal infection and occurs as a complication of acute tonsillitis. Consistent with its association with tonsillitis, adolescents are most commonly affected. Patients present with a sore throat, dysphagia, peritonsillar swelling, muffled voice, and uvular deviation to the contralateral side. The abscess material typically grows group A *Streptococcus* in conjunction with obligate anaerobes (e.g., *Bacteroides*, *Prevotella*, and *Peptostreptococcus* species) **(Chap. 35)**. Retropharyngeal abscesses typically occur in children 2–4 years of age, although they can occur at any age. Although a suppurative infection of the retropharyngeal lymph nodes is the usual precursor to these abscesses in children, foreign-body ingestion and/or local trauma is more commonly the inciting factor in adults. The clinical presentation shares many features with peritonsillar abscesses, but difficulty extending the neck and torticollis are more common with retropharyngeal abscesses. The etiologic agents are the same as in peritonsillar abscesses, with additional aerobic organisms (e.g., *S. aureus*, viridans streptococci) also playing a role.

SINUSITIS AND OTITIS Anaerobic bacteria have been implicated in chronic sinusitis but play little role in acute sinusitis. Numerous studies related to the microbiology of chronic sinusitis have been conducted; on average, anaerobic bacteria have been found in two-thirds of patients, with many studies demonstrating their presence in >90% of patients. Anaerobic bacteria represent ~40% of all bacteria cultured, with *Peptostreptococcus*, *Prevotella,* and *Porphyromonas* species the most commonly isolated anaerobes. *S. aureus* and Enterobacteriaceae are the aerobes most commonly recovered in chronic sinusitis. Anaerobic bacteria have been isolated in ~60% of cases of chronic suppurative otitis media in children, but they are not involved in acute otitis media.

COMPLICATIONS OF ANAEROBIC HEAD AND NECK INFECTIONS Direct extension of these infections into contiguous areas can result in additional disease manifestations. Cranial spread of these infections can result in osteomyelitis of the skull or mandible or in intracranial infections, such as brain abscess and subdural empyema. Caudal spread can produce mediastinitis or pleuropulmonary infection. Hematogenous complications can also result from anaerobic infections of the head and neck. Bacteremia, which occasionally is polymicrobial, can lead to endocarditis or other distant infections. Lemierre's syndrome **(Chap. 35)**, which is usually due to *F. necrophorum*, is an acute oropharyngeal infection with secondary septic thrombophlebitis of the internal jugular vein and frequent septic emboli, most commonly to the lung. This infection typically begins with pharyngitis, which is followed by local invasion in the lateral pharyngeal space, with resultant internal jugular vein thrombophlebitis.

Central Nervous System (CNS) Infections CNS infections associated with anaerobic bacteria are brain abscess, epidural abscess, and subdural empyema, in which anaerobes are recovered in up to 30, 20, and 10% of cases, respectively. The frequency with which anaerobes are recovered depends in large part on the underlying reason for the infection. For example, brain abscesses are typically due to hematogenous seeding, contiguous spread, penetrating head trauma, or recent surgical intervention. Anaerobic bacteria are most commonly associated with brain abscesses resulting from contiguous spread (related to otogenic, odontogenic, and sinus infections), and the pathogens recovered are the same as in these antecedent infections. Facultative or microaerophilic streptococci and coliforms are often part of a mixed infecting flora in brain abscesses. The location of the abscess may also provide insight into the pathogens. Abscesses in the frontal lobe (often associated with sinusitis) are due to anaerobes, streptococci, and staphylococci; temporal lobe and cerebellar abscesses are often related to the oral microbiota and middle-ear pathogens.

Obligate anaerobes rarely cause meningitis. Only one obligate anaerobe was identified in a seminal study of 188 bacterial meningitis isolates, and a U.S. national surveillance study of 18,642 such isolates collected between 1977 and 1981 found only five obligate anaerobes. This low incidence may be due, in part, to the fact that many clinical microbiology laboratories do not routinely culture cerebrospinal fluid (CSF) for anaerobes.

Pleuropulmonary Infections The lungs are constantly seeded with organisms from the oral microbiota via subclinical microaspiration that normally occurs in all people. Even though the lung is the site of oxygen exchange and is therefore an overwhelmingly aerobic environment, the organisms most abundant in the lower respiratory tract (as assessed by culture-independent methods) include anaerobes such as *Prevotella* and *Veillonella* species, with oral microaerophilic streptococcal species (e.g., the *Streptococcus milleri* group) also present in significant abundances. In patients who have impaired bacterial clearance (due to decreased cough, dysfunctional mucociliary transport, or alcohol intoxication) and/or increased rates of aspiration (due to neurologic disorders, impaired consciousness, or swallowing dysfunction), these anaerobic bacteria can establish an infection and result in aspiration pneumonia, lung abscess, or empyema. These anaerobic infections have an indolent course that may serve as a clinical clue differentiating them from conditions with other etiologies (e.g., chemical pneumonitis, pneumococcal pneumonia) that often present more acutely.

ASPIRATION PNEUMONIA Bacterial aspiration pneumonia must be distinguished from two other clinical syndromes associated with aspiration that are not of bacterial etiology. One syndrome results from aspiration of food or, rarely, other foreign bodies. Obstruction of major airways typically results in difficulty breathing, atelectasis, and moderate nonspecific inflammation. Therapy consists of removal of the foreign body. The second aspiration syndrome relates to chemical pneumonitis caused by inhalation or aspiration of alveolar irritants. Perhaps the most common cause of chemical pneumonitis is *Mendelson syndrome*, which results from regurgitation and aspiration of acidic gastric juices. Pulmonary inflammation—including the destruction of the alveolar lining, with transudation of fluid into the alveolar space—occurs with remarkable rapidity. This syndrome typically develops within 4–6 h, often following anesthesia when the gag reflex is depressed. The patient becomes tachypneic, tachycardic, and hypoxic, often in the absence of fever. The leukocyte count may rise, and the chest x-ray may evolve from normal to a complete bilateral "whiteout" within 8–24 h. Sputum production is minimal. The pulmonary signs and symptoms often resolve quickly with symptom-based therapy, but this condition can culminate in respiratory failure due, in part, to pulmonary edema. Antibiotic therapy is not indicated unless bacterial superinfection occurs.

In contrast to these syndromes, bacterial aspiration pneumonia develops over a period of several days or weeks rather than hours. The pathogenesis includes some combination of an increased bacterial burden, increased virulence of the organisms aspirated, and potential airway damage related to aspiration of gastric fluid. Patients generally report fever, malaise, and sputum production. In some patients, weight loss and anemia reflect a more chronic process. Usually the history reveals factors predisposing to aspiration, such as significant alcohol consumption or neurologic impairment due to a previous stroke. Severe dental disease is often associated with aspiration pneumonia, but it is not clear whether this association relates to an increased number of oral microbes and/or the presence of organisms with increased virulence. Sputum characteristically is not malodorous unless the process has been ongoing for at least a week. Chest x-rays show consolidation in dependent pulmonary segments: in the basilar segments of the lower lobes if the patient has aspirated while upright and in either the posterior segment of the upper lobe (usually on the right side, given that the right mainstem bronchus has a more vertical orientation) or the superior segment of the lower lobe if the patient has aspirated while supine.

A mixed bacterial population with many PMNs is evident on Gram's staining of sputum. Expectorated sputum is unreliable for anaerobic cultures because of inevitable contamination by the normal oral microbiota. Reliable specimens for culture can be obtained by transtracheal or transthoracic aspiration—techniques that are rarely used at present. Although the culture of protected-brush specimens or bronchoalveolar lavage fluid obtained by bronchoscopy is controversial, more recent data suggest that these approaches can be used without oropharyngeal contamination and can recover anaerobic organisms from the lower respiratory tract in a site-directed manner. Further research is needed to determine how these approaches compare with the previous gold standards.

ANAEROBIC LUNG ABSCESSES **(See also Chap. 127)** These abscesses result from subacute anaerobic pulmonary infection. The clinical presentation typically involves a history of constitutional signs and symptoms (including malaise, weight loss, fever, night sweats, and foul-smelling sputum) that have typically persisted for 1–3 weeks prior to hospitalization. Patients who develop lung abscesses often, but not always, have an antecedent dental infection. Abscess cavities may be single or multiple and generally occur in dependent pulmonary segments **(Fig. 177-3)**. The differential diagnosis for lung abscesses includes pneumonia (including necrotizing pneumonia), a purulent pleural effusion with a bronchopleural fistula, and a pneumatocele. Of note, infection with some aerobic organisms, particularly *S. aureus*, can develop into a lung abscess without an anaerobic component. Approximately 90% of cases have an anaerobe identified—usually three to six isolates per sample—if careful attention is paid to handling and processing of the abscess sample. The most common isolates include peptostreptococci, *Prevotella* and *Porphyromonas* species, and *F. nucleatum*. An important finding is that ~90% of cultures also demonstrate the presence of aerobic organisms, such as *S. aureus*, *Streptococcus pneumoniae*, and *Klebsiella pneumoniae*. Consistent with the notion that anaerobes are contributing to disease, patients often do not improve clinically until they receive an antibiotic regimen that includes anaerobic coverage.

EMPYEMA Empyema is a manifestation of long-standing anaerobic pulmonary infection and manifests with thick, purulent material in the pleural space, often in association with a bronchopleural fistula. Alternatively, a subdiaphragmatic infection may extend into the pleural space and similarly result in an empyema. The clinical presentation resembles that of other anaerobic pulmonary infections and may include foul-smelling sputum, pleuritic chest pain, and marked chest-wall tenderness. This disease process must be differentiated from a parapneumonic effusion resulting from more routine causes of pneumonia (e.g., *S. pneumoniae*). In the latter instance, the fluid is a thin exudate that has a mean white blood cell (WBC) count of ~5000 cells/mL, a lactate dehydrogenase level of >200 IU/L, and a pH of ~7.4. In contrast, empyema is characterized by foul-smelling thick pus with a mean WBC count of ~55,000 cells/mL, a lactate dehydrogenase level of >1000 IU/L, and a pH of <7.2 as well as loculations and a thick pleural peel on imaging. Drainage and occasionally decortication of the visceral and parietal pleura are required. Defervescence, a return to a feeling of well-being, and resolution of the process may require several months, particularly in the absence of surgical intervention.

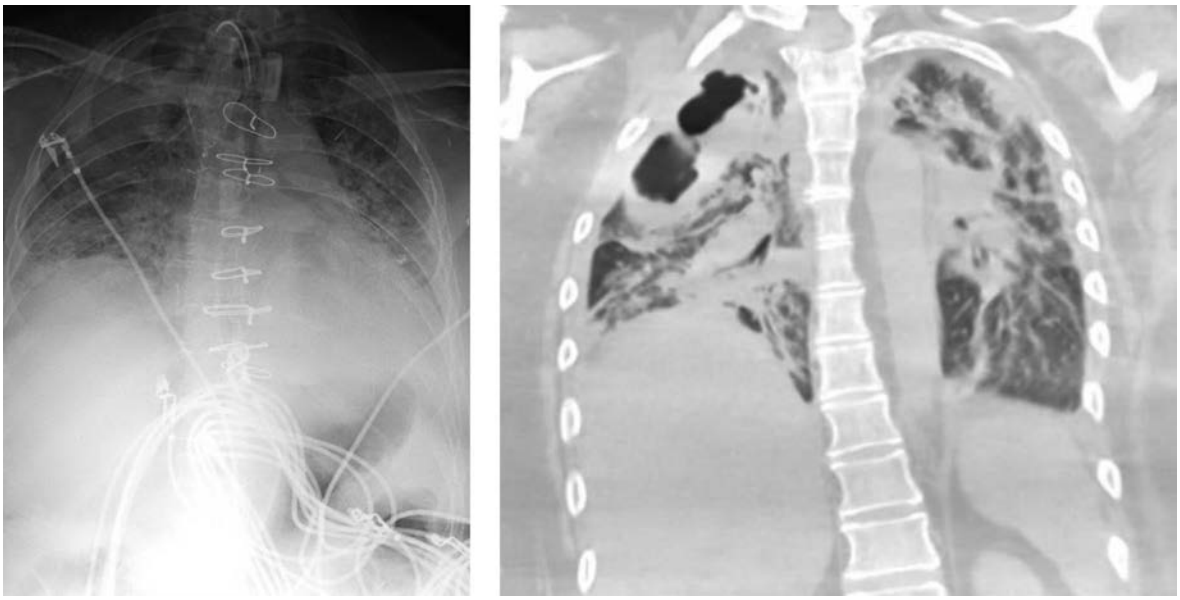

FIGURE 177-3 Chest radiograph (*left*) and CT image (*right*) of a lung abscess. The patient aspirated while supine and developed an abscess in the posterior segment of the right upper lobe. Cultures were pretreated and grew only *Klebsiella pneumoniae*. *(Images provided by Gita N. Mody, MD, MPH, Division of Cardiothoracic Surgery, Department of Surgery, The University of North Carolina at Chapel Hill.)*

Intraabdominal Infections Breach of the gut mucosal surface (e.g., due to trauma, intestinal perforation, or malignancy) allows members of the microbiota to enter the normally sterile peritoneum. Accordingly, the offending organisms reflect the microbiota in the affected intestinal region. For example, recovery of *Candida* species from intraabdominal infections should prompt evaluation of the stomach and proximal small bowel for potential perforation. Furthermore, a study of patients with perforated and gangrenous appendicitis demonstrated that virtually all samples yielded *E. coli* and members of the *B. fragilis* group; peptostreptococci and *Bilophila wadsworthia*—additional components of the appendiceal and colonic microbiota—were also recovered from >50% of samples. Notably, some studies have identified an average of 10 different bacterial species, with an anaerobe-to-aerobe ratio of ~3:1. Given that >1000 bacterial species are present in the colonic microbiota, the dominance of such a limited repertoire of bacterial genera and species recovered in intraabdominal infections reflects a combination of two factors: the increased propensity of these organisms to result in intraabdominal abscesses and the difficulty faced by clinical microbiology laboratories in culturing the diverse organisms present in these samples. **See Chap. 132 for a complete discussion of intraabdominal infections.**

Neutropenic enterocolitis (typhlitis) involves marked thickening of the bowel wall (typically >4 mm) in the setting of neutropenia, abdominal pain, and fever. This condition most commonly affects the cecum and may extend to the neighboring terminal ileum and/or proximal colon, but any intestinal region may be involved. Typhlitis generally occurs after 1–2 weeks of chemotherapy-induced neutropenia associated with treatment of hematologic or, less commonly, solid tumor malignancies, but it can occur regardless of the cause of neutropenia. At least 5% of adults hospitalized for malignancy are thought to develop typhlitis, but this is likely an underestimate. Although the right lower quadrant is the most common location of abdominal pain and tenderness, these symptoms are absent in nearly half of cases; moreover, some patients, particularly those taking glucocorticoids, may not experience abdominal pain at all. Given the weakened integrity of the bowel wall and the associated neutropenia, patients often develop bacteremia due to one or more organisms related to the microbiota of the affected intestinal segment. Patients who develop bacteremia due to *Clostridium septicum* often have relatively severe disease, and identification of this organism is highly associated with the presence of malignancy—notably, colon cancer. Medical management including bowel rest, intestinal decompression, and broad-spectrum antibiotic administration is generally successful, although surgical intervention may be required in cases of persistent intestinal bleeding, necrotic bowel, or clinical deterioration suggestive of an ongoing intestinal process.

Pelvic Infections Anaerobes are frequently encountered in pelvic inflammatory disease, pelvic abscess, endometritis, tubo-ovarian abscess, septic abortion, and postoperative or postpartum infections. These infections are often of mixed etiology, involving both anaerobes and coliforms; pure anaerobic infections without coliform or other facultative bacterial species occur more often in pelvic than in intraabdominal sites. The major anaerobic pathogens in pelvic abscesses are *P. bivia*, *P. disiens*, and the *B. fragilis* group, but many other anaerobes have also been implicated. **See Chap. 136 for a complete discussion of pelvic inflammatory disease.**

Anaerobic bacteria have been thought to be contributing factors in bacterial vaginosis. This syndrome of unknown etiology is characterized by a profuse malodorous discharge and a change in bacterial ecology that results in replacement of the *Lactobacillus*-dominated normal microbiota with an overgrowth of anaerobic bacterial species. Culture-based and culture-independent approaches have identified numerous organisms, including *Gardnerella vaginalis*, peptostreptococci, genital mycoplasmas, and species within the genera *Prevotella*, *Mobiluncus*, *Atopobium, Leptotrichia, Megasphaera*, and *Eggerthella*. This wide array of implicated bacteria may reflect differences in the overall disease spectrum of bacterial vaginosis and/or a shared physiologic response to these different organisms.

Skin and Soft Tissue Infections Similar to other anatomic sites, skin or soft tissue injured by trauma, ischemia, or surgery creates a suitable environment for anaerobic infections. The infecting bacteria either are introduced directly (e.g., wounds associated with intestinal surgery, decubitus ulcers, or human bites) or originate in contiguous areas (e.g., cutaneous abscesses, rectal abscesses, and axillary sweat gland infections [*hidradenitis suppurativa*]). Anaerobes also are often cultured from foot ulcers of diabetic patients. The most common locations for anaerobic cellulitis include the neck, trunk, groin (including the genitalia), and legs. The deep soft tissue infections associated with anaerobic bacteria are gas gangrene, synergistic cellulitis (both progressive and necrotizing), necrotizing fasciitis, and myositis **(Chaps. 129 and 154)**.

Gas gangrene (crepitus cellulitis) is most often due to *C. perfringens*, although other clostridial species have been implicated as well. This infection involves extensive gas formation in the tissue leading to crepitus and a thin, dark, occasionally malodorous discharge. True gas gangrene typically presents with fever and tenderness around the lesion and can rapidly spread; in contrast, there are somewhat more indolent

forms of anaerobic cellulitis that may involve some gas formation but often present without fever or extensive local pain and can spread over the course of days rather than minutes.

Progressive bacterial synergistic gangrene (*Meleney gangrene*) is characterized by an area of exquisite pain, redness, and swelling followed by ulceration. As the ulcer enlarges, it is surrounded by a violaceous ring that fades into a pink edematous border. If it is not promptly treated, the ulcer continues to enlarge, and new, distant ulcers may emerge. Symptoms are limited to pain; fever is not typical. Peptostreptococci and microaerophilic streptococci are commonly found in the leading edge of the lesions, and *S. aureus* and *Proteus* species can be isolated from the ulcerated lesion. Treatment includes surgical removal of necrotic tissue and antimicrobial administration. In contrast, synergistic necrotizing cellulitis involves the deep fascia and occurs near the point of bacterial entry. Pain, fever, and systemic symptoms are common. If this form of cellulitis involves the scrotum, perineum, and anterior abdominal wall, it is referred to as *Fournier gangrene*. *S. aureus*, the *B. fragilis* group, *Peptostreptococcus* species, *Clostridium* species, *Fusobacterium* species, and members of the family Enterobacteriaceae are the predominant organisms identified.

Necrotizing fasciitis, a rapidly spreading destructive disease of the fascia, is usually attributed to group A streptococci **(Chap. 148)** but can also be a mixed infection involving anaerobes and aerobes. Polymicrobial necrotizing fasciitis differs from stereotypical group A streptococcal necrotizing fasciitis in that the initial erythematous, swollen, tender lesions progress over 3–5 days (as opposed to 1–3 days), with consequent skin breakdown and cutaneous gangrene. Fever, subcutaneous gas, development of anesthesia (often before skin necrosis), and a foul-smelling discharge are common. The particular clinical findings sometimes suggest the causative agent: regional lymphadenopathy suggests the *B. fragilis* group; necrosis and gangrene suggest *Clostridium* species, peptostreptococci, the *B. fragilis* group, and Enterobacteriaceae; bullous lesions suggest Enterobacteriaceae; a foul-smelling odor suggests *Bacteroides* and *Clostridium* species; and subcutaneous gas suggests peptostreptococci, *Clostridium* species, and the *B. fragilis* group. Moreover, diabetic infections are often associated with *Bacteroides* species, Enterobacteriaceae, and *S. aureus*, and infections related to trauma are associated with *Clostridium* species.

Although *S. aureus* is the typical cause of myositis, anaerobes—particularly *C. perfringens*—are often recovered from patients with pyogenic myositis. In anaerobic streptococcal myonecrosis, peptostreptococci are often identified along with group A streptococci or *S. aureus*. Patients typically present with fever, muscle pain, fatigue, and an elevated creatinine kinase level suggestive of muscle inflammation.

Bone and Joint Infections A comprehensive review of the world literature on anaerobic bone infections included >650 cases. Of these, ~400 cases were caused by *Actinomyces* species; anaerobic cocci and *Bacteroides*, *Fusobacterium*, and *Clostridium* species were most commonly identified in the remaining cases. Actinomycotic involvement of the jaw was the most common bone infection, with the mandible involved four times as frequently as the maxilla. Patients with cervicofacial actinomycosis **(Chap. 175)** are often described as having a "lumpy jaw" because of the prominent soft tissue swelling that is sometimes mistaken for malignancy or granulomatous disease. These infections can be chronic in nature, can include the development of sinus tracts, can progress across normal tissue boundaries, and can require prolonged antibiotic treatment to prevent relapse. The vertebrae are the second most common location for *Actinomyces* infection; involvement of the thorax, abdomen, or pelvis is much less frequent.

Osteomyelitis involving anaerobes other than *Actinomyces* species most commonly develops by extension of an adjacent infection (e.g., soft tissue, paranasal sinus, or middle-ear infection). For example, diabetic foot ulcers and decubitus ulcers may be complicated by mixed aerobic–anaerobic osteomyelitis **(Chap. 131)**. Hematogenous seeding of bone by anaerobes is uncommon and is thought to occur in fewer than 10% of cases. The most common sites of anaerobic osteomyelitis are the head (skull and jaw) and the extremities. Fusobacteria have been isolated in pure culture from infections of the mastoid, mandible, and maxilla. *Clostridium* species have been reported as anaerobic pathogens in cases of osteomyelitis of the long bones following trauma. Anaerobic and microaerophilic cocci are most frequently isolated from infections involving the skull or mastoid; usually, these organisms are present in mixed cultures.

In contrast to anaerobic osteomyelitis, anaerobic arthritis **(Chap. 130)** is uncommon, typically involving a single isolate, and most cases are secondary to hematogenous spread. Although *Fusobacterium* species accounted for nearly one-third of cases in the preantibiotic era, *C. acnes*, peptostreptococci, and *B. fragilis* are now among the more frequent causes of anaerobic septic arthritis. Peptostreptococci and *C. acnes* are often found in association with prosthetic joints, *Fusobacterium* species have a predilection for the sternoclavicular and sacroiliac joints, and clostridial arthritis is especially common after trauma. As a frequent cause of bacteremia, *B. fragilis* is a common cause of anaerobic septic arthritis; however, arthritis occurs in fewer than 5% of patients with *B. fragilis* bacteremia.

Bacteremia *B. fragilis* is the anaerobe most commonly isolated from blood cultures. Although the frequency of positive cultures appeared to be decreasing in the 1980s, more recent evidence suggests that the rate is now increasing and that the increase may be related to changing demographics, with more patients who are elderly, immunocompromised, and/or receiving medications that may disrupt the mucosal barrier (e.g., chemotherapy). The source of bacteremia is most often an abscess in the abdomen, female genital tract, or soft tissue. At a large tertiary-care U.S. hospital, 0.8% of all positive blood cultures yielded an anaerobic gram-negative bacillus, with 0.5% yielding *B. fragilis*. A similar study in France revealed that 0.6% of all positive blood cultures yielded an anaerobic organism; 60% of these isolates were *Bacteroides* species, and 22% were *Clostridium* species. *Peptostreptococcus* and *Fusobacterium* species are also recovered with significant frequency.

Once the organism in the blood has been identified, both the portal of bloodstream entry and the underlying problem that probably led to seeding of the bloodstream can often be deduced from an understanding of the organism's normal site of residence. For example, mixed anaerobic bacteremia including *B. fragilis* usually implies a colonic pathology, with mucosal disruption from neoplasia, diverticulitis, or some other inflammatory lesion. The initial manifestations are determined by the portal of entry and reflect the localized condition. Although the clinical manifestations of *B. fragilis* bacteremia (e.g., rigors, hectic fevers) are similar to those of aerobic gram-negative bacillary bacteremia, the incidence of septic shock is lower with *B. fragilis*. This difference may be due to differences in the immunostimulatory effects of the different endotoxin structures.

In virtually all cases, isolation of a member of the *B. fragilis* group from blood indicates underlying infection that is associated with a mortality rate of 60% if untreated. It has been suggested that the mortality rate depends in part on the species recovered (*B. thetaiotaomicron* > *P. distasonis* > *B. fragilis*), but it is unclear whether differences in mortality rates relate to intrinsic differences in the virulence of these organisms, in their antimicrobial susceptibility profiles, and/or in the host's immune response. Case–fatality rates appear to increase with the increasing age of the patient (with reported rates of >66% among patients >60 years old), with the isolation of multiple species from the bloodstream, and with the failure to surgically remove a focus of infection.

Endocarditis **(See also Chap. 128)** Although gram-negative anaerobic bacteria only rarely cause endocarditis, their involvement is associated with significant mortality rates (21–43%). Members of the *B. fragilis* group are the most commonly identified gram-negative anaerobes in endocarditis. Anaerobic streptococci, which are often classified incorrectly, are likely responsible for this disease more frequently than is generally appreciated. Compared to aerobic bacterial endocarditis, endocarditis due to *Bacteroides* species is less likely to be associated with a history of cardiovascular disease and more likely to involve thromboembolic complications.

DIAGNOSIS

There are three critical steps in the diagnosis of anaerobic infection: (1) proper collection of specimens; (2) rapid transport of the specimens to

the microbiology laboratory, preferably in anaerobic transport media; and (3) proper handling of the specimens by the laboratory. Specimens must be collected by meticulous sampling of infected sites, with avoidance of contamination by the normal microbiota. Samples from sites known to harbor numerous anaerobes (e.g., the mouth, nose, vagina, feces) are not acceptable for anaerobic culture as the presence of the normal microbiota will complicate interpretation of the results in a clinically meaningful manner. In contrast, samples from normally sterile locations (e.g., blood, pleural fluid, peritoneal fluid, CSF, and aspirates or biopsy samples from normally sterile sites) are appropriate for anaerobic culture in clinical microbiology laboratories. As a general rule, liquid or tissue specimens are preferred; if swab specimens must be used, special anaerobic swab systems should be used to help maintain persistence of anaerobes. Liquid samples should be collected in an air-free syringe that is then capped, injected into anaerobic transport bottles, or quickly transported to the clinical microbiology laboratory for immediate culture.

Because of the time and difficulty involved in the isolation of anaerobic bacteria, the diagnosis of anaerobic infections must frequently be based on presumptive evidence. As mentioned previously, anaerobic infections are sometimes suggested by specific clinical factors, such as origins from a site with an anaerobic-rich microbiota (e.g., the intestinal tract, oropharynx), the presence of an abscess, involvement of sites with lowered oxidation-reduction potential (e.g., avascular necrotic tissues), a foul odor, and the presence of gas in tissues. None of these features is necessarily pathognomonic or required for the diagnosis of an anaerobic infection, but these are helpful clues to keep in mind when constructing a differential diagnosis.

When cultures of obviously infected sites or purulent material yield no growth, streptococci only, or a single aerobic species (such as *E. coli*) and Gram's staining reveals a mixed bacterial population, the involvement of anaerobes should be suspected; the implication is that the anaerobic microorganisms have failed to grow because of inadequate transport and/or culture techniques. It is also important to remember that prior antibiotic therapy reduces the cultivability of these bacteria. Failure of an infection to respond to antibiotics that are not active against anaerobes (e.g., aminoglycosides and—in some circumstances—penicillin, cephalosporins, or tetracyclines) suggests an anaerobic etiology.

TREATMENT

Anaerobic Infections

Similar to successful therapy for other types of infection, treatment for anaerobic infections requires the administration of appropriate antibiotics, surgical debridement of devitalized tissues, and drainage of any large abscess. Any mucosal breach must be closed promptly to prevent ongoing infection.

ANTIBIOTIC THERAPY AND RESISTANCE

The antibiotics used to treat anaerobic infections should be active against both aerobic and anaerobic organisms because many of these infections are of mixed etiology. Antibiotic regimens can usually be selected empirically on the basis of the location of infection (which provides insight into the likely species involved), the severity of infection, and knowledge of local antimicrobial resistance patterns. Other factors influencing the selection of antibiotics include need for penetration into certain organs (such as the brain) and associated toxicity **(Chap. 144)**. As with all infections, the general maxim is to use the least broad-spectrum agent(s) possible so as to minimize the impact on the normal microbiota and the development of resistance.

Because of the slow growth rate of many anaerobes, the lack of standardized testing methods and of clinically relevant standards for resistance, and the generally good results obtained with empirical therapy, the role of antibiotic susceptibility testing of these organisms has been limited in most clinical microbiology laboratories. Instead, isolates are sent to reference laboratories for susceptibility testing when an infection is serious (e.g., brain abscess, meningitis, joint infection), is refractory, or requires prolonged therapy (e.g., osteomyelitis, prosthetic joint infection, endocarditis). Such testing should also be considered when a patient is not responding to antimicrobial therapy as expected; multidrug-resistant anaerobes have been reported. Antimicrobial susceptibility testing is also helpful in monitoring the activity of new drugs and recording current resistance patterns among anaerobic pathogens.

The need for susceptibility testing of anaerobic organisms is highlighted by increasing rates of antimicrobial resistance, geographic and institutional differences in susceptibility profiles, species-specific antibiograms, and the potential for worse clinical outcomes when ineffective antibiotics are used. These differences preclude making any sweeping generalizations regarding antibiotic therapy for anaerobic infections. For example, rates of resistance to piperacillin-tazobactam have remained low (≤1%) for all *Bacteroides* species in the United States, but *B. thetaiotaomicron* isolates in Korea have a notably higher resistance rate (17%). Clindamycin was historically effective against members of the *B. fragilis* group, but rates of resistance have increased to 30–43% in the United States and are >80% in some parts of the world. Furthermore, metronidazole is effective against many different anaerobic organisms and is considered a first-line agent for many anaerobic infections worldwide, but, in a population of Colombian patients with refractory periodontitis, 45% of *Fusobacterium* isolates and 25% of *Prevotella* and *Porphyromonas* strains were resistant to metronidazole; this finding underscores the importance of understanding the local antibiogram and of assessing susceptibility profiles in refractory disease.

Empirical Therapy Not every anaerobe isolated must be specifically targeted by the antibiotic regimen. Given that infections involving anaerobes are typically polymicrobial, that the cultivation and identification of anaerobes are challenging (i.e., not all organisms may be recovered), and that organisms often depend on one another for persistence, clinical resolution of the infection is often achieved with empirical antibiotics targeting the bulk of the organisms recovered. Antibiotics that demonstrate no useful activity against anaerobes include aminoglycosides, monobactams, and trimethoprim-sulfamethoxazole. With the caveat that susceptibility profiles may change with time and geography, the antibiotics that are commonly used as empirical therapy against anaerobic bacteria include metronidazole, β-lactam/β-lactamase inhibitor combinations, clindamycin, carbapenems, and chloramphenicol **(Table 177-2)**.

Metronidazole is active against gram-negative anaerobes, including nearly all isolates of *Bacteroides* species, and gram-positive spore-forming organisms, such as *C. difficile* **(Chap. 134)** and other *Clostridium* species. Given intrinsically reduced susceptibility, metronidazole is clinically unreliable against gram-positive non-spore-forming organisms, such as *Actinomyces*, *Propionibacterium*, *Lactobacillus*, *Bifidobacterium*, *Eubacterium*, and *Peptostreptococcus*.

TABLE 177-2 Antimicrobial Therapy That Is Typically Active Against Commonly Encountered Anaerobes

ANTIBIOTIC(S)	CAVEATS
Metronidazole	This drug is clinically unreliable against gram-positive non-spore-forming anaerobes (e.g., *Actinomyces* spp., *Propionibacterium* spp., *Peptostreptococcus* spp.).
β-Lactam/β-lactamase inhibitor combinations (ampicillin-sulbactam, ticarcillin–clavulanic acid, piperacillin-tazobactam)	Rates of resistance are increasing in some gram-negative anaerobes. The newer cephalosporin/β-lactamase combinations have limited anaerobic activity.
Clindamycin	Rates of resistance are increasing in *Bacteroides* spp.
Carbapenems (meropenem, imipenem, ertapenem, doripenem)	Rates of resistance are currently very low (<5%), although some carbapenemase-producing strains have been identified.
Chloramphenicol	Some clinical failures have been noted, even when the isolate is found to be susceptible by in vitro testing.

Of note, a few metronidazole-resistant *Bacteroides* isolates have been identified in the United States, and rates of such resistance have been increasing in Europe. Moreover, the rate of resistance to metronidazole has probably been greatly underestimated in some countries (e.g., the United Kingdom) that use metronidazole susceptibility to discriminate between obligate and facultative anaerobes (with obligate anaerobes defined by their susceptibility). Although the majority of metronidazole-resistant isolates have been identified in patients who have been exposed to the drug, resistant organisms have also been found in metronidazole-naïve patients.

More than 90% of clinical isolates from the *B. fragilis* group produce β-lactamases that are predominantly active against cephalosporins and that are highly active, cell associated, and produced constitutively. Thus, members of the *B. fragilis* group are presumed to be resistant to penicillin and ampicillin but may remain susceptible to extended-spectrum penicillins, particularly in combination with a β-lactamase inhibitor (e.g., ampicillin-sulbactam, piperacillin-tazobactam). Rates of resistance to ampicillin-sulbactam are increasing, particularly in *P. distasonis*, which has a reported resistance rate of 21% in the United States. Because β-lactamase production is not common in *Clostridium* species, these combination agents are usually effective. Of note, the newer cephalosporin/β-lactamase inhibitors (e.g., ceftolozane-tazobactam, ceftazidime-avibactam) have limited anaerobic activity.

Clindamycin is active against many anaerobes. However, rates of resistance to clindamycin among *Bacteroides* species increased in the United States from 7% in 1981 to 33% in 2010–2012. Resistance to clindamycin among non-*Bacteroides* gram-negative anaerobes is much less common (<10%). Some *Clostridium* species are resistant to clindamycin, although *C. perfringens* typically is not.

Carbapenems (ertapenem, doripenem, meropenem, and imipenem) are active against anaerobes, with fewer than 3% of *Bacteroides* isolates resistant. There is little difference among resistance rates for specific species, and, of the carbapenems, imipenem typically has the lowest resistance rate. Although the β-lactamase produced by most *Bacteroides* species is unable to inactivate carbapenems, rare *B. fragilis* strains have been reported to produce a carbapenemase.

Resistance to chloramphenicol is rare in *Bacteroides* species. Nationwide surveys in the United States have identified no resistant organisms, but some isolates with elevated minimal inhibitory concentrations (MICs)—i.e., 16 μg/mL—have been noted. Although chloramphenicol has excellent in vitro activity against all clinically relevant anaerobes, some clinical failures have been documented. Therefore, this drug may be less preferable if other active agents are available.

Other antibiotics with more variable activity against anaerobes include the fluoroquinolones and tigecycline. Although many fluoroquinolones (e.g., ciprofloxacin, levofloxacin, ofloxacin) display reasonable activity against anaerobic organisms other than *Bacteroides* species, these agents exhibit poor activity against the *B. fragilis* group. Rates of resistance to moxifloxacin are relatively high (39–83%) among *Bacteroides* isolates obtained in the United States but are much lower among *B. fragilis* and *B. thetaiotaomicron* isolates collected in Korea (8 and 2%, respectively) or Taiwan (8 and 15%, respectively). Tigecycline is active against most anaerobic bacteria, although MICs are somewhat higher for *Clostridium* species. Tigecycline's efficacy for treatment of complicated intraabdominal infections is comparable to that of imipenem, and it is therefore recommended as single-agent therapy for these infections.

Infections at Specific Sites In clinical situations, specific antibiotic regimens and durations must be tailored to the initial site of infection; the reader is referred to specific chapters on infections at specific sites for recommendations. In general, anaerobic infections are often broadly categorized as originating above or below the diaphragm. This distinction is clinically useful in that the predominant pathogens—and therefore the empirical antibiotic regimens—differ between these two categories of infection.

Infections above the diaphragm usually reflect the orodental microbiota, which includes *Prevotella*, *Porphyromonas*, *Fusobacterium*, and *Bacteroides* species other than the *B. fragilis* group along with streptococci (both aerobic and microaerophilic). Accordingly, antibiotic regimens should cover both aerobic and anaerobic bacteria. Given that >70% of these infections include a β-lactamase-producing organism, β-lactam drugs (penicillins and cephalosporins) are poor options as monotherapy. The recommended regimens include clindamycin, a β-lactam/β-lactamase inhibitor combination, or metronidazole in combination with a drug active against microaerophilic and aerobic streptococci (e.g., penicillin).

Anaerobic infections arising below the diaphragm (e.g., colonic and intraabdominal infections) must be treated specifically with agents active against *Bacteroides* species, including *B. fragilis*. Single agents suitable for this purpose include cefoxitin, moxifloxacin, a β-lactam/β-lactamase inhibitor combination, or a carbapenem. A two-drug regimen is an alternative, with one drug active against anaerobes and the other against coliforms (e.g., metronidazole with either a cephalosporin or a fluoroquinolone). In addition, if the clinician suspects that gram-positive facultative organisms such as enterococci are involved, therapeutic regimens should include ampicillin or vancomycin. Although clindamycin and cefotetan were previously considered acceptable options for intraabdominal infections involving anaerobes, these drugs are no longer recommended because of escalating rates of resistance in the *B. fragilis* group. Ampicillin-sulbactam is not recommended because of high rates of resistance among community-acquired strains of *E. coli* rather than because of resistance in anaerobic bacteria.

CNS infections involving anaerobic organisms may be treated with metronidazole, a carbapenem, chloramphenicol, or—if only gram-positive anaerobes are involved—penicillin. Clindamycin and cefoxitin have poor penetration into the CSF and should not be used. Cases of osteomyelitis in which a polymicrobial infection is identified from a bone biopsy specimen should be treated with a regimen that covers both aerobes and anaerobes, as some organisms that are often regarded as a contaminant (e.g., *C. acnes*) may have a pathogenic role. When an anaerobic organism is recognized as a major or sole pathogen infecting a joint, the duration of treatment should be similar to that used for arthritis caused by aerobic bacteria **(Chap. 130)**.

Although not every anaerobe needs to be covered with pathogen-directed therapy in most polymicrobial infections, several studies of *Bacteroides* bacteremia have clearly demonstrated that patients receiving effective therapy have lower mortality rates and more rapid sterilization of blood cultures than patients receiving ineffective therapy.

FAILURE OF THERAPY

Anaerobic infections that fail to respond to treatment or that relapse should be reassessed. Potential causes include an uncontrolled source of infection (e.g., ongoing intestinal leak into the peritoneum), superinfection with a new organism, and/or antibiotic failure. Additional imaging may be useful to discern whether surgical drainage or debridement is warranted. Obtaining additional culture specimens will help identify whether an organism resistant to the antibiotics being used is present. Strong consideration should be given to obtaining susceptibility profiles for the isolates.

178 Tuberculosis

Mario C. Raviglione, Andrea Gori

Tuberculosis (TB), which is caused by bacteria of the *Mycobacterium tuberculosis* complex, is one of the oldest diseases known to affect humans and the top cause of infectious death worldwide excluding COVID-19. Population genomic studies suggest that *M. tuberculosis* may have emerged ~70,000 years ago in Africa and subsequently disseminated along with anatomically modern humans, expanding globally during the Neolithic Age as human density started to increase. Progenitors of *M. tuberculosis* are likely to have affected prehominids. This disease most often affects the lungs, although other organs are involved in up to one-third of cases. If properly treated, TB caused by drug-susceptible strains is curable in the vast majority of cases. If untreated, the disease may be eventually fatal in over 70% of people. Transmission usually takes place through the airborne spread of droplet nuclei produced by patients with infectious pulmonary TB. Through pharmacological prophylaxis the development of the disease can be prevented in those who have contracted TB infection.

ETIOLOGIC AGENT

Mycobacteria belong to the family Mycobacteriaceae and the order Actinomycetales. Of the pathogenic species belonging to the *M. tuberculosis* complex, which comprises eight distinct subgroups, the most common and important agent of human disease by far is *M. tuberculosis* (*sensu stricto*). A closely related organism isolated from cases in West, Central, and East Africa is *M. africanum*. The complex includes some zoonotic members, such as *M. bovis* (the bovine tubercle bacillus—characteristically resistant to pyrazinamide, once an important cause of TB transmitted by unpasteurized milk, and currently responsible for 140,000 human cases worldwide in 2019, half of them in Africa) and *M. caprae* (related to *M. bovis*). In addition, other organisms that have been reported rarely as causing TB include *M. pinnipedii* (a bacillus infecting seals and sea lions in the southern hemisphere and recently isolated from humans), *M. mungi* (isolated from banded mongooses in southern Africa), *M. orygis* (described in oryxes and other Bovidae in Africa and Asia and a potential cause of infection in humans), and *M. microti* (the "vole" bacillus, a less virulent organism). Finally, *M. canetti* is a rare isolate from East African cases that produces unusual smooth colonies on solid media and is considered closely related to a supposed progenitor type. There is no known environmental reservoir for any of these organisms.

M. tuberculosis is a rod-shaped, non-spore-forming, thin aerobic bacterium measuring 0.5 µm by 3 µm. Mycobacteria, including *M. tuberculosis*, are often neutral on Gram's staining. However, once stained, the bacilli cannot be decolorized by acid alcohol; this characteristic justifies their classification as acid-fast bacilli (AFB; **Fig. 178-1**). Acid fastness is due mainly to the organisms' high content of mycolic acids, long-chain cross-linked fatty acids, and other cell-wall lipids. Microorganisms other than mycobacteria that display some acid fastness include species of *Nocardia* and *Rhodococcus*, *Legionella micdadei*, and the protozoa *Isospora* and *Cryptosporidium*. In the mycobacterial cell wall, lipids (e.g., mycolic acids) are linked to underlying arabinogalactan and peptidoglycan. This structure results in very low permeability of the cell wall, thus reducing the effectiveness of most antibiotics. Another molecule in the mycobacterial cell wall, lipoarabinomannan, is involved in the pathogen–host interaction and facilitates the survival of *M. tuberculosis* within macrophages.

The complete genome sequence of *M. tuberculosis* comprises 4.4 million base pairs, 4043 genes encoding 3993 proteins, and 50 genes encoding stable RNAs; its high guanine-plus-cytosine content (65.6%) is indicative of an aerobic "lifestyle." A large proportion of genes are devoted to the production of enzymes involved in cell wall metabolism. Substantial genetic variability exists among the innumerable *M. tuberculosis* strains from different parts of the world. Based on such genetic variability it is possible to distinguish and compare different strains. Their distinction is important to study transmission dynamics and identify outbreaks. Starting in the 1990s, reproducible genotyping methods were developed to type the bacterium. Initially, they included insertion sequence 6110 (IS6110), restriction fragment length polymorphism (RFLP) typing, and spoligotyping. Lately, most studies utilize mycobacterial interspersed repetitive unit variable number tandem repeats (MIRU-VTNRs) and whole genome sequencing analysis.

EPIDEMIOLOGY

In 2019, 7.1 million new cases of TB (all forms, both pulmonary and extrapulmonary) were reported to the World Health Organization (WHO) by its member states; 97% of cases were reported from low- and middle-income countries. However, because of insufficient case detection and incomplete notification, reported cases represent only about two-thirds of the total estimated cases. The WHO estimated that 10 million (range 9-11 million; rate 130 per 100,000 people) new (incident) cases of TB occurred worldwide in 2019, 97% of them in low- and middle-income countries of Asia (6.1 million), Africa (2.4 million), the Middle East (0.8 million), and Latin America (0.28 million). Eight countries accounted for two-thirds of all new cases: India, Indonesia, China, the Philippines, Pakistan, Nigeria, Bangladesh, and South Africa. Of all cases, 57% occurred in male patients, 32% in female patients, and 11% in children. It is further estimated that 1.4 million (range, 1.3–1.6 million) deaths from TB, including 0.21 million among people with HIV co-infection, occurred in 2019; 98% of these deaths were in low- and middle-income countries. Estimates of TB incidence rates (per 100,000 population) and numbers of TB-related deaths in 2018 are depicted in **Figs. 178-2 and 178-3**, respectively. During the

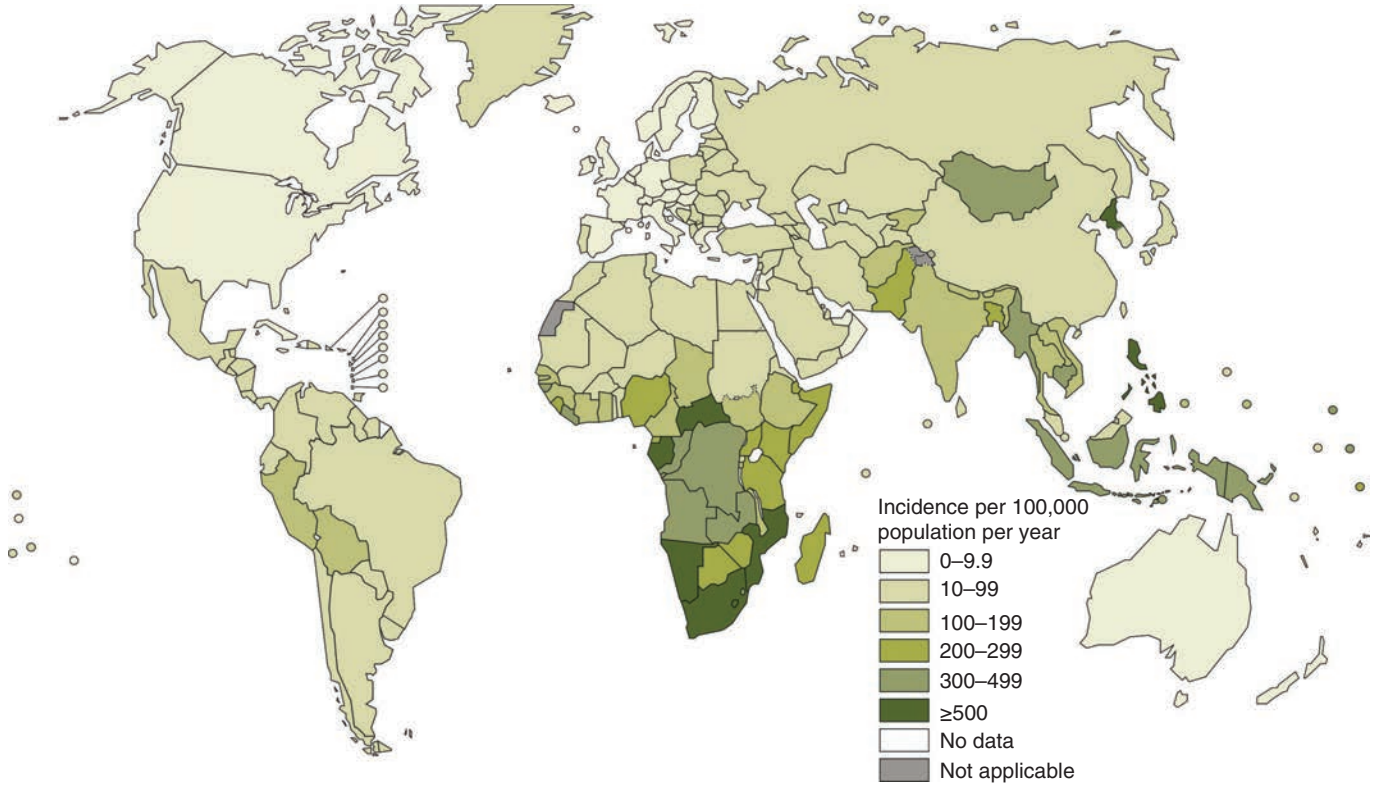

FIGURE 178-2 Estimated tuberculosis (TB) incidence rates (per 100,000 population) in 2018. The designations used and the presentation of material on this map do not imply the expression of any opinion whatsoever on the part of the World Health Organization (WHO) concerning the legal status of any country, territory, city, or area or of its authorities or concerning the delimitation of its frontiers or boundaries. *Dotted*, *dashed*, and *white lines* represent approximate border lines for which there may not yet be full agreement. *(Reproduced with permission from Global Tuberculosis Report 2019. Geneva, World Health Organization; 2019.)*

late 1980s and early 1990s, numbers of reported cases of TB increased in high-income countries after years of decline. These increases were related largely to immigration from countries with a high incidence of TB; the worldwide spread of the HIV epidemic; social problems, such as increase in urbanization and the related increased urban poverty, homelessness, and drug abuse; and dismantling of TB services. During the past few years, numbers of reported cases have begun to decline again or have stabilized in most industrialized nations. In the United States, with the re-establishment of stronger control programs, the decline resumed in 1993, and during the period 2007–2012, the decline rate was 6.5% annually on average. Later, between 2012 and 2019 this annual rate slowed down to 2.1%. In 2019, 8920 cases of TB

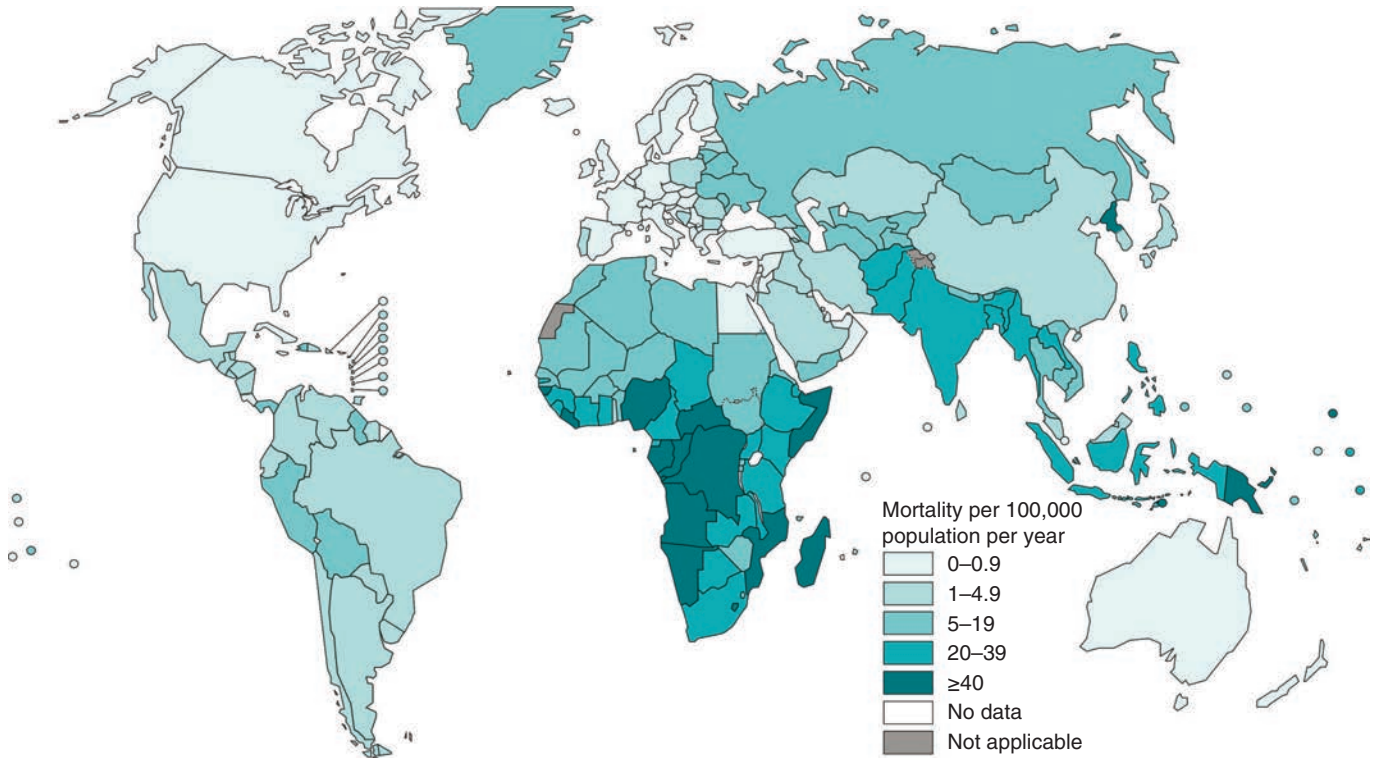

FIGURE 178-3 Estimated tuberculosis (TB) mortality rates in HIV-negative people in 2018. *(See disclaimer in Fig. 178-2. Reproduced with permission from Global Tuberculosis Report 2019. Geneva, World Health Organization; 2019.)*

(2.7 cases/100,000 population) were preliminarily reported to the U.S. Centers for Disease Control and Prevention (CDC).

In the United States, TB is uncommon among young white adults of European descent, who have only rarely been exposed to *M. tuberculosis* infection during recent decades. In contrast, because of a high risk of transmission in the past, the prevalence of *M. tuberculosis* infection is relatively high among elderly whites. In general, adults ≥65 years of age have the highest incidence rate per capita and children <14 years of age the lowest. Among U.S.-born persons, African Americans accounted for the highest proportion of cases (35%; 905 in 2019), followed by white persons (756 cases), and Hispanic/Latinos (628). TB in the United States is also a disease of adult members of the HIV-infected population (4.9% of all cases), the foreign-born population (71% of all cases in 2019), and disadvantaged/marginalized populations. Of the 6322 cases reported among non-U.S.-born persons in the United States in 2019, 33% occurred in Hispanic/Latinos and 47% in persons born in Asia. Overall, the highest rates per capita were among non-U.S.-born Asians (26 cases/100,000 population) and native Hawaiian/Pacific Islanders (25 cases/100,000 population). A total of 515 deaths was caused by TB in the United States in 2017. In Canada, TB cases and rates per 100,000 population have been increasing between 2014 and 2017 (from 1615/4.5 to 1796/4.9). In 2017, 1796 TB cases were reported (4.9 cases/100,000 population); 72% (1290) of these cases occurred in foreign-born persons, and 17.4% (313 cases) occurred in Canadian-born Indigenous Peoples, whose per capita rate is disproportionately high (21.5 cases/100,000 population). The highest rate was found in the territory of Nunavut, at 265 cases/100,000 population—a rate similar to that in many highly endemic countries. Similarly, in Europe, TB has reemerged as an important public health problem, mainly as a result of cases among immigrants from high-incidence countries and among marginalized populations, often in large urban settings such as London. In 2018, 36% of all cases reported from England occurred in London, 82% of them among people born abroad; although decreasing, the rate per capita (19 cases/100,000 population) is twice as high as that of England with a borough (Newham) reaching 47 cases per 100,000 population. Likewise, in most Western European countries, there are more cases annually among foreign-born than native populations.

Recent data on global trends indicate that in 2019 the TB incidence was stable or falling in most regions; this trend began in the early 2000s and appears to have continued, with an average annual decline of 1.7% globally and 2.3% between 2018 and 2019. This global decrease is explained largely by the reduction in TB incidence in sub-Saharan Africa, where rates had risen steeply since the 1980s as a result of the HIV epidemic and the lack of capacity of health systems and services to deal with the problem effectively, and, less so, in Eastern Europe, where incidence increased rapidly during the 1990s because of a deterioration in socioeconomic conditions and the health care infrastructure (although, after peaking in 2001, incidence in Eastern Europe has since declined slowly).

Of the estimated 10 million new cases of TB in 2019, 8.2% (0.82 million) were associated with HIV co-infection, and 73% of these HIV-associated cases occurred in Africa. An estimated 0.21 million persons with HIV-associated TB died in 2019. Furthermore, an estimated 465,000 (range 400,000-535,000) cases of rifampin- (also called rifampicin) resistant TB (RR-TB) and multidrug-resistant TB (MDR-TB)—a form of the disease caused by bacilli resistant at least to isoniazid and rifampin—occurred in 2019, representing 3.3% and 18%, respectively, of all new and previously treated cases. Only 44% of these cases were diagnosed because of a lack of culture and drug susceptibility testing (DST) capacity in many settings worldwide. As a consequence, an estimated 200,000 people with MDR/RR-TB died in 2019. The countries of the former Soviet Union reported the highest proportions of MDR/RR disease among new TB cases (37% in Belarus, 35% in Russia, 29% in Kyrgyzstan, Moldova, and Ukraine). Overall, half of all MDR/RR-TB cases occur in India (27%), China (14%), and the Russian Federation (9%). Since 2006, 131 countries, including the United States, have reported cases of extensively drug-resistant TB (XDR-TB), in which MDR-TB is compounded by additional resistance to any fluoroquinolones and at least one of the injectable drugs amikacin, kanamycin, and capreomycin. (N.B: In January 2021, the WHO published the following new definitions: (i) Pre-XDR-TB, as TB caused by *Mycobacterium tuberculosis* strains that fulfill the definition of MDR/RR-TB and that are also resistant to any fluoroquinolone. (ii) XDR-TB, as TB caused by *Mycobacterium tuberculosis* strains that fulfill the definition of MDR/RR-TB and that are also resistant to any fluoroquinolone and at least one additional Group A drug including levofloxacin or moxifloxacin, bedaquiline and linezolid.) About 6.2% of the MDR-TB cases worldwide may be XDR-TB, but the vast majority of XDR-TB cases remain undiagnosed because reliable methods for DST are lacking and laboratory capacity is limited mainly in low-income countries. Lately, a few cases deemed resistant to all anti-TB drugs have been reported; however, this information must be interpreted with caution because susceptibility testing for several second-line drugs is neither accurate nor reproducible.

FROM EXPOSURE TO INFECTION

M. tuberculosis is most commonly transmitted from a person with infectious pulmonary TB by droplet nuclei containing *M. tuberculosis* bacteria, which are aerosolized by coughing, sneezing, or speaking. The tiny droplets dry rapidly; the smallest (<5–10 μm in diameter) may remain suspended in the air for several hours and may reach the terminal air passages when inhaled. There may be as many as 3000 infectious nuclei per cough. Other routes of transmission of tubercle bacilli (e.g., through the skin or the placenta) are uncommon and of no epidemiologic significance. The risk of transmission and of subsequent acquisition of *M. tuberculosis* infection is determined mainly by exogenous factors, although endogenous factors may also play a role. The probability of contact with a person who has an infectious form of TB, the intimacy and duration of that contact, the degree of infectiousness of the case, and the shared environment in which the contact takes place are all important determinants of the likelihood of transmission. Several studies of close-contact situations have clearly demonstrated that TB patients whose sputum contains AFB visible by microscopy (sputum smear–positive cases) are the most likely to transmit the infection. The most infectious patients have cavitary pulmonary disease or, much less commonly, laryngeal TB and produce sputum containing as many as 10^5–10^7 AFB/mL. Patients with sputum smear–negative/culture-positive TB are less infectious, although they have been responsible for up to 20% of transmission in some studies in the United States. Those with culture-negative pulmonary TB and extrapulmonary TB are essentially noninfectious. Because persons with both HIV infection and TB are less likely to have cavitations, they may be less infectious than persons without HIV co-infection. Crowding in poorly ventilated rooms is one of the most important factors in the transmission of tubercle bacilli because it increases the intensity of contact with a case. The virulence of the transmitted organism is also an important factor in establishing infection. Endogenous factors such as the degree of immune competence are also important. In particular, HIV-infected patients, persons undergoing cancer treatment, or those administered immunosuppressive drugs may be at higher risk of TB infection acquisition.

Because of delays in seeking care and in making a diagnosis, it has been estimated that, in high-prevalence settings, up to 20 contacts (or 3–10 people per year) may be infected by each AFB-positive case before the index case is diagnosed. Attempts to estimate the basic reproductive number R_0 for TB have resulted in a wide range of values depending on environmental conditions and social behaviors of populations: from 0.24 in the Netherlands during the period 1933–2007 to 4.3 in China in 2012 reflecting the status of disease control.

FROM INFECTION TO DISEASE

Unlike the risk of acquiring infection with *M. tuberculosis*, the risk of developing disease after being infected depends largely on endogenous factors, such as the individual's innate immunologic and nonimmunologic defenses and the level at which the individual's cell-mediated immunity is functioning. Clinical illness directly following infection is classified as *primary TB* and is common among children in the first few years of life and among immunocompromised persons. Although primary TB may be severe and disseminated, it generally is not associated

TABLE 178-1 Risk Factors for Active Tuberculosis in Persons Who Have Been Infected with Tubercle Bacilli

FACTOR	RELATIVE RISK/ODDS[a]
Recent infection (<1 year)	12.9
Fibrotic lesions (spontaneously healed)	2–20
Comorbidities and iatrogenic causes	
HIV infection	21–>30
Silicosis	30
Chronic renal failure/hemodialysis	10–25
Diabetes	2–4
IV drug use	10–30
Excessive alcohol use	3
Immunosuppressive treatment	10
Tumor necrosis factor α inhibitors	4–5
Gastrectomy	2–5
Jejunoileal bypass	30–60
Posttransplantation period (renal, cardiac)	20–70
Tobacco smoking	2–3
Malnutrition and severe underweight	2

[a]Old infection = 1.

with high-level transmissibility. When infection is acquired later in life, the chance is greater that the mature immune system will contain it at least temporarily. Bacilli, however, may persist for years before reactivating to produce *secondary* (or *postprimary*) *TB*, which, because of frequent cavitation, is more often infectious than is primary disease. Overall, it is estimated that up to 10% of infected persons will eventually develop active TB in their lifetime—half of them during the first 18 months after infection. The risk is much higher among immunocompromised individuals and, particularly, HIV-infected persons. Reinfection of a previously infected individual, which is common in areas with high rates of TB transmission, may also favor the development of disease. At the height of the TB resurgence in the United States in the early 1990s, molecular typing and comparison of strains of *M. tuberculosis* suggested that up to one-third of cases of active TB in some inner-city communities were due to recent transmission rather than to reactivation of old infection. Age is an important determinant of the risk of disease after infection. Among infected persons, the incidence of TB is highest during late adolescence and early adulthood; the reasons are unclear. The incidence among women peaks at 25–34 years of age. In this age group, rates among women may be higher than those among men, whereas at older ages the opposite is true. The risk increases in the elderly, possibly because of waning immunity and comorbidity.

A variety of diseases and conditions favor the development of active TB (Table 178-1). In absolute terms, the most potent risk factor for TB among infected individuals is clearly HIV co-infection, which suppresses cellular immunity. The risk that infection will proceed to active disease is directly related to the patient's degree of immunosuppression. In a study of HIV-co-infected, tuberculin skin test (TST)–positive persons, this risk varied from 2.6 to 13.3 cases/100 person-years and increased as the CD4+ T-cell count decreased.

NATURAL HISTORY OF DISEASE

Studies conducted in various countries before the advent of antimicrobial TB therapy showed that untreated TB is often fatal. About one-third of patients died within 1 year after diagnosis. Historical data also show that 55% of sputum smear-positive cases were dead within 5 years and up to 86% (weighted mean 70%) within 10 years. A lower case fatality rate, around 20%, was estimated for untreated paucibacillary smear-negative cases at 5 years. Of the survivors at 5 years, ~60% had undergone spontaneous remission, while the remainder were still excreting tubercle bacilli. With effective, timely, and proper antimicrobial TB treatment, patients have a very high chance of being cured. However, improper use of anti-TB drugs, while reducing mortality rates, may also result in large numbers of chronic infectious cases, often with drug-resistant bacilli.

PATHOGENESIS AND IMMUNITY

INFECTION AND MACROPHAGE INVASION

The interaction of *M. tuberculosis* with the human host begins when droplet nuclei containing viable microorganisms, propelled into the air by infectious patients, are inhaled by a close bystander. Although the majority of inhaled bacilli are trapped in the upper airways and expelled by ciliated mucosal cells, a fraction (usually <10%) reach the alveoli, a unique immunoregulatory environment. There, in the very early phases of infection, the predominant cells infected by *M. tuberculosis* are myeloid dendritic cells. Subsequently, alveolar macrophages that have not yet been activated (prototypic alternatively activated macrophages) phagocytose the bacilli. Adhesion of mycobacteria to macrophages results largely from binding of the bacterial cell wall to a variety of macrophage cell-surface receptor molecules, including complement receptors, the mannose receptor, the immunoglobulin G Fcγ receptor, and type A scavenger receptors. Surfactants may also play a role in the early phase of interaction between the host and the pathogen, and surfactant protein D can prevent phagocytosis. Phagocytosis is enhanced by complement activation leading to opsonization of bacilli with C3 activation products such as C3b and C3bi. Concomitantly, binding of certain receptors, such as the mannose receptor, regulates postphagocytic events like phagosome–lysosome fusion and inflammatory cytokine production. After a phagosome forms, the survival of *M. tuberculosis* in the cell seems to depend in part on reduced acidification due to lack of assembly of a complete vesicular proton-adenosine triphosphatase. A complex series of events is generated by the bacterial cell-wall lipoglycan lipoarabinomannan, which inhibits the intracellular increase of Ca^{2+}. Thus, the Ca^{2+}/calmodulin pathway (leading to phagosome–lysosome fusion) is impaired, and the bacilli survive within the phagosomes by blocking fusion. The *M. tuberculosis* phagosome inhibits the production of phosphatidylinositol 3-phosphate, which normally earmarks phagosomes for membrane sorting and maturation (including phagolysosome formation), which would destroy the bacteria. Bacterial factors block the host defense of autophagy, in which the cell sequesters the phagosome in a double-membrane vesicle (*autophagosome*) that is destined to fuse with lysosomes. If the bacilli are successful in arresting phagosome maturation, then replication begins and the macrophage eventually ruptures and releases its bacillary contents. This process is mediated by the ESX-1 secretion system that is encoded by genes contained in the region of difference 1 (RD1). Other uninfected phagocytic cells are then recruited to continue the infection cycle by ingesting dying macrophages and their bacillary content, thus, in turn, becoming infected themselves and expanding the infection.

VIRULENCE OF TUBERCLE BACILLI

M. tuberculosis must be viewed as a complex formed by a multitude of strains that differ in virulence and are capable of producing a variety of manifestations of disease. Since the elucidation of the *M. tuberculosis* genome in 1998, large mutant collections have been generated, and many bacterial genes that contribute to *M. tuberculosis* virulence have been found. Moreover, different patterns of virulence defects have been defined in various animal models—predominantly mice but also guinea pigs, rabbits, and nonhuman primates. The *katG* gene encodes for a catalase/peroxidase enzyme that protects against oxidative stress and is required for isoniazid activation and subsequent bactericidal activity. RD1 is a 9.5-kb locus that encodes two key small protein antigens—6-kDa early secretory antigen (ESAT-6) and culture filtrate protein-10 (CFP-10)—as well as a putative secretion apparatus that may facilitate their egress; the absence of this locus in the vaccine strain *M. bovis* bacille Calmette-Guérin (BCG) is a key attenuating mutation. In *M. marinum*, a mutation in the RD1 virulence locus encoding the ESX-1 secretion system impairs the capacity of apoptotic macrophages to recruit uninfected cells for further rounds of infection. The results are less replication and fewer new granulomas. These observations in *M. marinum* are similar in part to events related to the virulence of *M. tuberculosis*; however, ESX-1, although necessary, is probably insufficient to explain virulence, and other mechanisms may be in play. Mutants lacking key enzymes of bacterial biosynthesis become auxotrophic for the

missing substrate and often are totally unable to proliferate in animals; these include the *leuCD* and *panCD* mutants, which require leucine and pantothenic acid, respectively. The isocitrate lyase gene (*icl1*) encodes a key step in the glyoxylate shunt that facilitates bacterial growth on fatty acid substrates; this gene is required for long-term persistence of *M. tuberculosis* infection in mice with chronic TB. *M. tuberculosis* mutants in regulatory genes such as sigma factor C and sigma factor H (*sigC* and *sigH*) are associated with normal bacterial growth in mice, but they fail to elicit full tissue pathology. Finally, the mycobacterial protein CarD (expressed by the *carD* gene) seems essential for the control of rRNA transcription that is required for mycobacterial replication and persistence in the host cell. Its loss exposes mycobacteria to oxidative stress, starvation, DNA damage, and ultimately sensitivity to killing by a variety of host mutagens and defense mechanisms.

INNATE RESISTANCE TO INFECTION

Several observations suggest that genetic factors play a key role in innate resistance to infection with *M. tuberculosis* and the development of disease. The existence of this resistance, which is polygenic in nature, is suggested by the differing degrees of susceptibility to TB in different populations. This mechanism of elimination of the pathogen may be accompanied by negative results in the TST and interferon-γ (IFN-γ) release assays (IGRAs). In mice, a gene called *Nramp1* (natural resistance–associated macrophage protein 1) plays a regulatory role in resistance/susceptibility to mycobacteria. The human homologue NRAMP1, which maps to chromosome 2q, may play a role in determining susceptibility to TB, as is suggested by a study among West Africans. Studies of mice identified a novel host resistance gene, *ipr1*, that is encoded within the *sst1* locus; *ipr1* encodes an IFN-inducible nuclear protein that interacts with other nuclear proteins in macrophages primed with IFNs or infected by *M. tuberculosis*. In addition, polymorphisms in multiple genes, such as those encoding for various major histocompatibility complex alleles, IFN-γ, T-cell growth factor β, interleukin (IL) 10, mannose-binding protein, IFN-γ receptor, Toll-like receptor 2, vitamin D receptor, and IL-1, have been associated with susceptibility to TB.

THE HOST RESPONSE, GRANULOMA FORMATION, AND "LATENCY"

In the initial stage of host–bacterium interaction, prior to the onset of an acquired cell-mediated immune (CMI) response, *M. tuberculosis* disseminates widely through the lymph vessels, spreading to other sites in the lungs and other organs, and undergoes a period of extensive growth within naïve inactivated macrophages; additional naïve macrophages are recruited to the early granuloma. How the bacillus accesses the parenchymal tissue still needs to be elucidated: it may directly infect epithelial cells or transmigrate through infected macrophages across the epithelium. Infected dendritic cells or monocytes then begin to transport bacilli to the lymphatic system. Studies suggest that *M. tuberculosis* uses specific virulence mechanisms to subvert host cellular signaling and to elicit an early regulated proinflammatory response that promotes granuloma expansion and bacterial growth during this key early phase. A study of *M. marinum* infection in zebrafish has delineated one molecular mechanism by which mycobacteria induce granuloma formation. The mycobacterial protein ESAT-6 induces secretion of matrix metalloproteinase 9 (MMP9) by nearby epithelial cells that are in contact with infected macrophages. MMP9 in turn stimulates recruitment of naïve macrophages, thus inducing granuloma maturation and bacterial growth. Disruption of MMP9 function results in reduced bacterial growth. Another study has shown that *M. tuberculosis*–derived cyclic AMP is secreted from the phagosome into host macrophages, subverting the cell's signal transduction pathways and stimulating an elevation in the secretion of tumor necrosis factor α (TNF-α) as well as further proinflammatory cell recruitment. Ultimately, the chemoattractants and bacterial products released during the repeated rounds of cell lysis and infection of newly arriving macrophages enable dendritic cells to access bacilli; these cells migrate to the draining lymph nodes and present mycobacterial antigens to T lymphocytes. At this point, the development of cell-mediated and humoral immunity begins. These initial stages of infection are usually asymptomatic.

About 2–4 weeks after infection, two host responses to *M. tuberculosis* develop: a macrophage-activating CMI response and a tissue-damaging response. The *macrophage-activating response* is a T-cell mediated phenomenon resulting in the activation of macrophages that are capable of killing and digesting tubercle bacilli. The *tissue-damaging response* is the result of a delayed-type hypersensitivity reaction to various bacillary antigens; it destroys inactivated macrophages that contain multiplying bacilli but also causes caseous necrosis of the involved tissues (see below). Although both of these responses can inhibit mycobacterial growth, it is the balance between the two that determines the forms of TB that will develop subsequently. With the development of specific immunity and the accumulation of large numbers of activated macrophages at the site of the primary lesion, granulomatous lesions (*tubercles*) are formed. These lesions consist of accumulations of lymphocytes and activated macrophages that evolve toward epithelioid and giant cell morphologies. Initially, the tissue-damaging response can limit mycobacterial growth within macrophages. As stated above, this response, mediated by various bacterial products, not only destroys macrophages but also produces early solid necrosis in the center of the tubercle. Although *M. tuberculosis* can survive, its growth is inhibited within this necrotic environment by low oxygen tension and low pH. At this point, some lesions may heal by fibrosis, with subsequent calcification, whereas inflammation and necrosis occur in other lesions. Some observations have challenged the traditional view that any encounter between mycobacteria and macrophages results in chronic infection. It is possible that an immune response capable of eradicating early infection may sometimes develop as a consequence, for instance, of disabling mutations in mycobacterial genomes rendering their replication ineffective. Individual granulomas that are formed during this phase of infection can vary in size and cell composition; some can contain the spread of mycobacteria, while others cannot. TB infection ensues as a result of this dynamic balance between the microorganism and the host. For many years, TB infection has been called "latent TB infection (LTBI)." This terminology was used to define a state of persistent immune response to stimulation by *M. tuberculosis* antigens with no evidence of clinically manifest, active TB. The qualification "latent" may offer some convenience of distinguishing infection from disease, albeit an inaccurate description of a process that encompasses bacterial generations that are not dormant. It has been speculated that *latency* may therefore be an inaccurate term because bacilli may remain active during this "latent" stage, forming biofilms in necrotic areas within which they temporarily hide. Thus some have proposed the term *persister* as more accurate to indicate the behavior of the bacilli in this phase. It is important to recognize that infection and disease represent not a binary state but rather a continuum along which infection will eventually move in the direction of full containment or disease. The ability to predict, through systemic biomarkers, which affected individuals will progress toward disease would be of immense value in devising prophylactic interventions at scale.

MACROPHAGE-ACTIVATING RESPONSE

Cell-mediated immunity is critical at this early stage. In the majority of infected individuals, local macrophages are activated when bacillary antigens processed by macrophages stimulate T lymphocytes to release a variety of lymphokines. These activated macrophages aggregate around the lesion's center and effectively neutralize tubercle bacilli without causing further tissue destruction. In the central part of the lesion, the necrotic material resembles soft cheese (*caseous necrosis*)—a phenomenon that may also be observed in other conditions, such as neoplasms. Even when healing takes place, viable bacilli may remain dormant within macrophages or in the necrotic material for many years. These "healed" lesions in the lung parenchyma and hilar lymph nodes may later undergo calcification.

DELAYED-TYPE HYPERSENSITIVITY

In a minority of cases, the macrophage-activating response is weak, and mycobacterial growth can be inhibited only by intensified delayed hypersensitivity reactions, which lead to lung tissue destruction. The lesion tends to enlarge further, and the surrounding tissue is

progressively damaged. At the center of the lesion, the caseous material liquefies. Bronchial walls and blood vessels are invaded and destroyed, and cavities are formed. The liquefied caseous material, containing large amount of bacilli, is drained through bronchi. Within the cavity, tubercle bacilli multiply, spill into the airways, and are discharged into the environment through expiratory maneuvers such as coughing and talking. In the early stages of infection, bacilli are usually transported by macrophages to regional lymph nodes, from which they gain access to the central venous return; from there they reseed the lungs and may also disseminate beyond the pulmonary vasculature throughout the body via the systemic circulation. The resulting extrapulmonary lesions may undergo the same evolution as those in the lungs, although most tend to heal. In young children with poor natural immunity, hematogenous dissemination may result in fatal miliary TB or tuberculous meningitis.

ROLE OF MACROPHAGES AND MONOCYTES

While cell-mediated immunity confers partial protection against *M. tuberculosis*, humoral immunity plays a less well-defined role in protection (although evidence is accumulating on the existence of antibodies to lipoarabinomannan, which may prevent dissemination of infection in children). In cell-mediated immunity, two types of cells are essential: macrophages, which directly phagocytose tubercle bacilli, and T cells (mainly CD4+ T lymphocytes, although the role of CD8+ T cells has recently been the subject of much research), which induce protection through the production of cytokines, especially IFN-γ. After infection with *M. tuberculosis*, alveolar macrophages secrete various cytokines responsible for a number of events (e.g., the formation of granulomas) as well as systemic effects (e.g., fever and weight loss). However, alternatively activated alveolar macrophages may be particularly susceptible to *M. tuberculosis* growth early on, given their more limited proinflammatory and bactericidal activity, which is related in part to being bathed in surfactant. New monocytes and macrophages attracted to the site are key components of the immune response. Their primary mechanism is probably related to production of oxidants (such as reactive oxygen intermediates or nitric oxide) that have antimycobacterial activity and increase the synthesis of cytokines such as TNF-α and IL-1, which in turn regulate the release of reactive oxygen intermediates and reactive nitrogen intermediates. In addition, macrophages can undergo apoptosis—a defensive mechanism to prevent the release of cytokines and bacilli via their sequestration in the apoptotic cell. Recent work also describes the involvement of neutrophils in the host response, although the timing of their appearance and their effectiveness remain uncertain.

ROLE OF T LYMPHOCYTES

Alveolar macrophages, monocytes, and dendritic cells are also critical in processing and presenting antigens to T lymphocytes, primarily CD4+ and CD8+ T cells; the result is the activation and proliferation of CD4+ T lymphocytes, which are crucial to the host's defense against *M. tuberculosis*. Qualitative and quantitative defects of CD4+ T cells explain the inability of HIV-infected individuals to contain mycobacterial proliferation. Activated CD4+ T lymphocytes can differentiate into cytokine-producing T_H1 or T_H2 cells. T_H1 cells produce IFN-γ—an activator of macrophages and monocytes—and IL-2. T_H2 cells produce IL-4, IL-5, IL-10, and IL-13 and may also promote humoral immunity. The interplay of these various cytokines and their cross-regulation determine the host's response. The role of cytokines in promoting intracellular killing of mycobacteria, however, has not been entirely elucidated. IFN-γ may induce the generation of reactive nitrogen intermediates and regulate genes involved in bactericidal effects. TNF-α is also important. Although its precise mechanisms are complex and not yet fully clarified, a model has been suggested that foresees an ideal setting for TNF-α between excessive activation—with consequent worsening of immunopathological reactions—and insufficient activation—with resulting lack of containment—in the control of TB infection. Observations made originally in transgenic knockout mice and more recently in humans suggest that other T-cell subsets, especially CD8+ T cells, may play an important role. CD8+ T cells have been associated with protective activities via cytotoxic responses and lysis of infected cells as well as with production of IFN-γ and TNF-α. Finally, natural killer cells act as co-regulators of CD8+ T-cell lytic activities, and γδ T cells are increasingly thought to be involved in protective responses in humans.

MYCOBACTERIAL LIPIDS AND PROTEINS

Lipids are involved in mycobacterial recognition by the innate immune system, and lipoproteins (such as 19-kDa lipoprotein) trigger potent signals through Toll-like receptors present in blood dendritic cells. *M. tuberculosis* possesses various protein antigens. Some are present in the cytoplasm and cell wall; others are secreted. That the latter are more important in eliciting a T lymphocyte response is suggested by experiments documenting the appearance of protective immunity in animals after immunization with live, protein-secreting mycobacteria. Among the antigens that may play a protective role are the 30-kDa (or 85B) and ESAT-6 antigens. Protective immunity is probably the result of reactivity to many different mycobacterial antigens. These antigens are being incorporated into newly designed vaccines on various platforms.

SKIN-TEST REACTIVITY

Coincident with the appearance of immunity, delayed-type hypersensitivity to *M. tuberculosis* develops. This reactivity is the basis of the TST, which is used primarily for the diagnosis of *M. tuberculosis* infection in persons without symptoms. The cellular mechanisms responsible for TST reactivity are related mainly to previously sensitized CD4+ T lymphocytes, which are attracted to the skin-test site. There, they proliferate and produce cytokines. Although delayed hypersensitivity is associated with protective immunity (TST-positive persons are less susceptible to a new *M. tuberculosis* infection than TST-negative persons), it by no means guarantees protection against reactivation. In fact, cases of active TB are often accompanied by strongly positive skin-test reactions. There is also evidence of reinfection with a new strain of *M. tuberculosis* in patients previously treated for active disease. This evidence underscores the fact that previous infection or active TB may not confer fully protective immunity.

CLINICAL MANIFESTATIONS

TB is classified as pulmonary, extrapulmonary, or both. Depending on several factors linked to host immunological status and bacterial strains, extrapulmonary TB may occur in 10–40% of patients. Furthermore, up to two-thirds of HIV-infected patients with TB may have both pulmonary and extrapulmonary TB or extrapulmonary TB alone.

PULMONARY TB

Pulmonary TB is conventionally categorized as primary or postprimary (adult-type, secondary). This distinction has been challenged by molecular evidence from TB-endemic areas indicating that a large percentage of cases of adult pulmonary TB result from recent infection (either primary infection or reinfection) and not from reactivation.

Primary Disease Primary pulmonary TB occurs soon after the initial infection. It may be asymptomatic or may present with fever and occasionally pleuritic chest pain. In areas of high TB transmission, this form of disease is often seen in children. Because most inspired air is distributed to the middle and lower lung zones, these areas are most commonly involved in primary TB. The lesion forming after initial infection (*Ghon focus*) is usually peripheral and accompanied by transient hilar or paratracheal lymphadenopathy, which may or may not be visible on standard chest radiography (CXR) **(Fig. 178-4)**. Some patients develop erythema nodosum on the legs **(see Fig. A1-39)** or phlyctenular conjunctivitis. In the majority of cases, the lesion heals spontaneously and becomes evident only as a small calcified nodule. Pleural reaction overlying a subpleural focus is also common. The Ghon focus, with or without overlying pleural reaction, thickening, and regional lymphadenopathy, is referred to as the *Ghon complex*.

In young children with immature cell-mediated immunity and in persons with impaired immunity (e.g., those with malnutrition or HIV infection), primary pulmonary TB may progress rapidly to clinical illness. The initial lesion increases in size and can evolve in different ways. Pleural effusion, which is found in up to two-thirds of cases,

FIGURE 178-4 Chest radiograph showing right hilar lymph node enlargement with infiltration into the surrounding lung tissue in a child with primary tuberculosis. *(Courtesy of Prof. Robert Gie, Department of Paediatrics and Child Health, Stellenbosch University, South Africa; with permission.)*

results from the penetration of bacilli into the pleural space from an adjacent subpleural focus. In severe cases, the primary site rapidly enlarges, its central portion undergoes necrosis, and cavitation develops (*progressive primary TB*). TB in young children is almost invariably accompanied by hilar or paratracheal lymphadenopathy due to the spread of bacilli from the lung parenchyma through lymphatic vessels. Enlarged lymph nodes may compress bronchi, causing total obstruction with distal collapse, partial obstruction with large-airway wheezing, or a ball-valve effect with segmental/lobar hyperinflation. Lymph nodes may also rupture into the airway with development of pneumonia, often including areas of necrosis and cavitation, distal to the obstruction. Bronchiectasis **(Chap. 290)** may develop in any segment/lobe damaged by progressive caseating pneumonia. Occult hematogenous dissemination commonly follows primary infection. However, in the absence of a sufficient acquired immune response, which usually contains the infection, disseminated or miliary disease may result **(Fig. 178-5)**. Small granulomatous lesions develop in multiple organs

FIGURE 178-5 Chest radiograph showing bilateral miliary (millet-sized) infiltrates in a child. *(Courtesy of Prof. Robert Gie, Department of Paediatrics and Child Health, Stellenbosch University, South Africa; with permission.)*

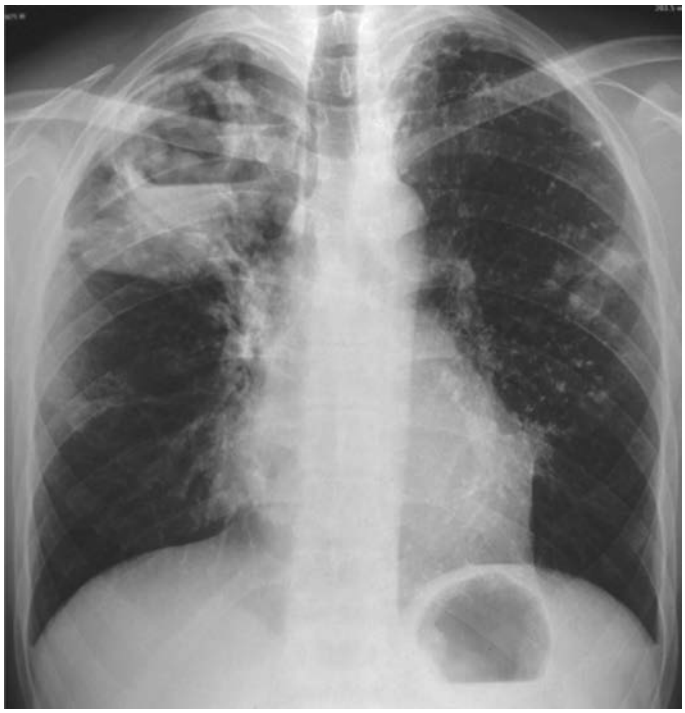

FIGURE 178-6 Chest radiograph showing a right-upper-lobe infiltrate and a cavity with an air-fluid level in a patient with active tuberculosis. *(Courtesy of Dr. Andrea Gori, Infectious Diseases Unit, Fondazione IRCCS Ca' Granda Ospediale Maggiore Policlinico, University of Milan, Milan, Italy; with permission.)*

and may cause locally progressive disease or result in tuberculous meningitis; this is a particular concern in very young children and immunocompromised persons (e.g., patients with HIV infection).

Postprimary (Adult-Type) Disease Also referred to as *reactivation* or *secondary TB*, postprimary TB is probably most accurately termed *adult-type TB* because it may result from endogenous reactivation of distant or recent infection (primary infection or reinfection). It is usually localized to the apical and posterior segments of the upper lobes, where the substantially higher mean oxygen tension (compared with that in the lower zones) favors mycobacterial growth. The superior segments of the lower lobes are also frequently involved. The extent of lung parenchymal involvement varies greatly, from small infiltrates to extensive cavitary disease. With cavity formation, liquefied necrotic contents are ultimately discharged into the airways and may undergo bronchogenic spread, resulting in satellite lesions within the lungs that may in turn undergo cavitation **(Figs. 178-6 and 178-7)**. Massive involvement of pulmonary segments or lobes,

FIGURE 178-7 CT scan showing a large cavity in the right lung of a patient with active tuberculosis. *(Courtesy of Dr. Elisa Busi Rizzi, National Institute for Infectious Diseases, Spallanzani Hospital, Rome, Italy; with permission.)*

with coalescence of lesions, produces caseating pneumonia. While up to one-third of untreated patients reportedly succumb to severe pulmonary TB within a few months after onset (the classic "galloping consumption" of the past), others may undergo a process of spontaneous remission or proceed along a chronic, progressively debilitating course ("consumption" or *phthisis*). Under these circumstances, some pulmonary lesions become fibrotic and may later calcify, but cavities persist in other parts of the lungs. Individuals with such chronic disease continue to discharge tubercle bacilli into the environment. Most patients respond to treatment, with defervescence, decreasing cough, weight gain, and a general improvement in well-being within several weeks.

Early in the course of disease, symptoms and signs are often nonspecific and insidious, consisting mainly of fever, often diurnal and night sweats due to defervescence, weight loss, anorexia, general malaise, and weakness. However, in up to 90% of cases, cough eventually develops—often initially nonproductive and limited to the morning and subsequently accompanied by the production of purulent sputum, sometimes with blood streaking. Hemoptysis develops in 20–30% of cases, and massive hemoptysis may ensue as a consequence of the erosion of a blood vessel in the wall of a cavity. Hemoptysis, however, may also result from rupture of a dilated vessel in a cavity (*Rasmussen's aneurysm*) or from aspergilloma formation in an old cavity. Pleuritic chest pain sometimes develops in patients with subpleural parenchymal lesions or pleural disease. Extensive disease may produce dyspnea and, in rare instances, adult respiratory distress syndrome. Physical findings are of limited use in pulmonary TB. Many patients have no abnormalities detectable by chest examination, whereas others have detectable rales in the involved areas during inspiration, especially after coughing. Occasionally, rhonchi due to partial bronchial obstruction and classic amphoric breath sounds in areas with large cavities may be heard. Systemic features include fever (often low-grade and intermittent) in up to 80% of cases and wasting. Absence of fever, however, does not exclude TB. In some recurrent cases and among people with low Karnofsky score, finger clubbing has been reported. The most common hematologic findings are mild anemia, leukocytosis, and thrombocytosis with a slightly elevated erythrocyte sedimentation rate and/or C-reactive protein level. None of these findings is consistent or sufficiently accurate for diagnostic purposes. Hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone has also been reported.

EXTRAPULMONARY TB

In descending order of frequency, the extrapulmonary sites most commonly involved in TB are the lymph nodes, pleura, genitourinary tract, bones and joints, meninges, peritoneum, and pericardium. However, virtually any organ system may be affected. As a result of hematogenous dissemination in HIV-infected individuals, extrapulmonary TB is seen more commonly today than in the past in settings of high HIV prevalence.

Lymph Node TB (Tuberculous Lymphadenitis) The most common presentation of extrapulmonary TB in both HIV-seronegative individuals and HIV-infected patients (35% of cases worldwide and >40% of cases in the United States in recent series), lymph node disease is particularly frequent among HIV-infected patients and among children **(Fig. 178-8)**. In the United States, besides children, women (particularly non-Caucasians) seem to be especially susceptible. Once caused mainly by *M. bovis*, tuberculous lymphadenitis today is due largely to *M. tuberculosis*. Lymph node TB presents as painless swelling of the lymph nodes, most commonly at posterior cervical and supraclavicular sites (a condition historically referred to as *scrofula*). Lymph nodes are usually discrete in early disease but develop into a matted nontender mass over time; a fistulous tract draining caseous material may result. Associated pulmonary disease is present in fewer than 50% of cases, and systemic symptoms are uncommon except in HIV-infected patients. The diagnosis is established by fine-needle aspiration biopsy (with a yield of up to 80%) or surgical excision biopsy. Bacteriologic confirmation is achieved in the vast majority of cases,

FIGURE 178-8 Tuberculous lymphadenitis affecting the cervical lymph nodes in a 2-year-old child from Malawi. *(Courtesy of Prof. S. Graham, Centre for International Child Health, University of Melbourne, Australia; with permission.)*

granulomatous lesions with or without visible AFBs are typically seen, and cultures are positive in 70–80% of cases. Among HIV-infected patients, granulomas are less well organized and are frequently absent entirely, but bacterial loads are heavier than in HIV-seronegative patients, with higher yields from microscopy and culture. Differential diagnosis includes a variety of infectious conditions, neoplastic diseases such as lymphomas or metastatic carcinomas, and rare disorders like Kikuchi's disease (necrotizing histiocytic lymphadenitis), Kimura's disease, and Castleman's disease.

Pleural TB Involvement of the pleura accounts for ~20% of extrapulmonary cases in the United States and elsewhere. Isolated pleural effusion usually reflects recent primary infection, and the collection of fluid in the pleural space represents a hypersensitivity response to mycobacterial antigens. Pleural disease may also result from contiguous parenchymal spread, as in many cases of pleurisy accompanying postprimary disease. Depending on the extent of reactivity, the effusion may be small, remain unnoticed, and resolve spontaneously or may be sufficiently large to cause symptoms such as fever, pleuritic chest pain, and dyspnea. Physical findings are those of pleural effusion: dullness to percussion and absence of breath sounds. CXR reveals the effusion and, in up to one-third of cases, also shows a parenchymal lesion. Thoracentesis is required to ascertain the nature of the effusion and to differentiate it from manifestations of other etiologies. The fluid is straw-colored and at times hemorrhagic; it is an exudate with a protein concentration >50% of that in serum (usually ~4–6 g/dL), a normal to low glucose concentration, a pH of ~7.3 (occasionally <7.2), and detectable white blood cells (usually 500–6000/μL). Neutrophils may predominate in the early stage, but lymphocyte predominance is the typical finding later. Mesothelial cells are generally rare or absent. AFBs are rarely seen on direct smear, and cultures often may be falsely negative for *M. tuberculosis*; positive cultures are more common among postprimary cases. Determination of the pleural concentration of adenosine deaminase may be a useful screening test, and TB may be excluded if the value is very low. Lysozyme is also present in the pleural effusion. Measurement of IFN-γ, either directly or through stimulation of sensitized T cells with mycobacterial antigens, can be diagnostically helpful. Needle biopsy of the pleura is often required for diagnosis and is recommended over pleural fluid analysis; it reveals granulomas and/or yields a positive culture in up to 80% of cases. Pleural biopsy can yield a positive result in ~75% of cases when real-time automated nucleic acid amplification is used (the Xpert MTB/RIF assay [Cepheid; Sunnyvale, CA]; see "Nucleic Acid Amplification Technology," below); testing of pleural fluid with this assay is not recommended because of low sensitivity. This form of pleural TB responds rapidly to chemotherapy and may resolve spontaneously. Concurrent glucocorticoid

administration may reduce the duration of fever and/or chest pain but is not of proven benefit.

Tuberculous empyema is a less common complication of pulmonary TB. It is usually the result of the rupture of a cavity, with spillage of a large number of organisms into the pleural space. This process may create a bronchopleural fistula with evident air in the pleural space. CXR shows hydropneumothorax with an air-fluid level. The pleural fluid is purulent and thick and contains large numbers of lymphocytes. Acid-fast smears and mycobacterial cultures are often positive. Surgical drainage is usually required as an adjunct to chemotherapy. Tuberculous empyema may result in severe pleural fibrosis and restrictive lung disease. Removal of the thickened visceral pleura (*decortication*) is occasionally necessary to improve lung function.

TB of the Upper Airways Nearly always a complication of advanced cavitary pulmonary TB, TB of the upper airways may involve the larynx, pharynx, and epiglottis. Symptoms include hoarseness, dysphonia, and dysphagia in addition to chronic productive cough. Findings depend on the site of involvement, and ulcerations may be seen on laryngoscopy. Acid-fast smear of the sputum is often positive, but biopsy may be necessary in some cases to establish the diagnosis. Carcinoma of the larynx may have similar features but is usually painless.

Genitourinary TB Genitourinary TB, which accounts for ~10–15% of all extrapulmonary cases in the United States and elsewhere, may involve any portion of the genitourinary tract. Clinical manifestations are cryptic and protean. Patients may be asymptomatic and their disease discovered only after destructive lesions of the kidneys have developed. Symptoms are often nonspecific, and include those of urinary tract infection with frequency, dysuria, nocturia and hematuria, and abdominal or flank pain. Without a high index of suspicion, this form of TB may result in delayed diagnosis with irreversible organ damage. Up to 75% of patients have abnormalities on CXR suggesting previous or concomitant pulmonary disease. Urinalysis gives abnormal results in 90% of cases, revealing pyuria and hematuria. The documentation of culture-negative pyuria in acidic urine should raise the suspicion of TB. IV pyelography, abdominal CT, or MRI **(Fig. 178-9)** may show deformities and obstructions; calcifications and ureteral strictures are suggestive findings. Culture of three morning urine specimens yields a definitive diagnosis in nearly 90% of cases. Severe ureteral strictures may lead to hydronephrosis, serious renal damage, and, ultimately, renal failure. Genital TB is diagnosed more commonly in female than in male patients. In female patients, it affects the fallopian tubes and the endometrium and may cause infertility, pelvic pain, and menstrual abnormalities. Diagnosis requires biopsy or culture of specimens obtained by dilation and curettage. In male patients, genital TB preferentially affects the epididymis, producing a slightly tender mass that may drain externally through a fistulous tract; orchitis and prostatitis may also develop. In almost half of cases of genitourinary TB, urinary tract disease is also present. Genitourinary TB responds well to chemotherapy.

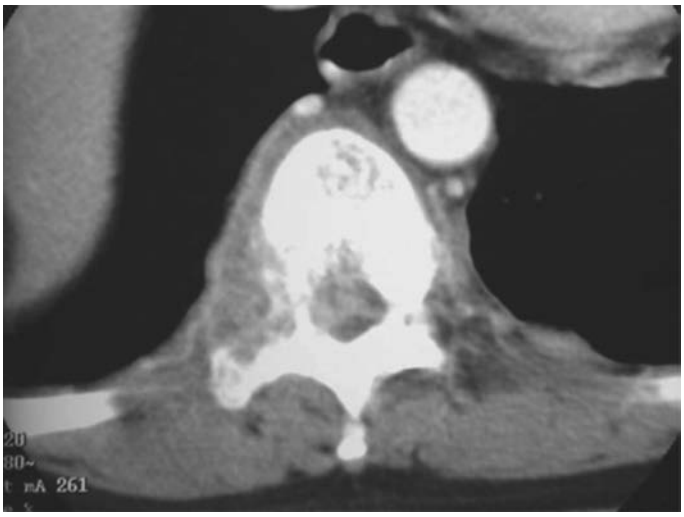

FIGURE 178-10 CT scan demonstrating destruction of the right pedicle of T10 due to Pott's disease. The patient, a 70-year-old Asian woman, presented with back pain and weight loss and had biopsy-proven tuberculosis. *(Courtesy of Charles L. Daley, MD, University of California, San Francisco; with permission.)*

Skeletal TB In the United States, TB of the bones and joints is responsible for ~10% of extrapulmonary cases. In bone and joint disease, pathogenesis is related to reactivation of hematogenous foci or to spread from adjacent paravertebral lymph nodes. Weight-bearing joints (the spine in 40% of cases, the hips in 13%, and the knees in 10%) are most commonly affected. Spinal TB (Pott's disease or tuberculous spondylitis; **Fig. 178-10**) often involves two or more adjacent vertebral bodies. Whereas the upper thoracic spine is the most common site of spinal TB in children, the lower thoracic and upper lumbar vertebrae are usually affected in adults. From the anterior superior or inferior angle of the vertebral body, the lesion slowly reaches the adjacent body, later affecting the intervertebral disk. With advanced disease, collapse of vertebral bodies results in kyphosis (*gibbus*). A paravertebral "cold" abscess may also form. In the upper spine, this abscess may track to and penetrate the chest wall, presenting as a soft tissue mass; in the lower spine, it may reach the inguinal ligaments or present as a psoas abscess. CT or MRI reveals the characteristic lesion and suggests its etiology. The differential diagnosis includes tumors and other infections. Pyogenic bacterial osteomyelitis, in particular, involves the disk very early and produces rapid sclerosis. Aspiration of the abscess or bone biopsy confirms the tuberculous etiology, as cultures are usually positive and histologic findings highly typical. A catastrophic complication of Pott's disease is paraplegia, which is usually due to an abscess or a lesion compressing the spinal cord. Paraparesis due to a large abscess is a medical emergency and requires rapid drainage. TB of the hip joints, usually involving the head of the femur, causes pain; TB of the knee produces pain and swelling. If the disease goes unrecognized, the joints may be destroyed. Diagnosis requires examination of the synovial fluid, which is thick in appearance, with a high protein concentration and a variable cell count. Although synovial fluid culture is positive in a high percentage of cases, synovial biopsy and tissue culture may be necessary to establish the diagnosis. Skeletal TB responds to chemotherapy, but severe cases may require surgery.

Tuberculous Meningitis and Tuberculoma TB of the central nervous system (CNS) accounts for ~5% of extrapulmonary cases in

the United States. It is seen most often in young children but also develops in adults, especially those infected with HIV. Tuberculous meningitis results from the hematogenous spread of primary or postprimary pulmonary TB or from the rupture of a subependymal tubercle into the subarachnoid space. In more than half of cases, evidence of old pulmonary lesions or a miliary pattern is found on CXR. The disease often presents subtly as headache and slight mental changes after a prodrome of weeks of low-grade fever, malaise, anorexia, and irritability. If not recognized, tuberculous meningitis may evolve acutely with severe headache, confusion, lethargy, altered sensorium, and neck rigidity. Typically, the disease evolves over 1–2 weeks, a course longer than that of bacterial meningitis. Because meningeal involvement is pronounced at the base of the brain, paresis of cranial nerves (ocular nerves in particular) is a frequent finding, and the involvement of cerebral arteries may produce focal ischemia. The ultimate evolution is toward coma, with hydrocephalus and intracranial hypertension.

Lumbar puncture is the cornerstone of diagnosis. In general, examination of cerebrospinal fluid (CSF) reveals a high leukocyte count (up to 1000/μL), usually with a predominance of lymphocytes but sometimes with a predominance of neutrophils in the early stage; a protein content of 1–8 g/L (100–800 mg/dL); and a low glucose concentration. However, any of these three parameters can be within the normal range. AFBs are infrequently seen on direct smear of CSF sediment, and repeated lumbar punctures increase the yield. Culture of CSF is diagnostic in up to 80% of cases and remains the gold standard. Real-time automated nucleic acid amplification (the Xpert MTB/RIF assay) has a sensitivity of up to 80% and is the preferred initial diagnostic option. Treatment should be initiated immediately upon a positive Xpert MTB/RIF result. A negative result does not exclude a diagnosis of TB and requires further diagnostic workup. Imaging studies (CT and MRI) may show hydrocephalus and abnormal enhancement of basal cisterns or ependyma. If unrecognized, tuberculous meningitis is uniformly fatal. This disease responds to chemotherapy; however, neurologic sequelae are documented in 25% of treated cases, in most of which the diagnosis has been delayed. Clinical trials have demonstrated that patients given adjunctive glucocorticoids may experience faster resolution of CSF abnormalities and elevated CSF pressure, resulting in lower rates of death or severe disability and relapse. In one study, adjunctive dexamethasone significantly enhanced the chances of survival among persons >14 years of age but did not reduce the frequency of neurologic sequelae. The dexamethasone schedule was (1) 0.4 mg/kg per day given IV with tapering by 0.1 mg/kg per week until the fourth week, when 0.1 mg/kg per day was administered; followed by (2) 4 mg/d given by mouth with tapering by 1 mg per week until the fourth week, when 1 mg/d was administered. The WHO now recommends that adjuvant glucocorticoid therapy with either dexamethasone or prednisolone, tapered over 6–8 weeks, should be used in CNS TB.

Tuberculoma, an uncommon manifestation of TB of the CNS, presents as one or more space-occupying lesions and usually causes seizures and focal signs. CT or MRI reveals contrast-enhanced ring lesions, but biopsy is necessary to establish the diagnosis.

Gastrointestinal TB Gastrointestinal TB is uncommon, making up only 3.5% of extrapulmonary cases in the United States. Various pathogenetic mechanisms are involved: swallowing of sputum with direct seeding, hematogenous spread, or (largely in developing areas) ingestion of milk from cows affected by bovine TB. Although any portion of the gastrointestinal tract may be affected, the terminal ileum and the cecum are the sites most commonly involved. Abdominal pain (at times similar to that associated with appendicitis) and swelling, obstruction, hematochezia, and a palpable mass in the abdomen are common findings at presentation. Fever, weight loss, anorexia, and night sweats are also common. With intestinal wall involvement, ulcerations and fistulae may simulate Crohn's disease; the differential diagnosis of this entity is always difficult. Anal fistulae should prompt an evaluation for rectal TB. Because surgery is required in most cases, the diagnosis can be established by histologic examination and culture of specimens obtained intraoperatively.

Tuberculous peritonitis follows either the direct spread of tubercle bacilli from ruptured lymph nodes and intraabdominal organs (e.g., genital TB in women) or hematogenous seeding. Nonspecific abdominal pain, fever, and ascites should raise the suspicion of tuberculous peritonitis. The coexistence of cirrhosis (Chap. 342) in patients with tuberculous peritonitis complicates the diagnosis. In tuberculous peritonitis, paracentesis reveals an exudative fluid with a high protein content and leukocytosis that is usually lymphocytic (although neutrophils occasionally predominate). The yield of direct smear and culture is relatively low; culture of a large volume of ascitic fluid can increase the yield, but peritoneal biopsy (with a specimen best obtained by laparoscopy) is often needed to establish the diagnosis.

Pericardial TB (Tuberculous Pericarditis) Due either to direct extension from adjacent mediastinal or hilar lymph nodes or to hematogenous spread, pericardial TB has often been a disease of the elderly in countries with low TB prevalence. However, it also develops frequently in HIV-infected patients. Case–fatality rates are as high as 40% in some series. The onset may be subacute, although an acute presentation, with dyspnea, fever, dull retrosternal pain, and a pericardial friction rub, is possible. An effusion eventually develops in many cases; cardiovascular symptoms and signs of cardiac tamponade may ultimately appear (Chap. 270). In the presence of effusion, TB must be suspected if the patient belongs to a high-risk population (HIV-infected, originating in a high-prevalence country); if there is evidence of previous TB in other organs; or if echocardiography, CT, or MRI shows effusion and thickness across the pericardial space. A definitive diagnosis can be obtained by pericardiocentesis under echocardiographic guidance. The pericardial fluid must be submitted for biochemical, cytologic, and microbiologic evaluation. The effusion is exudative in nature, with a high count of lymphocytes and monocytes. Hemorrhagic effusion is common. Direct smear examination is very rarely positive. Culture of pericardial fluid reveals *M. tuberculosis* in up to two-thirds of cases, whereas pericardial biopsy has a higher yield. High levels of adenosine deaminase, lysozyme, and IFN-γ may suggest a tuberculous etiology.

Without treatment, pericardial TB is usually fatal. Even with treatment, complications may develop, including chronic constrictive pericarditis with thickening of the pericardium, fibrosis, and sometimes calcification, which may be visible on a chest radiograph. Systematic reviews and meta-analyses show a trend toward benefit from glucocorticoid treatment with regard to death and constrictive pericarditis. However, the largest and most recent study—the IMPI study—failed to show such a benefit. Of the patients enrolled in this trial, 67% were infected with HIV, and only a fraction were receiving antiretroviral treatment (ART). A supplemental analysis among HIV-negative people showed a small mortality benefit, as did another small study among HIV-infected people. The WHO currently recommends that, in patients with tuberculous pericarditis, initial adjuvant glucocorticoid therapy may be used. The 2016 guidelines of the American Thoracic Society (ATS), the CDC, and the Infectious Diseases Society of America (IDSA), on the other hand, suggest that glucocorticoid therapy should not be routinely administered.

Caused by direct extension from the pericardium or by retrograde lymphatic extension from affected mediastinal lymph nodes, tuberculous myocarditis is an extremely rare disease. Usually, it is fatal and is diagnosed postmortem.

Miliary or Disseminated TB Miliary TB is due to hematogenous spread of tubercle bacilli. Although in children it is often the consequence of primary infection, in adults it may be due to either recent infection or reactivation of old disseminated foci. The lesions are usually yellowish granulomas 1–2 mm in diameter that resemble millet seeds (thus the term *miliary*, coined by nineteenth-century pathologists). Clinical manifestations are nonspecific and protean, depending on the predominant site of involvement. Fever, night sweats, anorexia, weakness, and weight loss are presenting symptoms in the majority of cases. At times, patients have a cough and other respiratory symptoms due to pulmonary involvement as well as abdominal symptoms.

Physical findings include hepatomegaly, splenomegaly, and lymphadenopathy. Eye examination may reveal choroidal tubercles, which are pathognomonic of miliary TB, in up to 30% of cases. Meningismus occurs in fewer than 10% of cases.

A high index of suspicion is required for the diagnosis of miliary TB. Frequently, CXR (Fig. 178-5) reveals a miliary reticulonodular pattern (more easily seen on underpenetrated film), although no radiographic abnormality may be evident early in the course and among HIV-infected patients. Other radiologic findings include large infiltrates, interstitial infiltrates (especially in HIV-infected patients), and pleural effusion. Sputum-smear microscopy is negative in most cases. Various hematologic abnormalities may be seen, including anemia with leukopenia, lymphopenia, neutrophilic leukocytosis and leukemoid reactions, and polycythemia. Disseminated intravascular coagulation has been reported. Elevation of alkaline phosphatase levels and other abnormal values in liver function tests are detected in patients with severe hepatic involvement. TST results may be negative in up to half of cases, but reactivity may be restored during chemotherapy. Bronchoalveolar lavage and transbronchial biopsy are more likely to provide bacteriologic confirmation, and granulomas are evident in liver or bone-marrow biopsy specimens from many patients. If it goes unrecognized, miliary TB is lethal; with proper early treatment, however, it is amenable to cure. Glucocorticoid therapy has not proved beneficial.

A rare presentation seen in the elderly, *cryptic miliary TB* has a chronic course characterized by mild intermittent fever, anemia, and—ultimately—meningeal involvement preceding death. An acute septicemic form, *nonreactive miliary TB*, occurs very rarely and is due to massive hematogenous dissemination of tubercle bacilli. Pancytopenia is common in this form of disease, which is rapidly fatal. At postmortem examination, multiple necrotic but nongranulomatous ("nonreactive") lesions are detected.

Less Common Extrapulmonary Forms TB may cause chorioretinitis, uveitis, panophthalmitis, and painful hypersensitivity-related phlyctenular conjunctivitis. Tuberculous otitis is rare and presents as hearing loss, otorrhea, and tympanic membrane perforation. In the nasopharynx, TB may simulate granulomatosis with polyangiitis. Cutaneous manifestations of TB include primary infection due to direct inoculation, abscesses and chronic ulcers, scrofuloderma, lupus vulgaris (a smoldering disease with nodules, plaques, and fissures), miliary lesions, and erythema nodosum. Tuberculous mastitis results from retrograde lymphatic spread, often from the axillary lymph nodes. Adrenal TB is a manifestation of disseminated disease presenting rarely as adrenal insufficiency. Finally, congenital TB results from transplacental spread of tubercle bacilli to the fetus or from ingestion of contaminated amniotic fluid. This rare disease affects the liver, spleen, lymph nodes, and various other organs.

Post-TB Complications TB may cause persisting pulmonary damage in patients whose infection has been considered cured on clinical grounds. Chronic impairment of lung functions, bronchiectasis, aspergillomas, and chronic pulmonary aspergillosis **(Chap. 217)** have been associated with TB. Chronic pulmonary aspergillosis may manifest as simple aspergilloma (fungal ball) or chronic cavitary aspergillosis. Early studies revealed that, especially in the presence of large residual cavities, *Aspergillus fumigatus* may colonize the lesion and produce symptoms such as respiratory impairment, hemoptysis, persistent fatigue, and weight loss, often resulting in the erroneous diagnosis of TB recurrence. The detection of *Aspergillus* precipitins (IgG) in the blood suggests chronic pulmonary aspergillosis, as do radiographic abnormalities such as thickening of the pleura and cavitary walls or the presence of a fungal ball inside the cavity. Treatment is difficult. Recent preliminary studies on the use of itraconazole for ≥6 months indicate improvement or stabilization of 60–75% of the radiologic and clinical manifestations. Surgical removal of lesions is risky except in simple aspergilloma.

HIV-Associated TB (See also Chap. 202) TB is one of the most common diseases among HIV-infected persons worldwide. Responsible for up to 30% of all HIV-related mortality (208,000 deaths per year), TB is likely the main cause of death in this population. In certain urban settings in some African countries, the prevalence of HIV infection among TB patients reaches 70–80% **(Fig. 178-11)**.

A person with a positive TST who acquires HIV infection has a 3–13% annual risk of developing active TB, with the exact risk depending on the degree of immunosuppression when observation begins. Furthermore, a new TB infection acquired by an HIV-infected individual may evolve into active disease in a matter of weeks rather

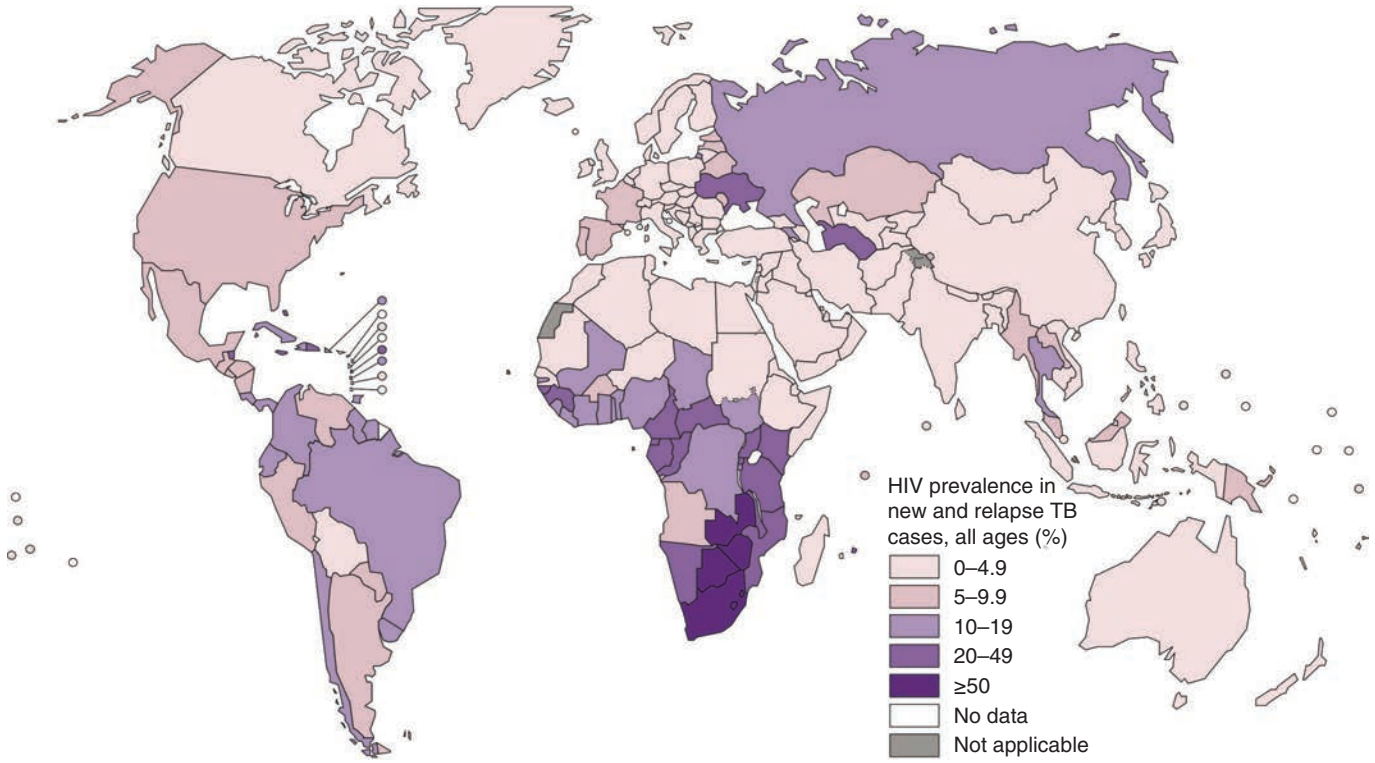

FIGURE 178-11 Estimated HIV prevalence in new and relapse tuberculosis (TB) cases in 2018. *(See disclaimer in Fig. 178-2. Reproduced with permission from Global Tuberculosis Report 2019. Geneva, World Health Organization; 2019.)*

than months or years. TB can appear at any stage of HIV infection, and its presentation varies with the stage. When cell-mediated immunity is only partially compromised, pulmonary TB presents in a typical manner (Figs. 178-6 and 178-7), with upper-lobe infiltrates and cavitation and without significant lymphadenopathy or pleural effusion. In late stages of HIV infection, when the CD4+ T-cell count is <200/μL, a primary TB–like pattern, with diffuse interstitial and subtle infiltrates, little or no cavitation, pleural effusion, and intrathoracic lymphadenopathy, is more common. However, these forms are becoming less common because of the expanded use of ART. Overall, sputum smears are less frequently positive among TB patients with HIV infection than among those without; thus the diagnosis of TB with traditional technology may be difficult, especially in view of the variety of HIV-related pulmonary conditions mimicking TB. Extrapulmonary TB is common among HIV-infected patients. In various series, extrapulmonary TB—alone or in association with pulmonary disease—has been documented in 40–60% of all cases in individuals co-infected with HIV. The most common forms are lymphatic, disseminated, pleural, and pericardial. Mycobacteremia and meningitis are also common, particularly in advanced HIV disease. The diagnosis of TB in HIV-infected patients may be complicated not only by the increased frequency of sputum-smear negativity (up to 40% in culture-proven pulmonary cases) but also by atypical radiographic findings, a lack of classic granuloma formation in the late stages, and a negative TST. The Xpert MTB/RIF assay is the preferred initial diagnostic option for pulmonary TB ensuring a sensitivity of 81% and a specificity of 98%, and therapy should be started on the basis of a positive result because treatment delays may be fatal. A negative Xpert MTB/RIF result, however, does not exclude a diagnosis of TB. Culture remains the gold standard. Recent assessment of a test based on the detection of mycobacterial lipoarabinomannan antigen in urine has shown favorable results in assisting with the detection of TB in HIV-positive people (see "Additional Diagnostic Procedures," below).

The *immune reconstitution inflammatory syndrome* (*IRIS*) or *TB immune reconstitution disease* consists of exacerbations in systemic manifestations (lymphadenopathy, fever) or respiratory signs (worsening of pulmonary infiltrations, pleural effusion) as well as laboratory or radiographic manifestations of TB. This syndrome has been associated with the administration of ART and occurs in ~10% of HIV-infected TB patients. Usually developing 1–3 months after initiation of ART, IRIS is more common among patients with advanced immunosuppression and extrapulmonary TB. "Unmasking IRIS" may develop after the initiation of ART in patients with undiagnosed subclinical TB. The earlier ART is started and the lower the baseline CD4+ T-cell count, the greater the risk of IRIS. Death due to IRIS is relatively infrequent and occurs mainly among patients who have a high preexisting mortality risk. The presumed pathogenesis of IRIS consists of an immune response that is elicited by antigens released as bacilli are killed during effective chemotherapy and that is temporally associated with improving immune function. There is no diagnostic test for IRIS, and its confirmation relies heavily upon case definitions incorporating clinical and laboratory data; a variety of case definitions have been suggested. The first priority in the management of a possible case of IRIS is to ensure that the clinical syndrome does not represent a failure of TB treatment or the development of another infection. Mild paradoxical reactions can be managed with symptom-based treatment and do not worsen outcomes of treatment for TB. However, IRIS can result in serious neurologic complications or death in patients with CNS TB. Therefore, ART should not be initiated during the first 8 weeks of TB treatment in patients with TB meningitis. Glucocorticoids have been used for severe paradoxical reactions; prednisolone given for 4 weeks at a low dosage (1.5 mg/kg per day for 2 weeks and half that dose for the remaining 2 weeks) has reduced the need for hospitalization and therapeutic procedures and has hastened alleviation of symptoms, as reflected by Karnofsky performance scores, quality-of-life assessments, radiographic response, and C-reactive protein levels. The effectiveness of glucocorticoids in alleviating the symptoms of IRIS is probably linked to suppression of proinflammatory cytokine concentrations as these medications reduce serum concentrations of IL-6, IL-10, IL-12p40, TNF-α, IFN-γ, and IFN-γ-inducible protein 10. Recommendations for the prevention and treatment of TB in HIV-infected individuals are provided below.

DIAGNOSIS

The key to the early diagnosis of TB is a high index of suspicion. Diagnosis is not difficult in persons belonging to high-risk populations who present with typical symptoms and a classic chest radiograph showing upper-lobe infiltrates with cavities (Fig. 178-6). On the other hand, the diagnosis can easily be missed in an elderly nursing-home resident or a teenager with a focal infiltrate. Often, the diagnosis is first entertained when the chest radiograph of a patient being evaluated for respiratory symptoms is abnormal. If the patient has no complicating medical conditions that cause immunosuppression, the chest radiograph may show typical upper-lobe infiltrates with cavitation (Fig. 178-6). The longer the delay between the onset of symptoms and the diagnosis, the more likely is the finding of cavitary disease. In contrast, immunosuppressed patients, including those with HIV co-infection, may have "atypical" findings on CXR—e.g., lower-zone infiltrates without cavity formation—or interstitial disease only.

The several approaches to the diagnosis of TB require, above all, a well-organized microbiology laboratory network with an appropriate distribution of tasks at different levels of the health care system. Besides clinical assessment and radiography, screening and referral are the principal tasks at the peripheral and community levels. Diagnosis at a secondary level (e.g., a traditional district hospital in a high-incidence setting) can be accomplished nowadays through real-time automated nucleic acid amplification technology (e.g., the Xpert MTB/RIF assay, which also allows detection of drug resistance) or through traditional AFB microscopy, where new tools have not yet been introduced. At a tertiary level, additional technology is necessary, including molecular tests, rapid culture, and DST.

NUCLEIC ACID AMPLIFICATION TECHNOLOGY

Several test systems based on amplification of mycobacterial nucleic acid have become available in the past few years and are now the preferred first-line diagnostic tests. These tests are progressively replacing smear microscopy, as they ensure rapid confirmation of all types of TB. One system that permits rapid diagnosis of TB with high specificity and sensitivity (approaching that of liquid culture) is the fully automated, real-time nucleic acid amplification technology known as the Xpert MTB/RIF assay. Xpert MTB/RIF can simultaneously detect TB and rifampin resistance in <2 h and has minimal biosafety and training requirements. Therefore, it can be housed in nonconventional laboratory settings as long as a stable and uninterrupted power supply can be assured. The WHO recommends its use worldwide as the first-line diagnostic test in all adults and children with signs or symptoms of active TB. Given the test's high sensitivity, the WHO also recommends its use as the initial diagnostic test for people living with HIV in whom TB is suspected. In the diagnosis of pulmonary TB, this test has an overall sensitivity of 85% reaching 98% among AFB-positive cases and ~70% among AFB-negative specimens; its specificity is 98%. When compared to phenotypic drug susceptibility testing for simultaneous detection of rifampin resistance, Xpert MTB/RIF has an overall sensitivity of 96% and a specificity of 98%. The newer Xpert MTB/RIF Ultra assay (Ultra), which uses the same GeneXpert diagnostic platform, has an overall sensitivity of 90% including "trace calls" (i.e., the "noise" produced by detection of DNA from nonviable bacilli) as positive with the greatest increases among smear-negative, culture-positive cases (+17%) and among HIV-infected persons (+12%). If "trace calls" are excluded, sensitivity decreases to 86%. Because of this greater sensitivity and the capacity to also detect nonviable bacilli, the new Ultra cartridge has 2% lower specificity than the original test. However, excluding "trace calls," specificity increases to 98%. Among people with HIV co-infection, Ultra sensitivity is 88% and specificity 95%. Sensitivity and specificity for detection of rifampin resistance by Ultra are 94% and 99%, respectively, similar to those by the Xpert MTB/RIF assay.

In the diagnosis of extrapulmonary TB, Xpert MTB/RIF and Ultra should be the initial test applied to CSF from patients in whom TB

meningitis is suspected as well as a replacement test (preferable to conventional microscopy, culture, and histopathology) for selected nonrespiratory specimens—those obtained by gastric lavage, fine-needle aspiration, or pleural or other biopsies. Sensitivity varies according to specimen type being the lowest in pleural fluid (50% with Xpert MTB/RIF and 71% with Ultra) and the highest in synovial fluid (97%) and lymph node biopsy (100% with Ultra). "Trace calls" in specimens from persons with extrapulmonary TB, as well as for HIV-infected patients and children, should be considered true positives, given the high risk of severe morbidity and premature death, while among other cases they warrant additional tests to confirm the diagnosis of TB and prevent overtreatment. Among patients with a recent history of TB, "trace calls" may represent false positivity due to DNA from dead bacilli under degradation.

Truenat MTB and MTC Plus are two newly introduced rapid molecular tests with a sensitivity of 83% and 89%, respectively, if compared to bacteriological culture, and with specificity of 98% and 99%, respectively. Truenat MTB-Rif Dx detects rifampin resistance with a sensitivity of 93% and a specificity of 95%. These rapid tests, developed in India by MolBio Diagnostics Pvt Ltd Goa, have accuracy comparable to that of Xpert MTB/RIF and Ultra. Being portable and battery-operated, they can be used in the most peripheral care settings. New high-throughput automated platforms for TB diagnosis and drug-resistant variants are becoming available (Abbott RealTime MTB and RIF/INH, FluoroType MTBDR, BD Max MDR-TB). These platforms are suitable for centralized laboratories and have the advantage of processing a large number of samples in a reasonable time. Sensitivity is higher than 91% and specificity ranges from 97 to 100%. Head-to-head studies with Xpert MTB/RIF have shown comparable performance. Another available molecular test for detection of *M. tuberculosis* is based on the loop-mediated isothermal amplification (LAMP) temperature-independent technology that amplifies DNA, is relatively simple to use, and is interpreted through a visual display. The TB-LAMP assay (LoopampTM *M. tuberculosis* complex detection kit; Eiken Chemical Company, Japan) requires minimal laboratory infrastructure and has few biosafety requirements. It may be used as a replacement for sputum-smear microscopy for the diagnosis of adult pulmonary TB and as a follow-up test to smear microscopy for the further investigation of smear-negative specimens from adults with suspected pulmonary TB. The TB-LAMP assay should not replace rapid molecular tests that detect both TB and rifampin resistance, and its usefulness in HIV-infected people in whom TB is suspected remains unclear.

AFB MICROSCOPY

In many low- and middle-income settings, a presumptive diagnosis is still commonly based on the finding of AFB on microscopic examination of a diagnostic specimen, such as a smear of expectorated sputum or of tissue (e.g., a lymph node biopsy). Although inexpensive, AFB microscopy has relatively low sensitivity (40–60%) in culture-confirmed cases of pulmonary TB. The traditional method—light microscopy of specimens stained with Ziehl-Neelsen basic fuchsin dyes—is satisfactory, although time consuming and operator dependent. Most modern laboratories processing large numbers of diagnostic specimens use auramine–rhodamine staining and fluorescence microscopy; this approach is more sensitive than the Ziehl-Neelsen method. However, it is expensive because it requires high-cost mercury vapor light sources and a darkroom. Less expensive light-emitting diode (LED) fluorescence microscopes are now recommended by the WHO as the microscopy tool of choice. They are as sensitive as—or more sensitive than—traditional fluorescence microscopes. As a result, conventional light and fluorescence microscopes are being replaced with this more recent technology, especially in developing countries. For patients with signs or symptoms of pulmonary TB, it has been recommended that one or two sputum specimens, preferably collected early in the morning, should be submitted to the laboratory for AFB smear and mycobacterial culture. If tissue is obtained, it is critical that the portion of the specimen intended for culture not be put in preservation fluid such as formaldehyde. The use of AFB microscopy in examining urine or gastric lavage fluid is limited by the low numbers of organisms, which can cause false-negative results, or the presence of commensal mycobacteria, which can cause false-positive results.

MYCOBACTERIAL CULTURE

Definitive diagnosis depends on the isolation and identification of *M. tuberculosis* from a clinical specimen. Commercial liquid-culture systems such as the Mycobacterial Growth Indicator Tube (MGIT) system (Becton Dickinson; Franklin Lakes, NJ) are recommended by the WHO as the reference standard for culture. The MGIT system uses a fluorescent compound sensitive to the presence of oxygen dissolved in the liquid medium. The appearance of fluorescence, detected by fluorometric technology, indicates active growth of mycobacteria. MGIT cultures usually become positive after a period ranging from 10 days to 2–3 weeks; the tubes are read weekly until the eighth week of incubation before the result is declared to be negative. Specimens may also be inoculated onto egg- or agar-based medium (e.g., Löwenstein-Jensen or Middlebrook 7H10 or 7H11) and incubated at 37°C (under 5% CO_2 for Middlebrook medium). Because most species of mycobacteria, including *M. tuberculosis*, grow slowly, 4–8 weeks may be required before growth is detected on these conventional culture media. Although *M. tuberculosis* may be identified presumptively on the basis of growth time and colony pigmentation and morphology, a variety of biochemical tests have traditionally been used to speciate mycobacterial isolates. In modern, well-equipped laboratories, commercial liquid culture for isolation and species identification by molecular methods or high-pressure liquid chromatography of mycolic acids has replaced isolation on solid media and identification by biochemical tests. A low-cost, rapid immunochromatographic lateral-flow assay based on detection of MTP64 antigen may also be used for species identification of the *M. tuberculosis* complex in culture isolates. These new methods, which are increasingly used in limited-resource settings, have decreased the time required for bacteriologic confirmation of TB to 2–3 weeks.

DRUG SUSCEPTIBILITY TESTING

Universal DST is considered by the WHO as the current standard of care for all TB patients and should consist of DST to at least rifampin for all initial isolates of *M. tuberculosis*, as rifampin resistance is an excellent proxy for MDR-TB diagnosis. Susceptibility testing is particularly important if one or more risk factors for drug resistance are identified or if the patient either fails to respond to initial therapy or has a relapse after the completion of treatment (see "Treatment Failure and Relapse," below). In addition, expanded and rapid susceptibility testing for isoniazid and key second-line anti-TB drugs (especially the fluoroquinolones and the injectable drugs) is mandatory when RR-TB is found in order to guide selection of the appropriate treatment regimens. Susceptibility testing may be conducted directly by molecular techniques (with the clinical specimen) or indirectly (with mycobacterial cultures) on solid or liquid medium. Results are obtained rapidly by direct susceptibility testing on liquid medium, with an average reporting time of 3 weeks. With indirect testing on solid medium, results may not be available for ≥8 weeks. Highly reliable genotypic methods for the rapid identification of genetic mutations in gene regions known to be associated with resistance to rifampin (such as those in *rpo*B) and isoniazid (such as those in *kat*G and *inh*A) have been developed and are being widely implemented for screening of patients at increased risk of drug-resistant TB. Apart from the Xpert MTB/RIF, Xpert MTB/RIF Ultra, and Truenat MTB-Rif Dx assays, which, as mentioned above, effectively detect rifampin resistance, the most widely used tests are molecular line probe assays (LPAs). LPAs are a family of DNA strip-based tests capable of detecting bacterial DNA and identifying drug resistance-associated mutations. After extraction of DNA from *M. tuberculosis* isolates or from clinical specimens, the resistance gene regions are amplified by polymerase chain reaction (PCR), and labeled and probe-hybridized PCR products are detected by colorimetric development. This assay reveals the presence of *M. tuberculosis* as well as mutations in target resistance-gene regions. Given the rapidity and accuracy of commercially available LPAs, the WHO recommends that they (rather than phenotypic culture-based tests) may be used to detect resistance to isoniazid and rifampin when

patients have sputum smear–positive specimens or a cultured isolate of *M. tuberculosis*. These recommendations do not eliminate the need for conventional culture-based testing to identify resistance to other drugs and to monitor emergence of additional drug resistance. A similar approach has been developed for second-line anti-TB drugs, such as the fluoroquinolones and the injectable drugs kanamycin, amikacin, and capreomycin. Therefore, second-line LPAs (instead of phenotypic culture-based DST) are now recommended by the WHO as the initial test for rapid detection of resistance to the fluoroquinolones or the second-line injectable drugs in isolates from patients with confirmed RR-TB or MDR-TB. As with first-line LPAs, these recommendations do not eliminate the need for conventional phenotypic, culture-based testing to identify resistance to other drugs and to monitor for the emergence of additional resistance. Detection of pyrazinamide resistance is important among persons with MDR/RR-TB. The WHO has recently recommended the use of a LPA with reverse hybridization-based technology in culture isolates rather than phenotypic culture-based DST. Finally, a few noncommercial, inexpensive culture and susceptibility testing methods (e.g., microscopically observed drug susceptibility, nitrate reductase, and colorimetric redox indicator assays) have been used in resource-limited settings. Their use is restricted to national reference laboratories with proven proficiency and adequate external quality control as an interim solution while genotypic or automated liquid-culture technology is introduced.

Whole genome sequencing (WGS) of *M. tuberculosis* provides comprehensive information on mutations conferring resistance and is a promising alternative to existing phenotypic and molecular DST methods. Recent studies have confirmed the potential for WGS to identify genetic polymorphisms that reliably predict drug susceptibility phenotype within a clinically relevant timeframe and a comparable cost range. The clinical use of WGS, however, has been hampered by the requirement for a culture sample before DNA processing. Recently, amplification and sequencing of relevant genomic targets directly from sputum samples have been successfully tested and targeted next-generation sequencing (tNGS) is now a possible option. Evidence is accumulating supporting the clinical application of NGS-based diagnostic systems for TB to replace traditional diagnostic tests in the future.

RADIOGRAPHIC PROCEDURES

CXR is a rapid imaging technique that has historically been used as a primary tool to detect pulmonary TB. CXR has high sensitivity but poor specificity. Although TB may often present with typical patterns strongly suggesting the disease, some abnormalities seen in TB are also present in several other lung conditions. The initial suspicion of pulmonary TB is often based on abnormal CXR findings in a patient undergoing triage for respiratory symptoms. The presence of lesions suggestive of TB should prompt bacteriologic investigations in all cases, without exception. Although the "classic" picture is that of upper-lobe disease with infiltrates and cavities (Fig. 178-6), virtually any radiographic pattern—from a normal film or a solitary pulmonary nodule to diffuse alveolar infiltrates in a patient with adult respiratory distress syndrome—may be seen. In the era of HIV/AIDS, no radiographic pattern can be considered pathognomonic, but CXR can assist in diagnosing TB or ruling it out before initiation of any preventive treatment. CXR is also helpful as a screening test used preceding rapid molecular assays to improve their predictive value. Digital CXR technology, which allows display of images in a digital format on a computer screen instead of on x-ray film, offers several advantages: the procedure time is reduced, the running costs are lower, the imaging is of superior quality, and telemedicine assistance is available, including computer-aided detection (CAD) and interpretation of findings using software programs that analyze digital imaging for abnormalities compatible with TB. However, the limited evidence available suggests that while sensitivity may be high, specificity is variable. A recent systematic review of CAD studies concluded that the diagnostic accuracy of this technology is still limited and that generalizability to low-prevalence settings is still uncertain.

CT (Fig. 178-7) may be useful in interpreting questionable findings on plain CXR and in diagnosing some forms of extrapulmonary TB (e.g., intrabdominal disease, Pott's disease; Fig. 178-10). A recent study has shown the potential of positron emission tomography combined with CT for detection of subclinical disease that may be progressing toward full-blown TB in HIV-infected people. MRI is useful in the diagnosis of bone lesions and intracranial TB.

ADDITIONAL DIAGNOSTIC PROCEDURES

Other diagnostic tests may be used when pulmonary TB is suspected. Sputum induction by ultrasonic nebulization of hypertonic saline may be useful for patients who cannot produce a sputum specimen spontaneously. Frequently, patients with radiographic abnormalities that are consistent with other diagnoses (e.g., bronchogenic carcinoma) undergo fiberoptic bronchoscopy with bronchial brushings and endobronchial or transbronchial biopsy of the lesion. Bronchoalveolar lavage of a lung segment containing an abnormality may also be performed. In all cases, it is essential that specimens be submitted for molecular testing with the Xpert MTB/RIF assay, mycobacterial culture, and AFB smear. For the diagnosis of primary pulmonary TB in children, who often do not expectorate sputum, induced sputum specimens and specimens from early-morning gastric lavage may yield positive results in the Xpert MTB/RIF assay or on culture.

Invasive diagnostic procedures are indicated for patients with suspected extrapulmonary TB. In addition to testing of specimens from involved sites (e.g., CSF for tuberculous meningitis, pleural fluid and biopsy samples for pleural disease), biopsy and culture of bone marrow and liver tissue have a good diagnostic yield in disseminated (miliary) TB, particularly in HIV-infected patients, who also have a high frequency of positive blood cultures. Xpert MTB/RIF should always be the initial diagnostic test in patients where TB meningitis is suspected; any positive results should prompt immediate treatment initiation, while negative results should be followed up by additional testing. In some cases, the results of culture or Xpert MTB/RIF are negative but a clinical diagnosis of TB is supported by consistent epidemiologic evidence (e.g., a history of close contact with an infectious patient) and a compatible clinical and radiographic response to treatment. In the United States and other industrialized countries with low rates of TB, some patients with limited abnormalities on CXR and sputum positive for AFB are infected with nontuberculous mycobacteria, most commonly organisms of the *M. avium* complex or *M. kansasii* (Chap. 180). Factors favoring the diagnosis of nontuberculous mycobacterial disease over TB include an absence of risk factors for TB and the presence of underlying chronic pulmonary disease.

Patients with HIV-associated TB pose several diagnostic problems (see "HIV-Associated TB," above). HIV-infected patients with sputum culture–positive, AFB-positive TB may present with a normal chest radiograph. The Xpert MTB/RIF assay is the preferred rapid diagnostic test in this population of patients because of its simplicity and increased sensitivity (~60–70% among AFB-negative, culture-positive cases and 97–98% among AFB-positive cases). With the advent of ART, the occurrence of disseminated *M. avium* complex disease that can be confused with TB has become much less common. A test based on the detection of mycobacterial lipoarabinomannan antigen in urine has emerged as a potentially useful point-of-care test for TB in HIV-infected persons with low CD4+ T-cell counts. The lateral-flow urine lipoarabinomannan assay can be performed manually and read by eye. After a systematic review of the evidence, the WHO recommends that this assay be used to assist in the diagnosis of TB in HIV-positive adults who have signs and symptoms of TB and a CD4+ T-cell count of ≤100 cells/μL or in HIV-positive patients who are seriously ill regardless of CD4+ T-cell count or with an unknown CD4+ count. The WHO recommends that this test not be used, pending information on recent promising technological test advances, for TB diagnosis or as a screening test for TB in any other patient categories. One limitation of the available lipoarabinomannan point-of-care test, AlereLAM (Alere Determine TB LAM Ag), is the low sensitivity (45%). A novel assay, FujiLAM (SILVAMP TB LAM) has recently shown a sensitivity of 70%.

SEROLOGIC AND OTHER DIAGNOSTIC TESTS FOR ACTIVE TB

Several serologic tests based on detection of antibodies to a variety of mycobacterial antigens have been carefully assessed by the WHO

and found not to be useful as diagnostic aids because of their low sensitivity and specificity and their poor reproducibility. In 2011, after a rigorous evaluation of these tests, the WHO issued a "negative" recommendation in order to prevent their abuse in the private sector of many resource-limited countries. Various methods aimed at detection of mycobacterial antigens in diagnostic specimens are being investigated but are limited at present by low sensitivity. Determinations of adenosine deaminase and IFN-γ levels in pleural fluid may be useful adjunctive tests in the diagnosis of pleural TB; their utility in the diagnosis of other forms of extrapulmonary TB (e.g., pericardial, peritoneal, and meningeal) is less clear.

BIOMARKERS

In view of the limitations of current diagnostics, research on TB biomarkers and multiple marker biosignatures that could be used as a point-of-care test for disease or triage is a high priority and has been crystallized in well-defined target product profiles by the WHO. Recent systematic reviews revealed that promising host biomarkers under study, such as antibodies, cytokines, chemokines, and RNA signatures, by far exceed pathogen biomarkers that can be obtained from urine or blood. However, currently, candidate biomarkers require additional studies to fully assess their performance.

DIAGNOSIS OF *M. TUBERCULOSIS* INFECTION

Two tests currently exist for identification of individuals with TB infection: the TST and IGRA, both of which measure host immunological response to TB antigens. These tests have limitations, especially in settings or populations with high TB and/or HIV prevalence.

Tuberculin Skin Testing In 1891, Robert Koch discovered that components of *M. tuberculosis* in a concentrated liquid-culture medium, subsequently named "old tuberculin," were capable of eliciting a skin reaction when injected subcutaneously into patients with TB. In 1932, Seibert and Munday purified this product by ammonium sulfate precipitation to produce an active protein fraction known as *tuberculin purified protein derivative* (*PPD*). In 1941, PPD-S, developed by Seibert and Glenn, was chosen as the international standard. Later, the WHO and UNICEF sponsored large-scale production of a master batch of PPD (RT23) and made it available for general use. The greatest limitation of PPD is its lack of mycobacterial species specificity, a property due to the large number of proteins in this product that are highly conserved in the various species. In addition, subjectivity of the skin-reaction interpretation that is dependent on the operator, deterioration of the product, and batch-to-batch variations limit the usefulness of PPD.

The skin test with tuberculin PPD (TST) is most widely used in screening for TB infection. It probably measures the response to antigenic stimulation by T cells that reside in the skin rather than the response of recirculating memory T cells. The test is of limited value in the diagnosis of active TB because of its relatively low sensitivity and specificity and its inability to discriminate between TB infection and active disease. False-negative reactions are common in immunosuppressed patients and in those with overwhelming TB. False-positive reactions may be caused by infections with nontuberculous mycobacteria **(Chap. 180)** and by BCG vaccination. A repeated TST can produce larger reaction sizes due to either boosting or true conversion. The "boosting phenomenon" is a spurious TST conversion resulting from boosting of reactivity on a subsequent TST 1–5 weeks after the initial test. Distinguishing boosting from true conversion is difficult yet important and can be based on clinical and epidemiologic considerations. For instance, true conversions are likely after BCG vaccination in a previously TST-negative person or in a close contact of an infectious patient.

IFN-γ Release Assays Two in vitro assays that measure T-cell release of IFN-γ in response to stimulation with the highly TB-specific RD1-encoded antigens ESAT-6 and CFP-10 were introduced in the early 2000s and are commercially available. The T-SPOT.TB test (Oxford Immunotec; Oxford, United Kingdom) is an enzyme-linked immunospot assay, and the QuantiFERON-TB Gold test (Qiagen GmbH; Hilden, Germany) is a whole-blood enzyme-linked immunosorbent assay for measurement of IFN-γ. The QuantiFERON-TB Gold In-Tube (QFT-GIT) assay, which facilitates blood collection and initial incubation, also contains another specific antigen, TB7.7. These tests mainly measure the response of recirculating memory CD4+ T cells—normally part of a reservoir in the spleen, bone marrow, and lymph nodes—to persisting bacilli-producing antigenic signals. However, CD8+ cells can also release IFN-γ in vitro in response to stimulation with TB antigens, and they seem to do so especially in the early phase of infection and in the phase of reactivation. Therefore, a new version of the QFT-GIT assay, called QuantiFERON-TB Gold Plus (QFT-Plus), has been developed that operates through two antigen tubes: TB1, containing long peptides from ESAT-6 and CFP-10 and inducing a CD4+ T-cell response, and TB2 that also contains shorter peptides stimulating CD8+ cells. The QFT-Plus may have an increased sensitivity, compared to QFT-GID, but this conclusion needs confirmation.

In settings or population groups with low TB and HIV burdens, IGRAs have previously been reported to be more specific than the TST as a result of less cross-reactivity with BCG vaccination and sensitization by nontuberculous mycobacteria; i.e., RD1 antigens are not encoded in the genome of either BCG strains or most nontuberculous mycobacteria. Recent studies suggest that IGRAs may not perform well in serial testing (e.g., among health care workers) and that interpretation of results depends on cutoff values used to define positivity. Potential advantages of IGRAs include logistical convenience, the need for fewer patient visits to complete testing, and the avoidance of somewhat subjective measurements (e.g., skin induration). However, IGRAs require that blood be drawn and then delivered to the laboratory in a timely fashion. IGRAs also require that testing be performed by specially trained technicians in a laboratory setting. These requirements pose challenges similar to those faced with the TST, including cold-chain requirements and batch-to-batch variations. Because of higher specificity and greater availability of resources, IGRAs have usually replaced the TST for TB infection diagnosis in low-incidence, high-income settings. However, in high-incidence TB and HIV settings and population groups, evidence about the performance and usefulness of IGRAs is still limited, and cost considerations may currently limit wider use.

A number of national guidelines on the use of IGRAs for TB infection testing have been issued. In the United States, an IGRA is preferred to the TST for most persons over the age of 5 years who are being screened for TB infection. However, for individuals at high risk of progression to active TB (e.g., HIV-infected persons), either test—or, to optimize sensitivity, both tests—may be used. Because of the paucity of data on the use of IGRAs in children, the TST is preferred for TB infection testing of children aged <5 years. In Canada and some European countries, a two-step approach for those with positive TSTs—i.e., an initial TST followed by an IGRA—is often recommended. However, a TST may boost an IGRA response if the interval between the two tests exceeds 3 days.

In conclusion, both the TST and IGRA, although useful as diagnostic aids, are imperfect tests for TB infection: while they can identify infected persons, they have low predictive value in identifying individuals with the highest risk of progression toward disease, cannot differentiate between active TB and TB infection, cannot distinguish new infections from reinfections, and display reduced sensitivity in immunocompromised patients.

TREATMENT

Tuberculosis

The two main aims of TB treatment are (1) to prevent morbidity and death by curing TB while preventing recurrences and emergence of drug resistance, and (2) to interrupt transmission by rendering patients noninfectious to others. Chemotherapy for TB became possible with the discovery of streptomycin in 1943. Randomized clinical trials clearly indicated that the administration of streptomycin to patients with chronic TB reduced mortality rates and led to cure in the majority of cases. However, monotherapy with streptomycin

was soon associated with the development of resistance to this drug and the resulting failure of treatment. With the introduction into clinical practice of para-aminosalicylic acid (PAS) and isoniazid, it became axiomatic in the early 1950s that cure of TB required the concomitant administration of at least two agents to which the organism was susceptible. Furthermore, early clinical trials demonstrated that a long period of treatment—i.e., 12–24 months—was required to prevent recurrence. The introduction of rifampin in the early 1970s heralded the era of effective short-course chemotherapy, with a treatment duration of <12 months. The discovery that pyrazinamide, which was first used in the 1950s, augmented the potency of isoniazid/rifampin regimens led to the use of a 6-month course of this triple-drug regimen as standard therapy. Streptomycin was added as the fourth drug mainly to prevent the emergence of drug resistance. These four drugs (with streptomycin replaced by ethambutol) still form the basis of the optimal treatment regimen for rifampin-susceptible TB. The emergence of drug-resistant TB in the 1990s prompted attempts to standardize the approach to treatment of this condition mainly on the basis of expert opinion. This event has also stimulated research on and development of new anti-TB agents in the past 15 years. In 2013 and 2014, respectively, bedaquiline and delamanid—the first two drugs specifically developed for TB during nearly half a century—received conditional approval by the US Food and Drug Administration (FDA) and other drug-regulatory authorities; approval was based on the results of phase 2b clinical trials in which the drugs were added to the 18- to 24-month WHO-recommended regimen for MDR-TB. Bedaquiline and delamanid are now being used increasingly for treatment of MDR-TB under specific conditions. In 2019, another new drug, pretomanid, was approved by the FDA as part of a new combination regimen with bedaquiline and linezolid for patients with MDR-TB caused by a strain with additional resistance to a fluoroquinolone or a second-line injectable drug, or were intolerant of therapy, or in whom treatment had failed.

DRUGS

Four major drugs are considered first-line agents for the treatment of TB: isoniazid, rifampin, pyrazinamide, and ethambutol. **Table 178-2** presents currently recommended dosages in adults and children. Some studies have suggested increased effectiveness when isoniazid, rifampin, and pyrazinamide are given at higher dosage; thus if these findings are confirmed, dosages may be revised in the future. These drugs are well absorbed after oral administration, with peak serum levels at 2–4 h and nearly complete elimination within 24 h. Isoniazid and rifampin, two key anti-TB drugs, are recommended on the basis of their bactericidal activity (i.e., their ability to rapidly reduce the number of viable organisms and render patients noninfectious). All four agents are recommended in light of their sterilizing activity (i.e., their ability to sterilize the affected tissues, measured in terms of the ability to prevent relapses) and the lowered risk that drug-resistant mutant bacilli will be selected when the drugs are used in combination. Two additional rifamycins, rifapentine and rifabutin, are also available; however, their level of cross-resistance with rifampin is high. For a detailed discussion of the drugs used for the treatment of TB, see **Chap. 181.**

TABLE 178-2 Recommended Dosage[a] for Initial Treatment of Tuberculosis in Adults and Children

	DAILY DOSE	
DRUG	ADULT	PEDIATRIC
Isoniazid	5 mg/kg, max 300 mg	10 (7–15) mg/kg, max 300 mg
Rifampin	10 mg/kg, max 600 mg	15 (10–20) mg/kg, max 600 mg
Pyrazinamide	25 mg/kg, max 2 g	35 (30–40) mg/kg
Ethambutol[b]	15 mg/kg	20 (15–25) mg/kg

[a]The duration of treatment with individual drugs varies by regimen, as detailed in Table 178-3. [b]In certain settings, streptomycin (15 mg/kg daily, with a maximal dose of 1 g; or 25–30 mg/kg thrice weekly, with a maximal dose of 1.5 g) can replace ethambutol in the initial phase of treatment. However, streptomycin generally is no longer considered a first-line drug.

Source: Based on recommendations of the American Thoracic Society/Infectious Diseases Society of America/Centers for Disease Control and Prevention and the World Health Organization.

Because of a lower degree of effectiveness and tolerability, several classes of second-line drugs are generally used only for the treatment of patients with drug-resistant TB. These agents have previously been classified in various manners to facilitate a standardized approach to their use. In the latest WHO guidance on the treatment of MDR-TB, they are now grouped in three ranked categories for the purpose of designing more individualized regimens of 18–20 months' duration. Group A drugs include three classes of oral agents: the fluoroquinolones levofloxacin and moxifloxacin; the oxazolidinone linezolid; and the recently introduced diarylquinoline bedaquiline, which was granted accelerated approval by the FDA in late 2012. Group B drugs include two other oral agents: clofazimine and cycloserine (or its analogue terizidone). Group C drugs include the nitroimidazole delamanid; imipenem-cilastatin or meropenem; the injectable aminoglycosides amikacin and streptomycin (the latter formerly a first-line agent, now rarely used for drug-resistant TB because resistance levels worldwide are high and it is more toxic than the other drugs in the same class); ethionamide or prothionamide; and PAS. In addition, the first-line anti-TB drugs ethambutol and pyrazinamide (both included in Group C) as well as high-dose isoniazid (only for the shorter regimen; see below) are used for MDR-TB treatment. Information about drugs used in the treatment of drug-resistant TB (including dosages) can be found in the following WHO Handbook: *http://apps.who.int/iris/bitstream/10665/130918/1/9789241548809_eng.pdf.* Recent information from the phase 3 clinical trial of delamanid (a drug granted accelerated approval by the European Medicines Agency [EMA] in late 2013) added to an optimized longer WHO background regimen shows that treatment success is not different from that obtained with the addition of placebo. The future role of delamanid as a replacement drug in MDR-TB treatment remains to be assessed. The new classification scheme excludes the second-line injectable aminoglycoside kanamycin and the polypeptide capreomycin. Amithiozone, which has been associated with severe and at times fatal skin reactions—including Stevens-Johnson syndrome—among HIV-infected patients, is no longer recommended. Finally, amoxicillin–clavulanic acid is recommended only as an adjunct to carbapenems.

REGIMENS

Standard regimens are divided into an intensive (bactericidal) phase and a continuation (sterilizing) phase. During the intensive phase, the majority of tubercle bacilli are killed, symptoms resolve, and usually the patient becomes noninfectious. The continuation phase is required to eliminate persisting mycobacteria and prevent relapse.

The treatment regimen of choice for virtually all forms of drug-susceptible TB in adults consists of a 2-month initial (intensive) phase of isoniazid, rifampin, pyrazinamide, and ethambutol followed by a 4-month continuation phase of isoniazid and rifampin **(Table 178-3)**. This regimen can cure TB in >90% of patients. In children, most forms of TB in the absence of HIV infection or suspected isoniazid resistance can be safely treated without ethambutol in the intensive phase. Treatment should be given daily throughout the course. Systematic reviews have demonstrated that the use of an intermittent thrice-weekly regimen in the intensive phase is associated with increased risk of treatment failure, relapse, and acquisition of drug resistance. Furthermore, a thrice-weekly regimen in the continuation phase only has also been associated with increased rates of failure and relapse, while a twice-weekly regimen in the continuation phase increased the risk of acquisition of drug resistance as well as rates of failure and relapse. Therefore, the WHO now recommends that TB treatment in all cases be administered daily. The 2016 guidelines by the ATS, the CDC, and the IDSA, while recommending daily administration of drugs, include a provision for use of intermittent thrice-weekly supervised regimens among patients who are not infected with HIV and are at low risk of relapse (i.e., have pulmonary TB caused by drug-susceptible

TABLE 178-3 Recommended Antituberculosis Treatment Regimens

	INITIAL PHASE		CONTINUATION PHASE

Intolerance to Z	2	HRE	7	HR

[a]All drugs should be given daily. [b]A 4-month regimen of 8 weeks of once-daily rifapentine, isoniazid, pyrazinamide and moxifloxacin followed by 9 weeks of once-daily rifapentine, isoniazid, and moxifloxacin is a possible alternative. [c]A clinical trial showed that HIV-negative patients with noncavitary pulmonary tuberculosis who have negative sputum AFB smears after the initial phase of treatment can be given once-weekly rifapentine/isoniazid in the continuation phase. However, this regimen is rarely used. [d]The American Thoracic Society, the Centers for Disease Control and Prevention, and the Infectious Diseases Society of America suggest that a 2-month continuation phase could be used in HIV-seronegative patients with sputum smear–negative and culture-negative TB. [e]The 6-month regimen with pyrazinamide can probably be used safely during pregnancy and is recommended by the WHO and the International Union Against Tuberculosis and Lung Disease. If pyrazinamide is not included in the initial treatment regimen, the minimal duration of therapy is 9 months. [f]The availability of rapid molecular methods to identify drug resistance allows initiation of a proper regimen at the start of treatment.

Abbreviations: E, ethambutol; H, isoniazid; MDR-TB, multidrug-resistant tuberculosis; Q, a quinolone antibiotic; R, rifampin; WHO, World Health Organization; XDR-TB, extensively drug-resistant tuberculosis; Z, pyrazinamide.

organisms that, at the start of treatment, is noncavitary and/or sputum smear–negative). The same guidelines suggest that a 4-month regimen consisting of isoniazid, rifampin, pyrazinamide, and ethambutol may be adequate for treatment of HIV-negative adults with sputum smear–negative and culture-negative pulmonary TB (i.e., paucibacillary TB).

A continuation phase of once-weekly rifapentine and isoniazid is effective in HIV-seronegative patients without cavitation on CXR. In general, however, this regimen should be used with great caution. Patients with cavitary pulmonary TB and delayed sputum-culture conversion (i.e., those who remain culture-positive at 2 months) should be retested immediately for drug-resistant TB, and a change of regimen should be considered. A full course of 6 months with four-drug therapy should be performed not including interruptions of >4 weeks. In some developing countries where the ability to ensure adherence to treatment is limited, a continuation-phase regimen of daily isoniazid and ethambutol for 6 months has been used in the past. This regimen is clearly associated with a higher rate of relapse, treatment failure, and death, especially among HIV-infected patients, and is no longer recommended by the WHO. Several studies attempting to reduce treatment duration to 4 months by using fluoroquinolones (with moxifloxacin replacing ethambutol or isoniazid, or gatifloxacin replacing ethambutol) were conducted over the last decade. The main finding was that shorter (4-month) fluoroquinolone-containing regimens are associated with significantly higher rates of relapse at 18 months than the standard 6-month rifampin-containing regimen. In addition, the studies showed no reduction in adverse events with the fluoroquinolone-containing regimen and no difference in all-cause and TB-related mortality rates. Therefore, shortening of the treatment duration to 4 months through the use of fluoroquinolones has not been recommended. However, the recent Tuberculosis Trials Consortium Study 31/AIDS Clinical Trials Group A5349 (Study 31/A5349) showed that a 4-month daily regimen that included isoniazid, pyrazinamide, rifapentine at a daily dose of 1200 mg and moxifloxacin at a daily dose of 400 mg was noninferior to the standard 6-month regimen and had a similar adverse event profile. In early 2021, this option was therefore considered by the WHO as a possible alternative to the old standard provided that rigorous antibacterial stewardship is ensured especially to prevent fluoroquinolone resistance and that rifapentine becomes more widely available. Alternative regimens for patients who exhibit drug intolerance or adverse reactions are listed in Table 178-3. However, severe side effects prompting discontinuation of any of the first-line drugs and use of these alternative regimens are uncommon. To prevent isoniazid-related neuropathy, pyridoxine (10–25 mg/d) should be added to the regimen given to persons at high risk of vitamin B_6 deficiency (e.g., alcoholics; malnourished persons; pregnant and lactating women; and patients with conditions such as chronic renal failure, diabetes, and HIV infection, which are also associated with neuropathy). Finally, to facilitate absorption of rifampin, the drug should be taken on an empty stomach and without meals.

PATIENT CARE AND SUPPORT

Poor adherence to treatment is one of the most important impediments to cure. Moreover, the tubercle bacilli harbored by patients who do not fully adhere to the prescribed regimen are likely to become resistant to the drugs to which they are irregularly exposed. Both patient- and provider-related factors may affect adherence. Patient-related factors include a lack of belief that the illness is worth the cost of adherence; the existence of concomitant medical conditions (notably alcohol or substance abuse); lack of social support; fear of the stigma and discrimination associated with TB; and poverty, with attendant joblessness and homelessness. Provider-related factors that may prevent adherence include lack of support, education, and encouragement of patients and inconvenient clinical services.

A variety of interventions to increase the chances of completion of the months-long treatment course are available. First, a package of social support interventions that are complementary and not mutually exclusive, consisting of educational, psychological, and material goods and services, may enable people with TB to address hurdles to treatment adherence. Health education and counseling on the disease's seriousness and solutions and on the importance of treatment adherence until cure should be provided to all patients at the start of and throughout the course of TB therapy. Psychological support (i.e., counseling sessions or peer-group support) can be particularly relevant in the context of the stigma and discrimination often affecting people with TB and their families. Material support (e.g., food or financial support in forms such as meals, food baskets, food supplements, food vouchers, transport subsidies, living allowances, housing incentives, or financial bonuses) reduces indirect costs incurred by patients or their attendants in accessing health services and mitigates the consequences of income loss related to the disease.

Second, it is paramount that health services be arranged to meet the needs and reasonable expectations of patients. Components of optimal health services include a suitable geographic location, a schedule responsive to patients' needs, functional channels of communication between patients and their health care providers (e.g.,

a telephone short-messaging system, audio/video call capability, home or workplace visits), and a staff willing and competent to care for people with TB, to address their concerns, and to base the care they provide on sound ethical standards.

Third, it is crucial to offer the patient a suitable option for treatment administration that minimizes the chance of nonadherence. Such options traditionally include unsupervised, self-administered therapy; in-person directly observed therapy (DOT); and nondaily DOT (e.g., supervision not for every dose but weekly or a few times per week) at a location mutually agreed on by patient and health care provider, with supervisory responsibility delegated to a qualified person. Direct supervision of adherence is crucial in view of the lack of tools to accurately predict adherence to self-administered treatment and of the public health importance of TB. The WHO, along with the ATS, the CDC, and the IDSA, states that ideally all patients should have their therapy directly supervised, especially during the initial phase, with proper social support based on a patient-centered approach as described above. In several countries, personnel to supervise therapy are usually available through TB control programs of local public health departments, often involving members of the community who are accepted by the patient and who have been properly trained and educated by health workers to undertake the supervisory role. Direct supervision with social support has been shown to significantly increase the proportion of patients completing treatment in all settings and to lessen the chances of treatment failure, relapse, and default. In general, community- or home-based DOT is recommended over health facility–based DOT or unsupervised treatment; DOT administered by trained lay providers or health care workers is recommended over DOT administered by family members. Recently, comparison of video-observed therapy (VOT) with in-person DOT has shown similar outcomes. In a multicenter, analyst-blinded, randomized controlled superiority trial of VOT through daily remote observation using a smartphone app versus DOT done 3–5 times weekly at home, community, or clinic settings, VOT was superior to DOT in ensuring scheduled observation of drug intake. Therefore, VOT can replace DOT when Internet access is good and video communication technology (e.g., smartphones, tablets, computers) is available. The system can be appropriately organized and operated by health care providers and patients. Other digital health tools can facilitate the monitoring of adherence, including digital medication monitors; these monitors can register when the pillbox is opened, with options to emit audio signals or a short message to remind patients to take medicines. These tools are customized to the needs and preferences of the individual patient and the provider.

In addition to the above measures promoting adherence, provision of fixed-dose combination products that reduce the number of tablets the patient needs to swallow is recommended over separate drug formulations. Various fixed-dose combination products are available (e.g., isoniazid/rifampin, isoniazid/rifampin/pyrazinamide, and isoniazid/rifampin/pyrazinamide/ethambutol). Fixed-dose combinations increase patient satisfaction and minimize the likelihood of prescription error or of development of drug resistance resulting from monotherapy if a drug is out of stock or the patient prefers one drug over others. In addition, these combinations facilitate programmatic management of procurement and supply. In the past, the bioavailability of rifampin was found to be substandard in some formulations of fixed-dose combinations. Medical regulatory authorities should ensure that combination products are of good quality; however, top standards for drug quality assurance are not always operative, especially in limited-resource countries. Prescribers should be aware of this potential problem.

MONITORING TREATMENT RESPONSE AND DRUG TOXICITY

Bacteriologic evaluation through commercial liquid-culture systems (or—when liquid-culture capacity is not yet available—through smear microscopy) is essential in monitoring the response to TB treatment. In addition, the patient's weight should be monitored regularly and the drug dosage adjusted with any significant weight change. Patients with pulmonary disease should have their sputum examined monthly until cultures become negative to allow early detection of treatment failure. With the recommended 6-month standard first-line regimen, >80% of drug-susceptible TB patients will have negative sputum cultures at the end of the second month of treatment. By the end of the third month, the sputum of virtually all patients should be culture negative. In some patients, especially those with extensive cavitary disease and large numbers of organisms, AFB smear conversion may lag behind culture conversion as a result of the expectoration and microscopic visualization of dead bacilli. Therefore, as capacity is built, smear microscopy should be progressively abandoned as a monitoring tool in favor of liquid culture. As noted above, patients with cavitary disease in whom sputum culture conversion does not occur by 2 months require immediate testing or retesting for drug resistance. When a patient's sputum cultures or smears remain positive at ≥3 months despite good adherence, treatment failure caused by drug resistance is likely. The pattern of drug resistance should guide the choice of the best treatment option (see below). A sputum specimen should be collected at the end of treatment to document cure. In settings where mycobacterial cultures are not yet available, monitoring by AFB smear examination should be undertaken at 2, 5, and 6 months. Bacteriologic monitoring of patients with extrapulmonary TB is more difficult and often is not feasible. In these cases, the response to treatment must be assessed clinically with the help of medical imaging.

Monitoring of the response to chemotherapy by nucleic acid amplification technology, such as the Xpert MTB/RIF assay, is not suitable because these tests can produce positive results due to nonviable bacilli. Likewise, serial chest radiographs are not recommended because radiographic changes may lag behind bacteriologic response and are not highly sensitive. After the completion of treatment, neither sputum examination nor CXR is recommended for routine follow-up purposes. However, a chest radiograph obtained at the end of treatment may be useful for comparative purposes should the patient develop symptoms of recurrent TB months or years later. Patients should be instructed to report promptly for medical assessment if they develop any such symptoms.

During treatment, patients should also be monitored for drug toxicity. The most common adverse reaction of significance among people treated for drug-susceptible TB is hepatitis. Patients should be carefully educated about the signs and symptoms of drug-induced hepatitis (e.g., dark urine, loss of appetite, nausea) and should be instructed to discontinue treatment promptly and see their health care provider if these manifestations occur. Although biochemical monitoring is not routinely recommended, all adult patients should undergo baseline assessment of liver function (e.g., measurement of serum levels of hepatic aminotransferases and bilirubin). Older patients, those with concomitant diseases, those with a history of hepatic disease (especially hepatitis C), and those using alcohol daily should be monitored especially closely (i.e., monthly), with repeated measurements of aminotransferases, during the initial phase of treatment. Up to 20% of patients have small increases (up to three times the upper limit of normal) in serum levels of aspartate aminotransferase that are not accompanied by symptoms and are of no consequence. Suspension of treatment should be considered for patients with symptomatic hepatitis, especially when accompanied by at least a three-fold increase in serum levels of AST and/or ALT, and for patients without symptoms of hepatic injury who have marked (at least five-fold) elevations in serum levels of AST and/or ALT. Drugs should be reintroduced one at a time after liver function has returned to normal. Hypersensitivity reactions usually require the discontinuation of all drugs and rechallenge to determine which agent is the culprit. Because of the variety of regimens available, it usually is not necessary—although it is possible—to desensitize patients. Hyperuricemia and arthralgia caused by pyrazinamide can usually be managed by the administration of acetylsalicylic acid; however, pyrazinamide treatment should be stopped if the patient develops gouty arthritis. Individuals who develop autoimmune thrombocytopenia secondary to rifampin therapy should not receive the drug thereafter. Similarly, the occurrence of optic neuritis with ethambutol is an indication for permanent discontinuation of this drug. Other common

manifestations of drug intolerance, such as pruritus and gastrointestinal upset, can generally be managed without the interruption of therapy. Treatment with second-line agents for drug-resistant TB is associated with a variety of adverse drug reactions that are more frequent and severe than in patients receiving first-line TB regimens (see below). The likelihood of drug–drug interactions is also higher when second-line regimens are used.

TREATMENT FAILURE AND RELAPSE

As stated above, treatment failure should be suspected when a patient's cultures (or sputum smears, when cultures are not available) remain positive after 3 months of treatment. In the management of such patients, it is imperative that the current isolate be urgently retested (or tested for the first time if, for some reason, rapid molecular susceptibility testing was not performed at the start of treatment) for susceptibility to first-line agents and, if resistance to rifampin is detected, to second-line agents as well. The treatment approach should start with molecular testing for—at the least—resistance to rifampin and isoniazid. Because results are expected to become available within a few days, changes in the regimen can be postponed until that time. However, if the patient's clinical condition is deteriorating rapidly, an earlier change in regimen may be indicated. A cardinal rule in the latter situation is always to add more than one drug, preferably two or three, at a time to a failing regimen; in practice, starting an empirical regimen for MDR-TB (see "Drug-Resistant TB," below) is warranted. The patient may continue to take isoniazid and rifampin along with these new agents pending the results of susceptibility tests.

Patients who experience a recurrence after apparently successful treatment (i.e., a relapse) are less likely to harbor drug-resistant strains than are patients in whom treatment has failed. Acquired resistance is uncommon among strains from patients in whom relapse follows the proper completion of a standard 6-month regimen. The treatment decision depends on a general assessment of the risk of drug resistance, the severity of the case, and the results of rapid susceptibility testing. Patients whose treatment has been interrupted and who have a high likelihood of MDR-TB should receive an empirical MDR-TB regimen that includes second-line agents (Table 178-3). Once drug susceptibility results are available, the regimen can be adjusted accordingly.

DRUG-RESISTANT TB

Strains of *M. tuberculosis* resistant to individual drugs arise by spontaneous point mutations in the mycobacterial genome that occur at low but predictable rates (10^{-7}–10^{-10} for the key drugs). Resistance to rifampin is associated with mutations in the *rpoB* gene in 95% of cases, that to isoniazid with mutations mainly in the *katG* gene (50–95% of cases) and the *inhA* gene promoter region (up to 45%), that to pyrazinamide in the *pncA* gene (up to 98%), that to ethambutol in the *embB* gene (50–65%), that to the fluoroquinolones in the *gyrA–gyrB* genes (75–95%), and that to the aminoglycosides mainly in the *rrs* gene (up to 80%); the C-12T mutation is the most common mutation in the *eis* promoter region associated with aminoglycoside resistance, especially in Eastern European countries. Because there is no cross-resistance among the commonly used classes of drugs, the probability that a strain will be resistant to two drug classes is the product of the probabilities of resistance to each drug class and thus is low. The development of drug-resistant TB almost invariably follows monotherapy—i.e., the failure of the health care provider to prescribe at least two drugs to which tubercle bacilli are susceptible; of the patient to absorb or take properly prescribed therapy; or of the bioavailability of poor-quality drugs or preparations (e.g., due to crushing of tablets). Drug-resistant TB may be either primary or acquired. In primary drug resistance, the patient is infected from the start by a drug-resistant strain. Acquired resistance develops in the infecting strain during treatment. In North America, Western Europe, most of Latin America, and the Persian Gulf states, rates of primary resistance are generally low and isoniazid resistance is most common. In the United States, although rates of primary isoniazid resistance have been stable at ~7–8%, the rate of primary MDR-TB has declined from 2.5% in 1993 to <1% since 2000. As described above, MDR-TB is an increasingly serious problem in some regions, especially in the countries of the former Soviet Union and some countries of Asia **(Fig. 178-12)**. Even more serious is the occurrence of MDR strains that are also resistant to additional second-line agents used in treatment, such as the fluoroquinolones. Creation of

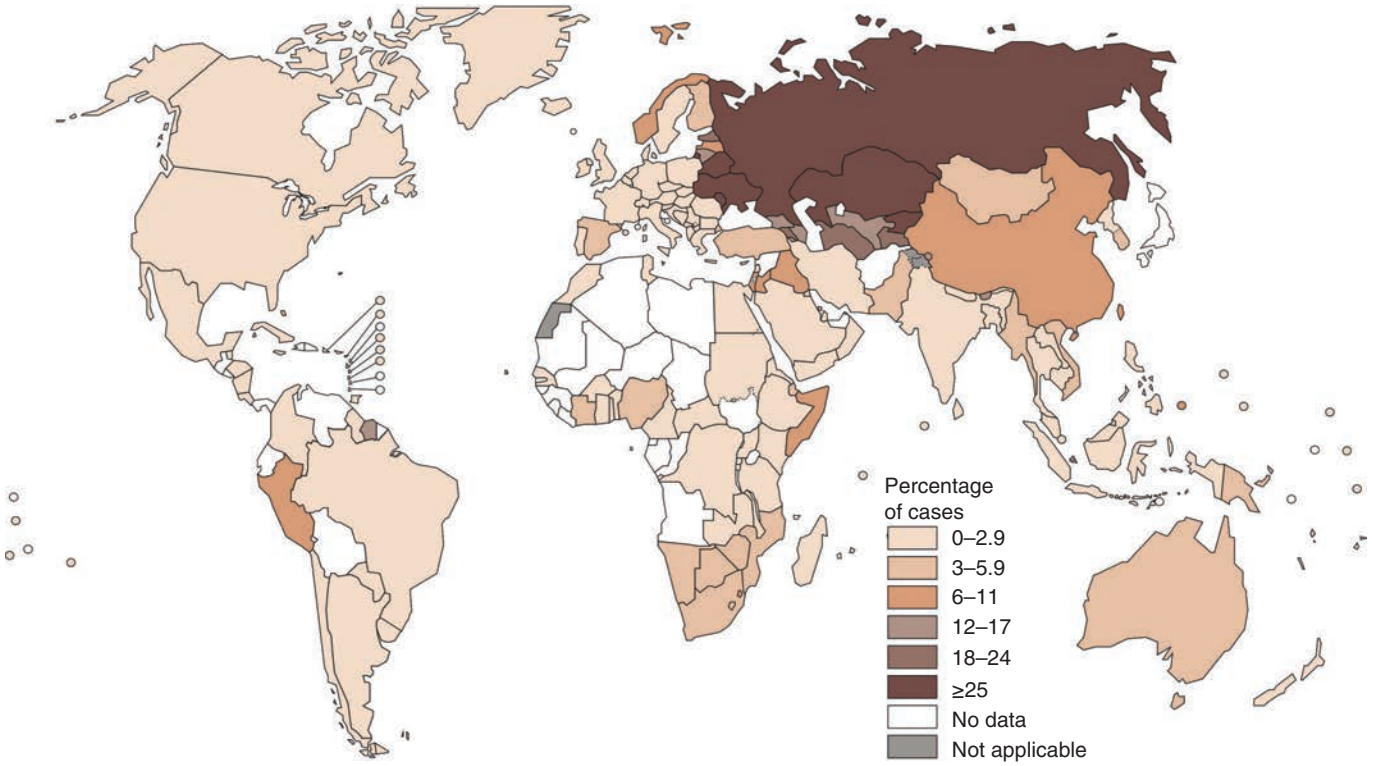

FIGURE 178-12 Percentage of new cases of multidrug-resistant/rifampin-resistant tuberculosis (TB) in all countries surveyed by the World Health Organization (WHO) Global Drug Resistance Surveillance Project during 1994–2018. Figures are based on the most recent year for which data have been reported, which varies among countries. Data reported before the year 2002 are not shown. *(See disclaimer in Fig. 178-2. Reproduced with permission from Global Tuberculosis Report 2019. Geneva, World Health Organization; 2019.)*

drug-resistant TB can be prevented by adherence to the principles of sound treatment: inclusion of at least two quality-assured, bactericidal drugs to which the organism is susceptible; use of effective combination regimens; supervision of treatment with patient support; and verification that patients complete the prescribed course. The use of fixed-dose combination products may prevent selective drug intake and therefore possibly protect against the creation of drug resistance. Transmission of drug-resistant strains can be prevented by the implementation of respiratory infection-control measures (see below) and by early detection of people with active TB followed by immediate initiation of treatment with an effective regimen.

Isoniazid-Resistant TB For the treatment of patients with isoniazid-resistant disease, a combination of rifampin, ethambutol, pyrazinamide, and levofloxacin for 6 months is recommended. This fluoroquinolone-containing regimen should not be used until rifampin resistance has been excluded by a reliable diagnostic test to avoid inadvertent treatment of MDR-TB with an inadequate regimen. Ideally, a laboratory test for susceptibility should also be done for the fluoroquinolones and pyrazinamide. If the fluoroquinolone is contraindicated because of intolerance or resistance, the patient can be given a 6-month regimen of rifampin, ethambutol, and pyrazinamide. Isoniazid probably does not contribute to a successful outcome in these regimens but may be retained (also to facilitate treatment with the four-drug fixed-dose formulation). Other drugs, such as the injectable aminoglycosides, are unlikely to play a role in the treatment of most isoniazid-resistant TB cases. However, they may be considered in the presence of additional resistance (e.g., to pyrazinamide or ethambutol) or of drug intolerance.

RR-, MDR-TB MDR-TB, in which bacilli are resistant to (at least) isoniazid and rifampin, is more difficult to manage than is disease caused by drug-susceptible organisms because these two bactericidal drugs are the most potent first-line agents available and because associated resistance to other first-line drugs as well (e.g., ethambutol) is not uncommon. Treatment for RR-TB and MDR-TB has traditionally been a topic of much debate, given its complexity, long duration, toxicity, and limited efficacy; the cost of most second-line drugs; and the lack of randomized controlled clinical trials to support combinations. Until recently, recommendations were therefore based largely on low-quality evidence from observational studies and on best-practice consensus among experts. Recent developments include the accrual of individual datasets for patients treated worldwide, the release of findings from two randomized controlled phase 3 clinical trials (the STREAM Stage 1 trial comparing a 9-month, shorter MDR-TB regimen with the previous optimized WHO background regimen; and Otsuka's phase 3 trial 213 comparing the addition of the new drug delamanid to the previous optimized WHO background regimen with the addition of placebo), the publication of results of an open-label, single group study enrolling highly drug-resistant cases on a regimen composed of three oral drugs (bedaquiline, pretomanid, and linezolid), and the assessment of programmatic data from South Africa on the large-scale use of a shorter all-oral bedaquiline-containing regimen. The assessment of this information resulted in an update of WHO guidance for the treatment of MDR-TB and all other RR-TB cases in which isoniazid resistance is absent or unknown.

As a result, two main approaches are now recommended by the WHO to treat MDR/RR-TB: (1) an individualized longer regimen of 18–20 months' duration (or 15-17 months after culture conversion) consisting of an optimal combination of oral drugs chosen according to a rational approach and using the WHO priority grouping of medicines **(Table 178-4)**; and (2) a shorter, all-oral, bedaquiline-containing regimen of 9–12 months' duration. While these recommendations may change when new data indicate the need, all-oral regimens are now the preferred options and the use of either a shorter or a longer regimen depends on the assessment of the severity of disease, knowledge of drug resistance pattern, and history of previous treatment.

TABLE 178-4 Groups of Drugs Recommended for Use in Longer MDR-TB Regimens and Approach to the Design of a Longer Regimen for Adults and Children

GROUP	DRUG
Group A: Drugs to be prioritized and included in all regimens, unless they cannot be used	Levofloxacin *or* moxifloxacin Bedaquiline Linezolid
Group B: Drugs to be added in all regimens, unless they cannot be used	Clofazimine Cycloserine *or* terizidone
Group C: Drugs to be used to complete the regimen and when drugs from groups A and B cannot be used	Ethambutol Delamanid Pyrazinamide Imipenem-cilastatin *or* meropenem Amikacin *or* streptomycin Ethionamide *or* prothionamide *p*-Aminosalicylic acid

Source: Adapted from the World Health Organization, 2018.

Longer MDR-TB Regimen In MDR/RR-TB patients where infecting strains have or are presumed to have additional resistance (e.g., resistance to the fluoroquinolones), in those who have severe pulmonary or extrapulmonary disease, or those who have been treated previously with second-line drugs, a longer regimen is recommended. Table 178-4 shows the priority grouping of drugs recommended by the WHO and the approach to the design of a longer regimen for both adults and children. As much as possible, the regimen is composed of all group A agents and at least one group B agent. The use of bedaquiline and linezolid is promoted, together with a fluoroquinolone (levofloxacin or moxifloxacin), whenever possible, in all patients. Clofazimine and cycloserine (group B) are the two preferred options to be added to group A drugs. Group C drugs can replace group A and B agents that cannot be used, and the choice should be based on drug susceptibility testing, drug resistance levels in the population, the patient's history of previous use of these drugs, and potential intolerance or toxicity. The injectable agents (e.g., amikacin, streptomycin, and the carbapenems) are assigned a lower priority because of inconvenience of use and the toxicity of aminoglycosides. A fully oral regimen is thus also the first choice and most desirable option even for the most severe cases who are ineligible for a shorter regimen. Nevertheless, when injectables are necessary and DST supports their use, amikacin has been found to be the most effective drug in this class, followed by streptomycin, while kanamycin and capreomycin seem less effective, both having been associated with higher risks of failure and relapse when compared with longer regimens in which other agents were used instead. A treatment course of at least 18–20 months is recommended, but duration may depend on the patient's response. Important considerations when treating MDR-TB patients include the safety and effectiveness of bedaquiline use beyond 6 months. Likewise, the ideal duration of use of linezolid, which is known to be highly effective but also very frequently produces toxicity (e.g., peripheral and optic neuropathy, and bone marrow suppression), is unclear. Additional considerations concern the use of pyrazinamide and of the aminoglycosides amikacin and streptomycin, which is now restricted to cases with proven susceptibility to those agents. The role of delamanid in the treatment of MDR-TB remains to be assessed, although, as stated earlier, data from the phase 3 clinical trial of this agent as an addition to the longer regimen previously recommended by the WHO did not demonstrate a higher rate of treatment success than was obtained with the background regimen plus placebo. Furthermore, evidence on the safety and effectiveness of delamanid given for >6 months is presently incomplete.

Shorter MDR-TB Regimen In MDR/RR-TB patients with no extensive pulmonary disease or severe extrapulmonary disease, without history of previous treatment with second-line drugs, and whose

infecting strains are not resistant to the fluoroquinolones, a shorter, all-oral, bedaquiline-containing regimen is recommended. Recent observational programmatic data from South Africa, assessed by WHO in 2019, showed that a fully oral regimen starting with 6 months of bedaquiline accompanied by 4–6 months of levofloxacin or moxifloxacin, ethionamide, ethambutol, pyrazinamide, high-dose isoniazid (10–15 mg/kg per day), and clofazimine, and followed by 5 months of levofloxacin (or moxifloxacin), clofazimine, pyrazinamide and ethambutol, was associated with low toxicity and better outcomes than the older, standardized, injectable-containing regimen when used in patients, including the HIV-infected, with no extensive pulmonary disease or severe extrapulmonary disease, fluoroquinolone resistance, or previous history of second-line drug use. The WHO therefore now recommends the adoption of this regimen and the progressive phasing-out of the previously recommended injectable-containing shorter regimen. The WHO also recommends that any modifications of a shorter regimen, where injectables are replaced by drugs other than bedaquiline, should be tested under operational research conditions and not adopted on a large programmatic scale until evidence shows their safety, tolerability, and efficacy.

The criteria used to define eligible patients are listed in **Table 178-5**. Adults and children eligible for the shorter regimen may still be offered the option of a new longer regimen if their completion of the full duration is adequately supported; with the longer regimen, the likelihood of relapse-free cure could be increased, and its administration is fully oral. As with any anti-TB regimen, the risk of creating additional resistance is high if the regimen is used incorrectly (e.g., in someone with preexisting fluoroquinolone resistance).

As in past recommendations, informed consent should be sought from patients treated with all MDR-TB regimens, and active TB drug safety monitoring is recommended. Patients taking QT interval–prolonging drugs (bedaquiline, delamanid, clofazimine, and fluoroquinolones) should be closely monitored, with electrocardiography performed at the start of treatment and repeated during treatment; patients with a QTc interval >500 ms or a history of ventricular arrhythmias should not be given these drugs. Patients taking amikacin should undergo serial audiometry to detect any hearing loss early on. Incentives and other forms of support can encourage patients not to interrupt treatment.

MDR-TB patients with additional resistance to fluoroquinolones and other second-line medicines have fewer treatment options and a poorer prognosis. However, the new longer regimen offers more options for a reasonably effective and tolerable regimen. The design of regimens for complex patterns of MDR-TB follows the same principles outlined in Table 178-4 through the selection of agents likely to be effective and tolerated. Observational studies have shown that aggressive management in such patients, with early drug susceptibility testing, use of a rational combination of at least five effective drugs, strict adherence to directly observed therapy, monthly bacteriologic monitoring, and intensive patient support, may—besides interrupting transmission—increase the chances of cure and avert death. For patients with localized disease and sufficient pulmonary reserve, lobectomy or wedge resection may be considered as part of treatment. A novel regimen composed of bedaquiline, the new nitroimidazole compound pretomanid, and linezolid (BPaL) administered orally for 6 months has been tested by the Global Alliance for TB Drug Development in South Africa in an open-label, single-group study enrolling 109 patients with MDR-TB caused by a strain with additional resistance to a fluoroquinolone or a second-line injectable drug, or were intolerant of therapy, or in whom treatment had failed. The cure rate was 90% after a 6-month course of treatment; the main toxicity, due to linezolid, consisted of peripheral neuropathy (81%) and myelosuppression (48%), which were manageable with dose reduction or interruption of the drug. Based on these findings, in August 2019 the FDA approved the new drug pretomanid under the Limited Population Pathway for Antibacterial and Antifungal Drugs (LPAD pathway) as part of a three-drug, 6-month, all-oral regimen for the treatment of a population of patients with MDR-TB caused by a strain with additional resistance to a fluoroquinolone or a second-line injectable drug, or who were intolerant of therapy, or in whom treatment had failed. Although approved by the FDA and proven as highly efficacious in the only trial available, in late 2019 the WHO suggested that this new 6–9 month regimen be used either under operational research conditions until more information is available on safety and efficacy or as a last resort in difficult-to-treat individual patients. A new, dose-blinded study reported in 2021 suggested that BPaL regimens where linezolid was used at reduced daily dose (from 1200 mg to 600 mg) and/or for a shorter period of time (from 6 to 2 months) were safer. Another regimen being tested by the Global Alliance is composed of bedaquiline, pretomanid, moxifloxacin, and pyrazinamide (BPaMZ). In a phase 2B trial, MDR-TB patients became culture-negative within 8 weeks of treatment three times faster than drug-sensitive TB patients treated with the standard regimen. The BPaMZ regimen is now being tested for both MDR-TB and drug-susceptible TB, with the aim of reducing treatment duration to 6 months and 4 months, respectively. Results are expected in late 2021.

Because the management of MDR-TB is complicated by both social and medical factors, care of seriously ill patients is ideally provided in specialized centers or, in their absence, in the context of programs with adequate resources and capacity, including community support. When patients are in stable condition, treatment and care on an ambulatory basis at a decentralized health care facility should be prioritized as this approach may increase treatment success and reduce loss to follow-up. This approach should not, however, preclude hospitalization when it is necessary. Respiratory infection-control measures should be observed throughout. As part of a patient-centered approach, palliative and end-of-life care should be provided as a priority when all recommended treatment options have been exhausted.

TABLE 178-5 Criteria for Offering a Shorter All-Oral Regimen (9–11 Months) to Patients with Confirmed Multidrug- or Rifampin-Resistant (MDR/RR) Tuberculosis (TB)

- Confirmed absence of resistance to or lack of suspicion of the ineffectiveness of a drug in the shorter MDR-TB regimen (except for isoniazid resistance)
- No history of exposure to one or more second-line drugs used in the shorter MDR-TB regimen (including bedaquiline) for >1 month
- Confirmed fluoroquinolone-susceptible disease
- No intolerance to drugs used in the shorter MDR-TB regimen or risk of toxicity (e.g., drug–drug interactions)
- No pregnancy
- No extensive pulmonary disease
- No disseminated, meningeal, or central nervous system TB
- Availability of all drugs in the shorter MDR-TB regimen

HIV-ASSOCIATED TB

Several observational studies and randomized controlled trials have shown that treatment of HIV-associated TB with anti-TB drugs and simultaneous use of ART is associated with significant reductions in mortality risk and AIDS-related events. Evidence from randomized controlled trials shows that early initiation of ART during anti-TB treatment is associated with a 34–68% reduction in mortality rates, with especially good results in patients with CD4+ T-cell counts of <50/μL. Therefore, the main aim in the management of HIV-associated TB is to initiate anti-TB treatment and to immediately consider initiating or continuing ART. All HIV-infected TB patients, regardless of CD4+ T-cell count, are candidates for ART, which optimally is initiated as soon as possible after the diagnosis of TB and with the strong recommendation to start within the first 8 weeks of anti-TB therapy; ART should be started within the first 2 weeks of TB treatment for profoundly immunosuppressed patients with CD4+ T-cell counts of <50/μL. In general, the standard 6-month daily regimen is equally efficacious in HIV-negative and HIV-positive patients with drug-susceptible TB. However, in the uncommon situation

where an HIV-infected patient cannot receive ART, prolongation of the continuation phase of TB treatment by 3 months can be considered. As in any other TB patient, intermittent regimens should not be used in HIV-infected people. As for any other adult living with HIV **(Chap. 202)**, first-line ART for TB patients consists of two nucleoside reverse transcriptase inhibitors plus a nonnucleoside reverse transcriptase inhibitor or an integrase or protease inhibitor. Recent guidelines have also considered a two-drug treatment consisting of one nucleoside reverse transcriptase inhibitor plus an integrase inhibitor. Although TB treatment modalities are similar to those in HIV-negative patients, adverse drug reactions may be more pronounced in HIV-infected patients. In this regard, three important considerations are relevant: an increased frequency of paradoxical reactions, interactions between ART components and rifamycins, and development of rifampin monoresistance with intermittent treatment. IRIS—i.e., the exacerbation of symptoms and signs of TB—has been described above. Rifampin, a potent inducer of enzymes of the cytochrome P450 system, lowers serum levels of many HIV protease inhibitors and some nonnucleoside reverse transcriptase inhibitors—essential drugs used in ART. In such cases, rifabutin, which has much less enzyme-inducing activity, has been used in place of rifampin. However, dosage adjustments for rifabutin and protease or integrase inhibitors are still being assessed. Several clinical trials have found that patients with HIV/TB co-infection whose degree of immunosuppression is advanced (e.g., CD4+ T-cell counts of <100/μL) are prone to treatment failure and relapse with rifampin-resistant organisms when treated with "highly intermittent" (i.e., once- or twice-weekly) rifamycin-containing regimens. Consequently, it is now recommended that all TB patients who are infected with HIV, like all other TB patients with rifampin-susceptible disease, receive a rifampin-containing regimen on a daily basis. Because recommendations are frequently updated, consultation of the following websites is advised: *www.who.int/hiv*, *www.who.int/tb*, *www.cdc.gov/hiv,* and *www.cdc.gov/tb.*

SPECIAL CLINICAL SITUATIONS

Although comparative clinical trials of treatment for extrapulmonary TB are limited, the available evidence indicates that most forms of disease should be treated with a 6-month regimen recommended for patients with pulmonary disease. For TB meningitis, the ATS, the CDC, and the IDSA recommend extension of the continuation phase for 7–10 months. The WHO and the American Academy of Pediatrics recommend that children with bone and joint TB, tuberculous meningitis, or miliary TB receive up to 12 months of treatment (2-month induction treatment followed by 10-month consolidation treatment). Treatment for TB may be complicated by underlying medical problems that require special consideration. As a rule, patients with chronic renal failure should not receive aminoglycosides and should receive ethambutol only if serum drug levels can be monitored. Isoniazid, rifampin, and pyrazinamide may be given in the usual doses in cases of mild to moderate renal failure, but the dosages of isoniazid and pyrazinamide should be reduced for all patients with severe renal failure except those undergoing hemodialysis. Patients with hepatic disease pose a special problem because of the hepatotoxicity of isoniazid, rifampin, and pyrazinamide. Patients with severe hepatic disease may be treated with ethambutol, streptomycin, and possibly another drug (e.g., a fluoroquinolone); if required, isoniazid and rifampin may be administered under close supervision. The use of pyrazinamide by patients with liver failure should be avoided. Silicotuberculosis necessitates the extension of therapy by at least 2 months.

The regimen of choice for pregnant women (Table 178-3) is 9 months of treatment with isoniazid and rifampin supplemented by ethambutol for the first 2 months. Although the WHO has recommended routine use of pyrazinamide for pregnant women in combination with isoniazid and rifampin, this drug has not been recommended for pregnant women in the United States because of insufficient data documenting its safety in pregnancy. Streptomycin is contraindicated because it is known to cause eighth-cranial-nerve damage in the fetus. The thioamides, bedaquiline, and delamanid should also be avoided in the treatment of pregnant women with MDR-TB. Treatment for TB is not a contraindication to breast-feeding; most of the drugs administered will be present in small quantities in breast milk, albeit at concentrations far too low to provide any therapeutic or prophylactic benefit to the child.

Medical consultation on difficult-to-manage cases is provided by the US CDC Regional Training and Medical Consultation Centers (*www.cdc.gov/tb/education/rtmc/*).

PREVENTION

The primary way to prevent TB is to diagnose and isolate infectious cases rapidly and to administer appropriate treatment until patients are rendered noninfectious (usually 2–4 weeks after the start of proper treatment) and the disease is cured. Additional strategies include BCG vaccination and preventive treatment of persons with TB infection who are at high risk of developing active disease.

BCG VACCINATION

Historically one of the most used vaccines in the history of medicine, BCG was derived from an attenuated strain of *M. bovis* and was first administered to humans in 1921. Many BCG vaccines are available worldwide; all are derived from the original strain, but the vaccines vary in efficacy, ranging from 80% to nil in randomized, placebo-controlled trials. A similar range of efficacy was found in observational studies (case-control, historic cohort, and cross-sectional) in areas where infants are vaccinated at birth. These studies and a meta-analysis also found higher rates of efficacy in the protection of infants and young children from serious disseminated forms of childhood TB, such as tuberculous meningitis and miliary TB. BCG vaccine is safe and rarely causes serious complications. The local tissue response begins 2–3 weeks after vaccination, with scar formation and healing within 3 months. Side effects—most commonly, ulceration at the vaccination site and regional lymphadenitis—occur in 1–10% of vaccinated persons. Some vaccine strains have caused osteomyelitis in ~1 case per million doses administered. Disseminated BCG infection ("BCGitis") and death have occurred in 1–10 cases per 10 million doses administered, although this problem is restricted almost exclusively to persons with impaired immunity, such as children with severe combined immunodeficiency syndrome or adults with HIV infection. BCG vaccination induces TST reactivity, which tends to wane with time. The presence or size of TST reactions after vaccination does not predict the degree of protection afforded.

BCG vaccine is recommended for routine use at birth in countries or among populations with high TB prevalence **(Fig. 178-13)**. However, because of the low risk of transmission of TB in the United States and other high-income countries, the variability in protection afforded by BCG, and its impact on the TST, the vaccine is not recommended for general use. HIV-infected adults and children should not receive BCG vaccine. Moreover, infants whose HIV status is unknown but who have signs and symptoms consistent with HIV infection or who are born to HIV-infected mothers should not receive BCG.

Over the past decade, renewed research and development efforts have been made toward a new TB vaccine, and several candidates have been developed and tested. The MVA-85A was the first new TB vaccine to be tested in a phase 2B proof-of-concept trial in infants in South Africa. Results published in 2013 showed that MVA-85A was well tolerated and modestly immunogenic but did not confer significant protection against clinical TB or *M. tuberculosis* infection. A second, more promising candidate vaccine, M72/AS01$_E$, a subunit vaccine pairing two *M. tuberculosis* antigens (32A and 39A) with the adjuvant M72/AS01$_E$, was recently tested in a randomized trial among 3575 patients with *M. tuberculosis* infection to prevent development of active disease. TB developed in 13 participants among those receiving the vaccine and in 26 among those receiving placebo with an estimated efficacy of 49.7% at 36 months. Adverse events were not different in the two groups. This vaccine is now being considered for further development.

As of the end of 2020, 14 candidate vaccines were in various stages of clinical trials. They included whole-cell or mycobacterial whole-cell

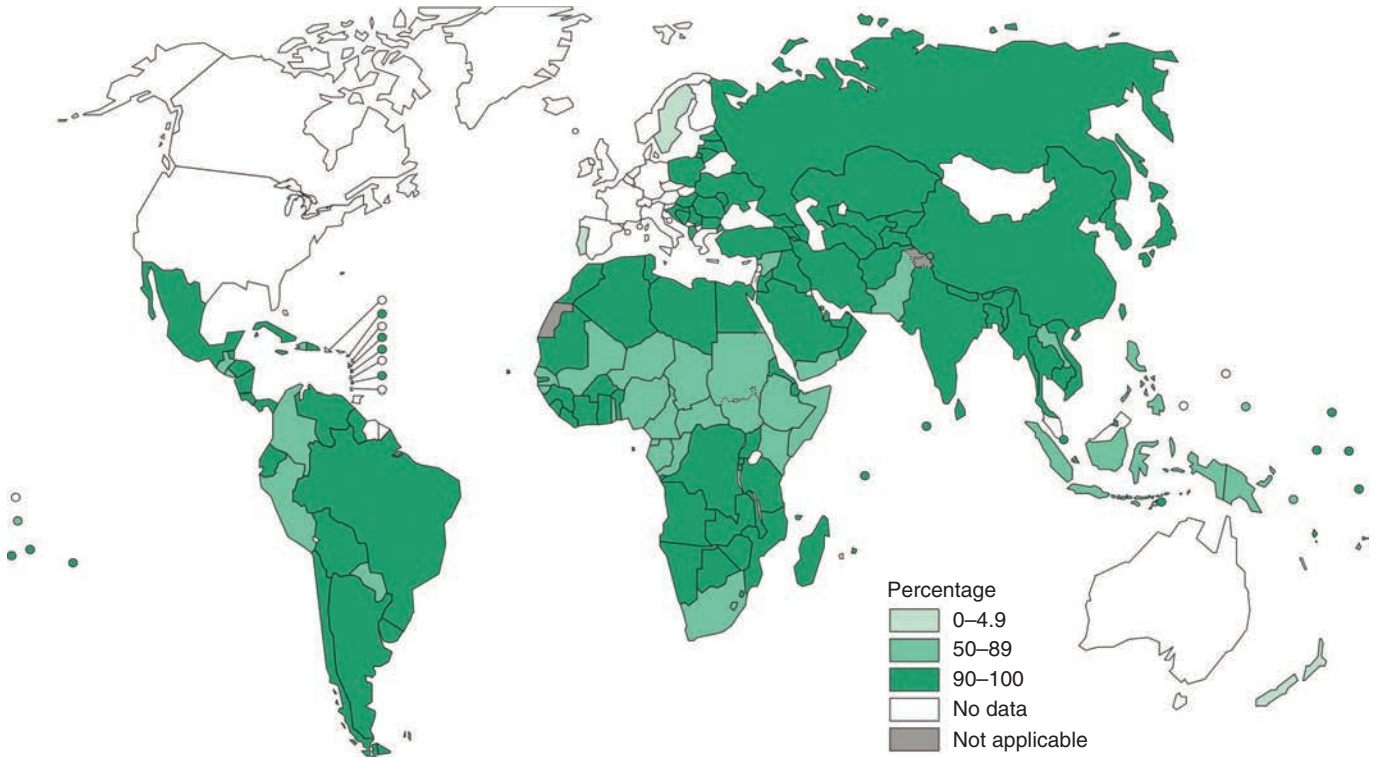

FIGURE 178-13 Coverage of BCG vaccination in 2018. The target population of BCG coverage varies depending on national policies but is typically for the number of live births in the year of reporting. *(See disclaimer in Fig. 178-2. Reproduced with permission from Global Tuberculosis Report 2019. Geneva, World Health Organization; 2019.)*

or lysates, viral vector vaccines, and adjuvant recombinant protein vaccines. Several challenges must be faced in the development of a TB vaccine. For instance, the lack of predictive animal models and protection correlates renders trials long and expensive. Furthermore, the decision about whether a candidate vaccine should be developed for prevention of infection (preexposure) or prevention of reactivation (postexposure) without an exact understanding of its precise mechanism of action is complex. Therefore, introduction of a new vaccine on a large scale is not likely in the near future. This step will require an intensified and much larger investment in research and development.

TB PREVENTIVE TREATMENT (TPT)

It is estimated that 1.7 billion people—more than one-quarter of the human population—have been infected with *M. tuberculosis*. Although only a small fraction of these infections will progress toward active disease in a lifetime, new active cases will continue to emerge from this pool of infected individuals. Therefore, TPT (also called *chemoprophylaxis* or *preventive chemotherapy*, and previously referred to as *treatment of latent TB infection*) is a fundamental intervention in TB control and elimination strategies.

Infection can be tested using TST or IGRA, although these tests just measure host immune response to TB antigens. Unfortunately, at present, there is no gold-standard diagnostic test that can confirm true infection (as opposed to immunologic memory of previous exposure) or predict which infected individuals will develop active TB. As a result, decisions to treat infection should include consideration of the risk of progression in an individual. For skin testing, five tuberculin units of polysorbate-stabilized PPD should be injected intradermally into the volar surface of the forearm (i.e., the Mantoux method). Multipuncture tests are not recommended. Reactions are read at 48–72 h as the transverse diameter (in millimeters) of induration; the diameter of erythema is not considered. In some persons, TST reactivity wanes with time but can be recalled by a second skin test administered ≥1 week after the first (i.e., two-step testing). For persons periodically undergoing the TST, such as health care workers and individuals admitted to long-term-care institutions, initial two-step testing may preclude subsequent misclassification of those who have boosted reactions as TST converters. The cutoff for a positive TST (and thus for TPT) is related both to the probability that the reaction represents true infection and to the likelihood that the individual, if truly infected, will develop TB. Table 178-6 suggests possible conventional cutoff by risk group. Thus, positive reactions for persons with HIV infection, recent close contacts of infectious cases, organ transplant recipients,

TABLE 178-6 Tuberculin Reaction Size and Cutoff for Tuberculosis (TB) Preventive Treatment

RISK GROUP	TUBERCULIN REACTION SIZE, mm
HIV-infected persons	≥5
Recent contacts of a patient with TB	≥5[a]
Organ transplant recipients	≥5
Persons with fibrotic lesions consistent with old TB on chest radiography	≥5
Persons who are immunosuppressed—e.g., due to the use of glucocorticoids or tumor necrosis factor α inhibitors	≥5
Persons with high-risk medical conditions[b]	≥5
Recent immigrants (≤5 years) from high-prevalence countries	≥10
Injection drug users	≥10
Mycobacteriology laboratory personnel; residents and employees of high-risk congregate settings[c]	≥10
Children <5 years of age; children and adolescents exposed to adults in high-risk categories	≥10
Low-risk persons[d]	≥15

[a]Tuberculin-negative contacts, especially children, should receive prophylaxis for 2–3 months after contact ends and should then undergo repeat tuberculin skin testing (TST). Those whose results remain negative should discontinue prophylaxis. HIV-infected contacts should receive a full course of treatment regardless of TST results. [b]These conditions include silicosis and end-stage renal disease managed by hemodialysis. [c]These settings include correctional facilities, nursing homes, homeless shelters, and hospitals and other health care facilities. [d]Except for employment purposes where longitudinal TST screening is anticipated, TST is not indicated for these low-risk persons. A decision to treat should be based on individual risk/benefit considerations.

Source: Adapted from Centers for Disease Control and Prevention: TB elimination—treatment options for latent tuberculosis infection (2011). Available at *http://www.cdc.gov/tb/publications/factsheets/testing/skintestresults.pdf.*

previously untreated persons whose chest radiograph shows fibrotic lesions consistent with old TB, and persons receiving drugs that suppress the immune system are defined as an area of induration ≥5 mm in diameter. A 10-mm cutoff is used to define positive reactions in most other at-risk persons. For persons with a very low risk of developing TB if infected, a cutoff of 15 mm is used. (Except for employment purposes where longitudinal screening is anticipated, the TST is not indicated for these low-risk persons.) A positive IGRA is based on the manufacturer's recommendations. Good clinical practice requires that, in addition to test results, epidemiologic and clinical factors also guide the decision to implement TPT and that active TB be definitively excluded before the initiation of a prophylactic regimen. The WHO recommends systematic testing for infection and TPT for the following groups at high risk of progression from infection to disease or of exposure and infection: adults, adolescents and children older than 12 months living with HIV; infants with HIV aged <12 months who are contacts of persons with TB; all household contacts of patients with infectious pulmonary TB including children <5 years of age; patients with silicosis, patients starting anti-TNF treatment, patients on dialysis, and patients preparing for organ or hematologic transplantation. In addition, testing and TPT may be considered for persons living or working in at-risk institutional or crowded settings, such as prisoners, health care workers, recent immigrants from high-TB-burden countries, and homeless people who use drugs.

Some TST- and IGRA-negative individuals are also candidates for TPT. Once an appropriate clinical evaluation has excluded active TB, infants and children <5 years of age who were in contact with infectious cases should be offered TPT even in the absence of a positive test for TB infection. HIV-infected persons >1 year of age who have been exposed to an infectious TB patient should receive TPT regardless of the TST result. Any HIV-infected candidate for TPT must be screened carefully to exclude active TB, which would necessitate full disease treatment. The use of a clinical algorithm based on four signs/symptoms (current cough, fever, weight loss, and night sweats) helps to decide which HIV-infected person can start TPT. The absence of all four symptoms tends to exclude active TB in people living with HIV. The presence of one of these four manifestations, on the other hand, warrants further investigation for active TB before TPT is started. Although a test of TB infection is prudent before starting TPT, this test is not an absolute requirement—given the logistical challenges—among contacts aged <5 years and people living with HIV in high-TB-incidence and low-resource settings.

Among people living with HIV and receiving ART, conversion of the TST from negative to positive can occur during the first few months of TPT. Conversions (from negative to positive) and reversions (from positive to negative) are more common with IGRAs than with TSTs among serially tested health care workers in the United States.

TPT in selected persons at risk aims at preventing active disease and, in the absence of an immunizing vaccine, is a critical component of TB elimination strategies. Potential candidates for TPT are listed in Table 178-6. This intervention is based on the results of a large number of randomized, placebo-controlled clinical trials demonstrating that a 6- to 9-month course of isoniazid reduces the risk of active TB in infected people by up to 90%. Analysis of available data indicated that the optimal duration of treatment with this drug was ~9 months. In the absence of reinfection, the protective effect is believed to be lifelong. Clinical trials have shown that isoniazid reduces rates of TB among TST-positive persons with HIV infection. Studies in HIV-infected patients have also demonstrated the effectiveness of shorter TPT regimens containing a rifamycin. Several TPT regimens **(Table 178-7)** can be used. The most widely used has been that based on isoniazid alone at a daily dose of 5 mg/kg (up to 300 mg/d) for 9 months. On the basis of cost–benefit analyses and concerns about feasibility, a 6-month period of treatment at the same dose is considered adequate by the WHO. An alternative regimen for adults is 4 months of daily rifampin, which should also be effective against isoniazid-resistant strains. A 3-month regimen of daily isoniazid and rifampin is used in some countries (e.g., the United Kingdom) for both adults and children who are known not to have HIV infection. A previously recommended 2-month regimen of rifampin and pyrazinamide has been associated with serious or even fatal hepatotoxicity and is not recommended. The rifampin-containing regimens should be considered for persons who are likely to have been infected with an isoniazid-resistant strain. A clinical trial showed that a regimen of isoniazid (900 mg) and rifapentine (900 mg), given once weekly for 12 weeks, is as effective as the standard 9-month isoniazid regimen. This regimen was associated with higher rates of treatment completion (82% vs 69%) and less hepatotoxicity (0.4% vs 2.7%) than isoniazid alone, although the rate of permanent discontinuation due to an adverse event was higher (4.9% vs 3.7%).

Currently, the isoniazid–rifapentine regimen is not recommended for children <2 years of age or pregnant women. Recently, an open-label, randomized, phase 3 noninferiority trial has shown that among HIV-infected persons, a 1-month regimen of daily rifapentine plus isoniazid was noninferior to the 9-month daily isoniazid regimen and ensured a higher treatment completion. As a result, the WHO has included a 1-month regimen composed of daily isoniazid (300 mg) and rifapentine (600 mg) among the available options for people aged 13 years or more. Rifampin and rifapentine are contraindicated in HIV-infected individuals receiving protease inhibitors, most nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine), and, for those with chronic hepatitis B, tenofovir alafenamide. However, efavirenz and tenofovir disoproxil can be used for simultaneous administration with a rifamycin without dose adjustment. However, the dose of the integrase inhibitor dolutegravir needs to be increased to 50 mg twice daily when given together with rifampin, a dose that is usually well tolerated and gives equivalent efficacy in viral suppression and recovery of CD4+ cell count compared with efavirenz. Administration of rifapentine with raltegravir was found to be safe and well tolerated. A recent phase 1/2 trial of the 3-month regimen isoniazid plus rifapentine and dolutegravir in adults with HIV reported good tolerance and viral load suppression, no adverse events of grade >3, and did not indicate that rifapentine reduced dolutegravir levels sufficiently to require dose adjustment. Clinical trials to assess the efficacy of long-term isoniazid administration (i.e., for at least 3 years) among people living with HIV in high-TB-transmission settings have shown that this regimen can be more effective than 9 months of isoniazid and is therefore

TABLE 178-7 Recommended Regimens and Drug Dosages for Tuberculosis Preventive Treatment[a]

REGIMEN	DOSE	ADVERSE EVENTS
Isoniazid alone for 6 or 9 months	Adults: 5 mg/kg (max, 300 mg) per day Children <10 years of age: 10 mg/kg per day (range, 7–15 mg)	Drug-induced liver injury, nausea, vomiting, abdominal pain, skin rash, peripheral neuropathy, dizziness, drowsiness, seizure
Rifampin alone for 4 months	Adults: 10 mg/kg per day Children <10 years of age: 15 mg/kg (range, 10–20 mg) per day	Flulike syndrome, skin rash, drug-induced liver injury, anorexia, nausea, abdominal pain, neutropenia, thrombocytopenia, renal reactions (e.g., acute tubular necrosis and interstitial nephritis)
Isoniazid plus rifampin for 3 months	As above	As above
Rifapentine plus isoniazid for 3 months	Adults and children: Isoniazid: 15 mg/kg (900 mg) weekly Rifapentine: 15–30 mg/kg (900 mg) weekly	Hypersensitivity reactions, petechial skin rash, drug-induced liver injury Anorexia, nausea, abdominal pain Hypotensive reactions
Rifapentine plus isoniazid for 1 month	Age >13 years only: Isoniazid 300 mg and rifapentine 600 mg daily (28 doses)	Essentially like those of isoniazid alone with neutropenia more common and elevation in liver enzyme levels and neuropathy less common

[a]See text for full description of evidence on and limitations of these regimens.

Source: Reproduced with permission from World Health Organization.

recommended under those circumstances. Studies looking at whether briefer treatment with rifapentine-based regimens could achieve similar efficacies have been undertaken. Isoniazid should not be given to persons with active liver disease. All isoniazid recipients at increased risk of hepatotoxicity (e.g., those abusing alcohol daily and those with a history of liver disease) should undergo baseline and then monthly assessment of liver function; they should be carefully educated about hepatitis and instructed to discontinue use of the drug immediately should any symptoms develop. Moreover, these patients should be seen and questioned monthly during therapy about adverse reactions and should be given no more than a 1-month supply of drug at each visit. Persons receiving high-dose isoniazid and who are at risk of vitamin B6 (pyridoxine) deficiency, as listed above, should receive pyridoxine to prevent peripheral neuropathy.

TPT among persons likely to have been infected by a multidrug-resistant strain is a challenge because no clinical trial results are available to guide treatment. Close observation for early signs of disease is one option. However, in selected high-risk household contacts of patients with MDR-TB (e.g., children, recipients of immunosuppressive therapy), TPT may be considered on the basis of individualized risk assessment and clinical criteria. In the absence of evidence of efficacy of any regimen, important factors in the decision to treat include intensity of exposure, certainty about a source case, information on the drug resistance pattern of the index case, and potential adverse events. Confirmation of infection with available testing is generally required. Drug selection should be based on the drug susceptibility profile of the index case. One regimen recommended by the WHO is daily levofloxacin (750–1000 mg daily among adults) for 6 months.

It may be more difficult to ensure adherence to TPT than when treating those with active TB. If family members of patients with active TB are being treated, adherence and monitoring may be easier. When feasible, supervised therapy may increase the likelihood of completion. As in active cases, the provision of incentives may also be helpful. Currently, no evidence shows that large-scale use of TPT leads to significant development of drug resistance. However, before TPT begins, it is mandatory to carefully exclude active TB in order to prevent undertreatment and promote development of drug resistance.

PRINCIPLES OF TB CONTROL

The highest priority in any TB control program is the prompt detection of cases and the provision of treatment to all TB patients under proper case-management conditions, including DOT and social support. In addition, screening of high-risk groups, including immigrants from high-prevalence countries, migrant workers, prisoners, homeless individuals, substance abusers, and HIV-seropositive persons, is recommended. TST- or IGRA-positive high-risk persons should receive TPT as described above. Contact investigation is an important component of efficient TB control. In the United States and other countries worldwide, a great deal of attention has been given to the transmission of TB (particularly in association with HIV co-infection) in institutional settings such as hospitals, homeless shelters, and prisons. Measures to limit such transmission include respiratory isolation of persons with suspected TB until they are proven to be noninfectious (at least by sputum AFB smear negativity), proper ventilation in rooms of patients with infectious TB, use of ultraviolet irradiation in areas of increased risk of TB transmission, correct use of personal protective equipment, and periodic screening of personnel who may come into contact with known or unsuspected cases of TB. In the past, radiographic surveys, especially those conducted with portable equipment and miniature films, were advocated for case finding. Today, however, the prevalence of TB in industrialized countries is sufficiently low that "mass miniature radiography" is not cost effective.

In high-prevalence countries, most TB control programs have made remarkable progress in reducing morbidity and mortality since the mid-1990s by adopting and implementing the standards and strategies internationally promoted by the WHO. Between 2000 and 2018, more than 60 million lives are estimated to have been saved. The essential elements of good TB care and control were established in the mid-1990s and consist of well-defined interventions that were the basis of the "DOTS strategy": early detection of cases and bacteriologic confirmation of the diagnosis; administration of standardized short-course chemotherapy, with direct supervision to ensure adherence to treatment and the provision of social support to patients; availability of drugs of proven quality, with an effective supply and management system; and a monitoring and evaluation system, including assessment of treatment outcomes—e.g., cure, completion of treatment without bacteriologic proof of cure, death, treatment failure, and default—in all cases registered and notified as well as measurement of the impact of control methods on classical TB indicators such as mortality, incidence, prevalence, and drug resistance. In 2006, the WHO indicated that, besides pursuing these essential elements that remain the fundamental components of any control strategy, additional steps had to be undertaken in order to reach international TB control targets. These steps included addressing HIV-associated TB and MDR-TB with additional measures; operating in harmony with general health services; engaging all care providers beyond the public providers; empowering people with TB and their communities; and enabling and promoting research. Evidence-based International Standards for Tuberculosis Care—focused on diagnosis, treatment, and public health responsibilities—were introduced for wide adoption by medical and professional societies, academic institutions, and all practitioners worldwide.

Care and control of HIV-associated TB are particularly challenging in poor countries because existing interventions require collaboration between HIV/AIDS and TB programs as well as standard services. TB programs must test every patient for HIV in order to provide access to trimethoprim-sulfamethoxazole prophylaxis against common infections and ART. HIV/AIDS programs must regularly screen persons living with HIV/AIDS for active TB, provide TPT, and ensure infection control in settings where people living with HIV congregate.

Early and active case detection is considered an important intervention not only among persons living with HIV/AIDS but also among other vulnerable populations, as it reduces transmission in a community and provides early effective care. Additional measures are indicated for the management of MDR-TB, RR-TB, and other forms of drug-resistant TB; they include upgrades of laboratory capacity to perform rapid DST and ensure surveillance of drug resistance; availability of drug regimens that are recommended for RR/MDR-TB, with assured quality of drugs; and infection control measures in all settings where patients with drug-resistant forms of TB may congregate. In the new era of the United Nations Sustainable Development Goals (2016–2030), the approach to TB control and care needs to evolve further and become multisectoral and more holistic. Engagement beyond dedicated programs and even the health sector is now essential. Therefore, the new "End TB" strategy promoted by the WHO since 2016 builds on three pillars and relies on increased investments and efforts by all governments, their national programs, and a multitude of partners within and beyond the health sector: (1) integrated, patient-centered care and prevention; (2) bold policies and supportive systems; and (3) intensified research and innovation. The first pillar incorporates all technological innovations, such as early diagnostic approaches (including universal DST and systematic screening of identified, setting-specific, high-risk groups); well-designed treatment regimens for all forms of TB; proper management of HIV-associated TB and other comorbidities; and preventive treatment of persons at high risk. The second pillar is fundamental and is normally beyond the scope of dedicated programs, relying on policies forged by the highest-level health and governmental authorities: availability of adequate human and financial resources; engagement of civil organizations and all relevant public and private providers to pursue proper care for all patients and prevention for all people at risk; a policy of universal health coverage (which, together with social protection, implies avoidance of catastrophic expenditures caused by TB among the poorest); regulatory frameworks for case notifications, vital registration, quality and rational use of medicines, and infection control; social protection mechanisms as part of poverty alleviation strategies; and promotion of interventions against the broader determinants of TB. Finally, the third pillar of the new strategy emphasizes intensification of research and development on new tools and interventions as well as optimal

implementation and rapid adoption of new tools in endemic countries. Besides specific clinical care and control interventions as described in this chapter, elimination of TB in a society ultimately will require control and mitigation of the multitude of direct risk factors (e.g., HIV infection, smoking, alcohol abuse, diabetes) and socioeconomic determinants (e.g., extreme poverty, inadequate living conditions and poor housing, malnutrition, indoor air pollution) with clearly implemented policies within the health sector and other sectors linked to human development and welfare.

179 Leprosy

Jan H. Richardus, Hemanta K. Kar, Zoica Bakirtzief, Wim H. van Brakel

Leprosy, also referred to as Hansen's disease, is a chronic infectious disease caused by *Mycobacterium leprae*. The clinical manifestations are largely confined to the skin, peripheral nervous system, eyes, and upper respiratory tract. The differing immune responses to *M. leprae* result in a spectrum of disease ranging from tuberculoid to lepromatous leprosy. *M. leprae* has a predilection for peripheral nerves, and immunologically mediated reactional states can cause nerve damage to the face, arms, and legs; this damage often results in disability, which in turn can lead to stigma and social exclusion. The physical disfigurement that accompanies leprosy has left marks on society that have endured long after the disease's disappearance in many countries. In everyday language, leprosy has become a metaphor for a horrible condition that warrants social exclusion. Leprosy is a neglected disease and is often thought no longer to exist. However, 202,185 new cases from 150 countries were reported in 2019. A general lack of awareness among both the public and medical practitioners often delays diagnosis and treatment and thus results in irreversible impairments. Early diagnosis and treatment of leprosy and leprosy reactions can cure the disease and prevent most chronic complications.

ETIOLOGY

M. leprae is an obligate, intracellular, acid-fast staining, rod-shaped bacterium, measuring 1–8 μm in length and 0.3 μm in diameter. *M. leprae* mostly appears irregularly stained and fragmented or granular, in which case the organism is usually considered to be dead. The few bacteria that are brightly and uniformly stained are thought to be solid, viable bacilli**.** The morphologic index is a measure of uniformly stained solid bacilli on slit-skin smear examination and is calculated as the percentage of viable bacilli among the total number of bacilli counted under oil-immersion microscopy. On slit-skin smear examination at the lepromatous end of the disease spectrum, *M. leprae* is predominantly found in clumps or globi within macrophages (*lepra cells*). Inside these cells, *M. leprae* multiplies in unrestricted fashion, and hundreds of bacilli may be present; the organisms are arranged in parallel arrays placed side by side as a result of the presence of surface lipids (*glial substances*). The bacteriologic index is a logarithmic-scaled measure of the density of bacilli of all forms found in the dermis upon slit-skin smear examination, varying from 0 to 6+ (with or without globi) from the tuberculoid to the lepromatous end of the disease spectrum. The bacteriological index falls an average of 1 log unit per year with multidrug therapy. *M. leprae* infects mainly macrophages and Schwann cells. It has never been grown in artificial media. Reproduction occurs by binary fission, and the organism grows slowly (over 12–14 days) in the footpads of mice. The temperature required for survival and proliferation—between 27°C and 30°C—explains the greater impact of the disease on surface areas such as the skin, peripheral nerves, testicles, and upper airways, with less inner visceral involvement. *M. leprae* remains viable for 9 days in the environment.

Ultrastructural Characteristics of *M. leprae* Electron microscopy reveals that *M. leprae* has a cytoplasm, plasma membrane, cell wall, and capsule. The cytoplasm contains structures common in gram-positive microorganisms. The plasma membrane has a permeable lipid bilayer containing interacting proteins—the protein surface antigens. Similar to that of other mycobacteria, *M. leprae*'s cell wall, which is attached to the plasma membrane, is composed of peptidoglycans bound to branched-chain polysaccharides; these peptidoglycans are arabinogalactans, which support mycolic acids, and lipoarabinomannan (LAM). The capsule—the outermost structure—contains lipids, particularly phthiocerol dimycocerosate and phenolic glycolipid (PGL-1), which has a trisaccharide bound to lipid by a molecule of phenol. Because this trisaccharide is antigenically specific for *M. leprae*, its detection is helpful in serologic diagnosis of leprosy.

Genome of *M. leprae* Comparative analysis of the genomics of single-nucleotide polymorphisms indicates that four distinct strains of *M. leprae* originated in East Africa or Central Asia. A mutation spread to Europe and subsequently underwent two separate mutations that were then followed by spread to West Africa and the Americas. The genome of *M. leprae* is circular. Its estimated molecular mass is 2.2×10^9 Da, with 3,268,203 base pairs and a guanine-pluscytosine content of 57.8%.

Culture Difficulties Compared to the genome of *Mycobacterium tuberculosis,* that of *M. leprae* underwent reductive evolution, resulting in a smaller genome rich in inactive or entirely deleted genes. This reductive evolution, gene decay, and genome downsizing all may explain the unusually long generation time and may account for the inability to culture the leprosy bacillus in artificial media. As a result,

propagation of *M. leprae* has been restricted to animal models, including the armadillo and normal, athymic, and gene-knockout mice. These systems have provided the basic resources for genetic, metabolic, and antigenic studies of the bacillus. Growth of *M. leprae* in mouse footpads also provides a tool for assessing the viability of the bacteria and testing the drug susceptibility of clinical isolates.

Immunologic Properties of *M. leprae* *M. leprae* induces both humoral and cell-mediated immune responses. The immunogenic components of *M. leprae* include polysaccharides and proteins. Polysaccharide components induce mainly a humoral immune response, whereas protein components induce both humoral and cell-mediated immune responses. The immunogens in *M. leprae* form two distinct groups: cytoplasmic antigens and antigens from the mycobacterial cell. As mentioned above, a species-specific phenolic glycolipid, PGL-1, has been identified in *M. leprae*. Other varieties of *M. leprae* antigens identified with monoclonal antibodies include antigens of 18, 28, 7, 14, 36, 65, and 70 kDa that may possibly induce an immune response.

Mycobacterium lepromatosis In 2008, a new mycobacterial species, *M. lepromatosis*, was isolated from patients with a special type of diffuse lepromatous leprosy known as *diffuse leprosy of Lucio and Latapí*. This clinical variety of leprosy is found mainly in Mexico and Central America. *M. lepromatosis* is very similar to *M. leprae* microbiologically and clinically. Microbiologically, both species are acid-fast and noncultivable and preferably infect skin and peripheral nerves. Clinically, differentiation of *M. lepromatosis* from *M. leprae* in individual patients is not diagnostically necessary since both organisms respond well to the same antimycobacterial regimens.

EPIDEMIOLOGY

Incidence, Prevalence, and Disability The true incidence of leprosy is difficult to establish because the figure is very low and because the initial signs and symptoms are often insidious, and thus not all cases are detected as they occur. In 2019, as stated earlier, 202,185 new cases were reported to the World Health Organization (WHO) from 150 countries. New case detection per year is commonly used as a proxy for incidence, but operational factors, such as the intensity of case detection, the use of surveys, the use of contact tracing, the level of community awareness, and the quality and availability of health care, have a profound effect on case detection rates. In nonendemic countries around the world, leprosy is often misdiagnosed simply because it is not considered.

The registered prevalence of leprosy is defined as the number of patients receiving treatment at a point in time (usually at the end of a calendar year). The registered prevalence is a proxy measure for true prevalence, which would include existing cases that have not yet been detected. The two factors that determine the registered prevalence are the new case detection rate and the duration of treatment; changes in either factor will affect the registered prevalence.

The WHO leprosy disability grading system scores patients according to the presence of disabilities of the eyes, hands, and feet. For the hands and feet, grade 0 means no anesthesia and no visible impairment; grade 1 signifies anesthesia but no visible impairment; and grade 2 indicates visible impairment. For the eyes, grade 0 signifies no eye problems due to leprosy and no evidence of visual loss; grade 1 signifies eye problems due to leprosy without severe effects on vision; and grade 2 indicates severe visual impairment (vision score worse than 6/60; inability to count fingers at 6 meters) and also includes lagophthalmos, iridocyclitis, and corneal opacities. The sum score for these six body sites is called the Eye-Hand-Foot (EHF) score and is used as an overall indicator of the impairment status of a person with leprosy. Leprosy-related grade 2 disability is usually reported as the proportion of people with such disability at any site among patients newly diagnosed with leprosy in a specific year.

The global trend in new case detection since 1985 is presented in Fig. 179-1. The trend was remarkably static up to the year 2001, with a peak around the year 2000; fell dramatically between 2001 and 2005; and has leveled off since 2006. The most important factor contributing to the fast downward trend was the decline in leprosy control activities following the declaration by the WHO in 2000 that leprosy was eliminated as a "public health problem." *Elimination* was defined as a prevalence of <1 case per 10,000 population at the global level. The attainment of this target was a great achievement but led many to believe that the problem of leprosy was solved altogether. This misunderstanding in turn led to reduced political commitment to leprosy control programs and facilities, with consequent downsizing and decreased funding. The stabilization of the new case detection rate at just over 200,000 cases annually since 2006 indicates that transmission of *M. leprae* is continuing unabated, posing an enormous challenge in leprosy control.

Sex, Age, and Geographic Distribution Approximately 40% of all reported leprosy patients are women, but the low proportion in some countries raises concerns about underdiagnosis in women due to poor access to health services, illiteracy, low status, and other cultural factors. The age-specific incidence often shows a bimodal pattern, with peaks in the teenage years and in adulthood. Around 8% of all newly detected cases are found in children (<15 years of age), a measure that is often taken as an indicator of continued (recent) transmission. Leprosy is rare among children <5 years of age. Around 5% of all patients have a grade 2 disability.

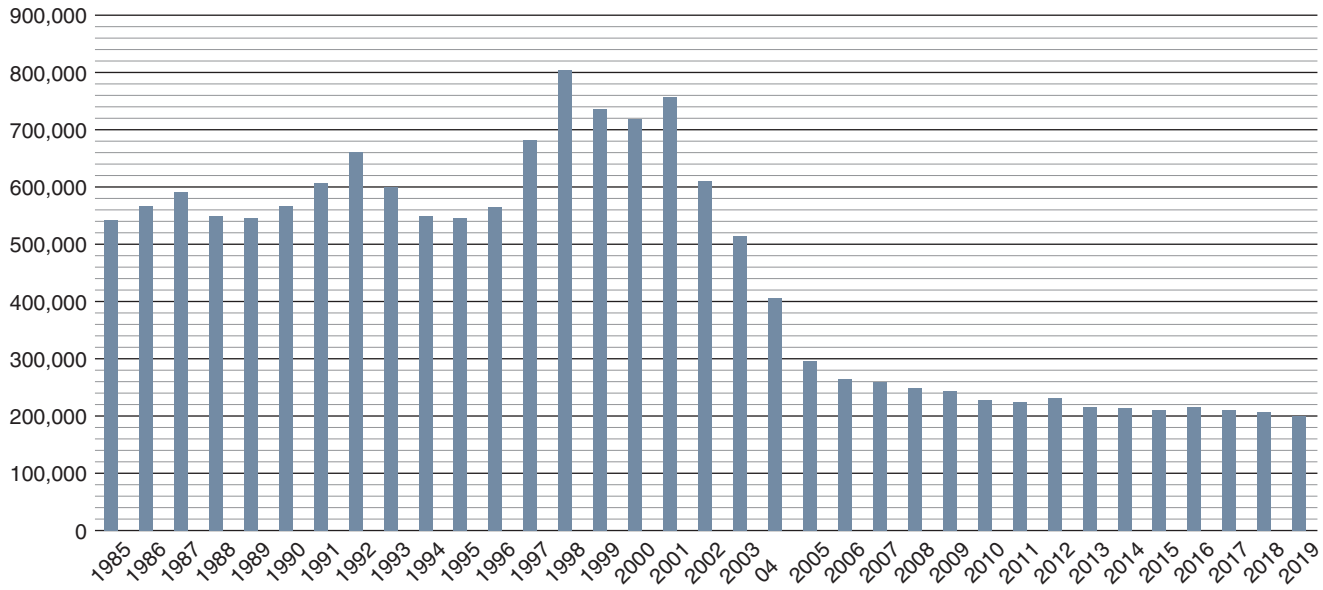

FIGURE 179-1 Global trend in leprosy new-case detection, 1985–2019.

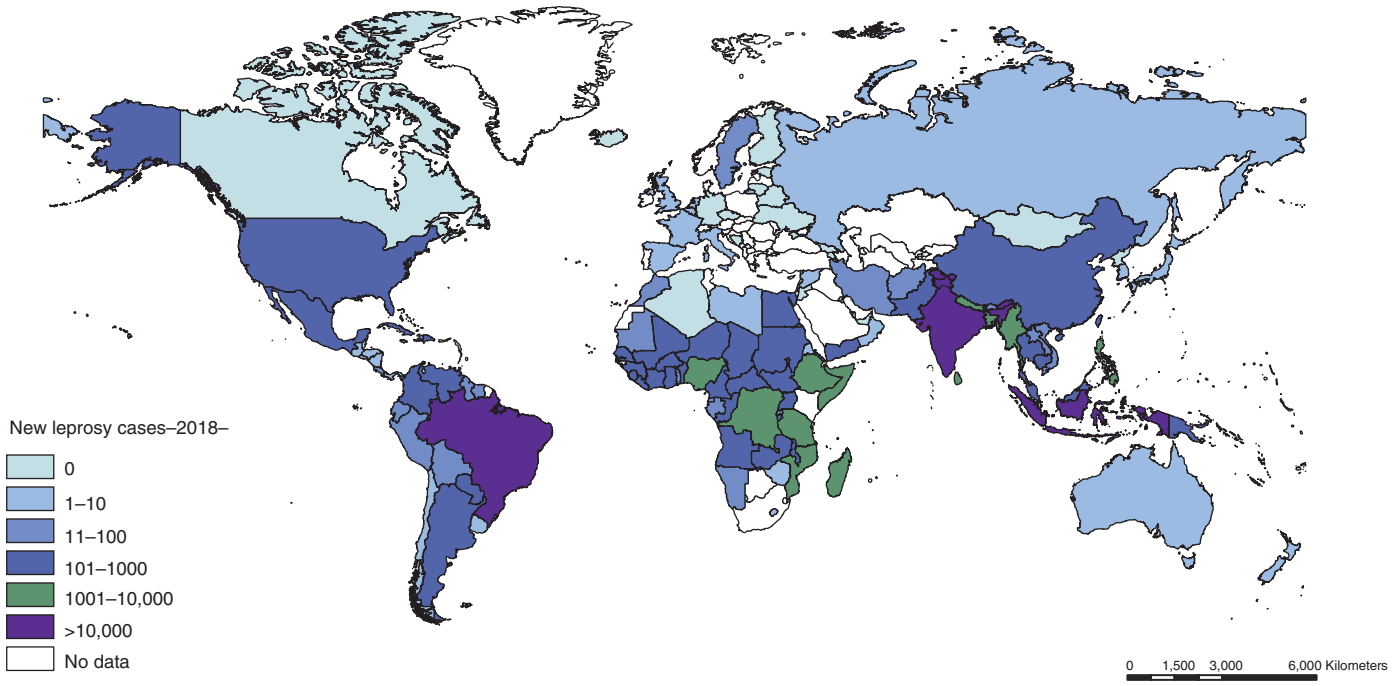

FIGURE 179-2 Geographic distribution of new leprosy cases, 2018. *(Reproduced with permission from Global leprosy update, 2018: moving towards a leprosy-free world. Wkly Epidemiol Rec 35/36:389, 2019.)*

There are large variations among world regions and countries in new case detection rates. Approximately 80% of global new case detection is reported from India, Brazil, and Indonesia. There are also distinct geographic variations within countries, with differences between urban and rural communities and clustering of cases at the village or neighborhood level. Geographic variations can be due to differences in health service provision, socioeconomic development, isolation, and poverty. Figure 179-2 depicts the geographic distribution of new leprosy cases in 2018.

Transmission Understanding of the transmission of *M. leprae* is limited. The existing evidence is largely circumstantial because of the long incubation period from exposure to disease, the inability to culture *M. leprae*, and the difficulty of diagnosing both infection and early disease. *M. leprae* organisms can be shed in large numbers from the mouth and nose of patients with untreated multibacillary leprosy (droplet infection) and sometimes from damaged skin, but it is unclear whether patients with paucibacillary leprosy can spread the bacillus. There is evidence for transmission between humans and—in southern U.S. states—for zoonotic transmission through wild armadillos. The main route of entry into the body is assumed to be the respiratory tract, but in patients with wounds or tattoos, transmission through the skin also is possible.

Reservoirs of Infection It is assumed that humans are the main reservoir of infection for *M. leprae*. The armadillo is also a reservoir for human infection. Certain species of monkeys and red squirrels are infected with *M. leprae* in the wild, but there is no evidence of transmission to humans through contact with these animals. Evidence is weak for the potential of water and soil as environmental sources of *M. leprae*. The higher incidence rate of leprosy among household contacts of multibacillary cases than among those of paucibacillary cases suggests that multibacillary cases represent an important reservoir for undetected and untreated cases in the community; that is, a prolonged period between the onset of signs of leprosy and treatment due to a delay in diagnosis and initiation of multidrug therapy increases exposure in the community. Persons with subclinical leprosy are likely to be a main source of infection, given that multidrug therapy for clinical leprosy apparently has not made an impact on transmission.

Incubation Period, the Role of Contacts, and Genetic Susceptibility The incubation period of leprosy is estimated to range from 2 to ≥10 years. The incubation period for multibacillary leprosy appears to be longer (5 to ≥10 years) than that for paucibacillary leprosy (~2–5 years). Poverty-associated factors such as low level of education, poor hygiene, and food shortages have been identified as risk factors for leprosy, but the most important risk factors are associated with intimacy and duration of contact with a leprosy patient, in particular with an index case with multibacillary leprosy, and the intensity of contact with and physical distance from the index patient. Increasing evidence from studies in twins and from observational studies supports host genetic susceptibility to leprosy. Ongoing studies are exploring the mechanism underlying genetic susceptibility to leprosy and its clinical manifestations.

PATHOGENESIS

Whatever the route of *M. leprae*'s entry into the human body, the pathogenic process usually starts in the peripheral nerves. Once bacilli are engulfed by Schwann cells, the histopathologic changes in nerve and skin—and thus the type of leprosy that develops—depend on the immunologic resistance of the person infected, in particular on the cell-mediated immune (CMI) response to the bacillus and its antigens.

Ridley-Jopling Classification of Leprosy In 1962, Ridley and Jopling described five overlapping categories of leprosy: tuberculoid (TT), borderline tuberculoid (BT), mid-borderline (BB), borderline lepromatous (BL), and lepromatous (LL). An early clinical manifestation is recognized and referred to as indeterminate leprosy (IL). Immunologic resistance is strong at the tuberculoid end of the spectrum, gradually diminishes through the borderline spectrum, and is weakest in lepromatous leprosy. The LL and TT types of leprosy are relatively stable, with little or no change in clinical disease expression over time, while the BL, BB, and BT types are unstable both clinically and immunologically. Further distinction indicates that subpolar types of TT and LL leprosy (TTs and LLs) are less stable than polar types (TTp and LLp). The immune reaction depends on predisposing genetic factors and the extent of exposure to *M. leprae*. The host tissue's reaction and related damage are largely due to delayed hypersensitivity. In response to the presence of *M. leprae*, a granuloma is formed either by macrophage–lymphocyte interaction when there is immunity or otherwise by macrophages only. The formation of a granuloma is preceded by a stage of infiltration by lymphocytes alone, as is seen in IL. Because of the strong immune response toward the tuberculoid end of

AFKEBOOKS
SINCE 2013

the spectrum, macrophages, along with many lymphocytes, become fixed epithelioid cells, and groups of these cells become giant cells. The tuberculoid granuloma leads to nerve destruction resulting in anesthesia and muscle weakness. The cellular response is less focal and less destructive in the borderline portion of the spectrum; consequently, there is less damage to nerves and few bacilli are present. In BL leprosy, there are macrophage granulomas along with lymphocytes, but little nerve damage and more bacilli. In LL leprosy, bacilli multiply within Schwann cells and perineural cells. Liberated bacilli from these cells are engulfed by histiocytes, becoming wandering macrophages and traveling throughout the body to other nerves and tissues via blood, lymph, and tissue fluids. In addition, there are diffuse lepromas in LL leprosy that consist of histiocytes and/or macrophages, with very few lymphocytes and plasma cells. The bacilli are packed within macrophages called *globi* and outside macrophages either singly or in small groups.

WHO Simplified Clinical Classification of Leprosy Ridley-Jopling classification requires clinical and pathologic expertise that does not exist in many settings. The WHO has therefore introduced a simplified classification system based on slit-skin smear: patients with negative slit-skin smear results at all body sites are classified as having paucibacillary leprosy, whereas patients with positive smears at any body site are classified as having multibacillary leprosy. However, because slit-skin smear facilities are not available or dependable in many countries, most leprosy control programs use clinical criteria only for classifying leprosy and deciding on the appropriate treatment regimen for individual patients. In this circumstance, paucibacillary leprosy is defined as one to five skin lesions and no or only one involved peripheral nerve, while multibacillary leprosy is defined as six or more skin lesions and/or more than one involved peripheral nerve.

CLINICAL MANIFESTATIONS

Leprosy is a disease affecting mainly the skin, cutaneous and peripheral nerves, mucous membranes, and, less commonly, other sites such as joints, lymph nodes, eyes, and testes. Other systemic manifestations may occur, particularly in BL and LL disease, with or without leprosy reactions. Most dermal and cutaneous nerves feeding skin lesions are affected—e.g., the supraorbital, great auricular, radial cutaneous, infrapatellar, superficial fibular, and sural nerves and the cutaneous nerves of the thigh. The peripheral nerves involved include the ulnar, median, radial (in upper limbs), lateral popliteal, and posterior tibial (in lower limbs). The cranial nerves commonly involved are the trigeminal and facial.

Indeterminate Leprosy (IL) This early clinical type manifests as one or a few hypopigmented or faintly erythematous, ill-defined to well-defined macular lesions measuring 1–5 cm in diameter. These lesions invariably occur on the external aspects of the limbs, buttocks, and face, with mild to moderate impairment of touch and/or thermal sensations. There is no thickening of the corresponding cutaneous and peripheral nerves. IL is often, but not always, the first clinical sign of leprosy. This type either heals spontaneously or progresses to a determinate form of the disease (TT, BT, BB, BL, or LL), depending on CMI status.

Tuberculoid (TT) Leprosy TT leprosy (Fig. 179-3) presents either as a well-defined, hypopigmented macule or as a raised, erythematous/brown/copper-colored plaque with a well-defined edge. The lesions may be found on any part of the skin and are characterized by complete loss of fine touch and temperature sensations over their surface. Skin lesions are single or few (up to three) in number and can be of any size, but they seldom measure >10 cm in diameter. In plaque-type lesions, the raised clear-cut edge often slopes inward to a flattened and sometimes hypopigmented central area, acquiring an annular configuration. The skin surface of both macular and plaque lesions is dry, hairless, and anesthetic because of destruction of underlying superficial cutaneous nerves. Larger corresponding cutaneous nerves are thickened in a limited number of cases. On the face, sensory impairment may be difficult to demonstrate because of the generous and bilateral supply of sensory nerve endings. Autonomic nerve damage within the lesion is responsible for surface dryness and loss of sweating over the lesion. A solitary peripheral-nerve trunk in the vicinity of a lesion may be thickened, with sensory loss of the area supplied and with or without motor disfigurement. On slit-skin smear examination, no acid-fast bacilli (AFB) are normally found. The lepromin skin test is strongly positive, signifying good host CMI status.

FIGURE 179-3 Tuberculoid (TT) leprosy. Hypopigmented macular lesion with a well-defined edge and loss of fine-touch sensation. *(From Dr. H. K. Kar, with permission.)*

Borderline Tuberculoid (BT) Leprosy BT leprosy (Fig. 179-4) is characterized by either macular or plaque-type lesions numbering three to nine or more and asymmetrically located on any part of the body, with variable sizes and contours. The margins of the lesions range from poorly defined to well defined; sometimes both forms of margin are seen in one lesion. There may be smaller satellite lesions around a larger one, especially on sides where the margin is less defined; this characteristic indicates downgrading of the lesion from TT to BT leprosy. The edges of plaque lesions may slope outward in contrast to TT lesions, which slope inward; plaques may gradually fade outward and eventually blend into normal-looking skin. Loss of sensation is less intense than it is in TT lesions and dryness on the surface less conspicuous. Several peripheral nerves are likely to be enlarged in an asymmetrical pattern, with sensory and motor deficits. One of the most striking features of BT leprosy is susceptibility to a type 1 leprosy reaction (T1R; see below) that exacerbates skin lesions and/or peripheral nerves. If not diagnosed and treated early, disease in these patients tends to downgrade across the spectrum to BB, BL, or LLs leprosy, with an increasing bacteriologic index and a regressed CMI response causing nerve damage along the way. Slit-skin smears show bacteriologic indices varying from negative to 1+.

FIGURE 179-4 Borderline tuberculoid (BT) leprosy. Macular lesion with irregular, moderately defined edge and satellite lesion, with loss of sensation. *(From Dr. W. H. van Brakel, with permission from NLR.)*

Mid-Borderline (BB) Leprosy This form of leprosy is unstable. Many cases downgrade toward BL and LLs disease, especially if not treated. There are multiple plaque lesions and, not infrequently, macular lesions; the lesions are of various shapes and sizes, are bilateral, and usually occur in a more or less symmetrical distribution. In annular lesions, the inner edge is well demarcated and "punched out," and the outer edge is ill defined and merges with normal-looking skin. The surface of the lesions is moderately shiny and the central area looks pale. There is minimal loss of sensation over the lesions. Nerve damage is variable in BB leprosy. Many nerves may be thickened, and this effect may be asymmetrical. BB leprosy is not commonly observed and rapidly changes its spectrum—rarely to BT leprosy but more often to BL disease. The lepromin test is negative. Slit-skin smears of lesions show a moderate number of AFB (2+ to 3+).

Borderline Lepromatous (BL) Leprosy In BL leprosy (Fig. 179-5) there are numerous bilateral, round or oval, macular, diffusely infiltrated, erythematous or hypopigmented lesions with moderately defined borders. The lesions are usually 2–3 cm in diameter, may have a coppery hue, and tend to become symmetrical. Some loss of sensation may be detected, particularly over older lesions; however, no loss of sensation is observed over fresh lesions. With disease progression, papules, nodules, and plaques develop over the macular lesions. In untreated patients, new ill-defined skin lesions continue to develop. Widespread but asymmetrical thickening of peripheral nerves, with or without tenderness, leads to sensory and motor deficits. The lepromin test gives negative results, as it does in all degrees of lepromatous leprosy. Slit-skin smear examination of lesions shows a bacteriologic index varying from 3+ to 4+.

Lepromatous (LL) Leprosy LL leprosy (Fig. 179-6) presents with innumerable bilateral, symmetrically distributed, diffusely indurated, erythematous, copper-colored or skin-colored patches or plaques. There is no loss of sensation over these lesions, which have a smooth, shiny surface. The lesions spread over the face, earlobes, ears, extensor aspects of the upper and lower extremities, back, and buttocks. Induration can readily be recognized when lesions are viewed tangentially under natural sunlight. The induration initially is of a finer type but gradually becomes coarse, and lesions then progress to papules, plaques, and nodules. Bilateral earlobe thickening and eyebrow loss occur. Coarse induration on the face sometimes results in gross skin folds that lead to an appearance referred to as "lion face," particularly when associated with loss of eyebrows and thickening of earlobes. Of all cases of LL leprosy, 10–15% are of the polar type (LLp) from the time of lesion onset; the remaining cases downgrade from the untreated borderline spectrum to subpolar LLs leprosy. Patients with LLs disease develop nerve damage during the borderline stages. In LLp disease, involvement of peripheral nerves occurs late and is bilateral and symmetrical, with sensory loss in a "glove-and-stocking" distribution. Slit-skin smear examination shows a bacteriologic index of 4+ to 6+ with globi.

FIGURE 179-6 Lepromatous (LL) leprosy. Multiple nodules on ears and face and loss of eyebrows. *(From Dr. K. Mponda, Department of Dermatology, Queen Elisabeth Central Hospital, Blantyre, Malawi, with permission.)*

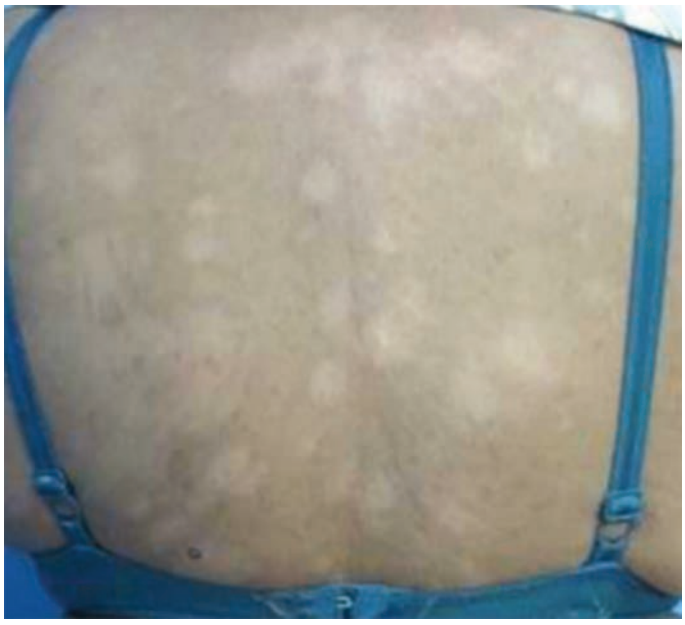

FIGURE 179-5 Borderline lepromatous (BL) leprosy. Numerous diffusely infiltrated erythematous and hypopigmented macules, downgrading from borderline tuberculoid to lepromatous leprosy. *(From Dr. C. L. M. van Hees, Department of Dermatology, Erasmus MC, University Medical Center, Rotterdam, the Netherlands, with permission.)*

SYSTEMIC INVOLVEMENT In LL leprosy, AFB are found in the lymph nodes, spleen, liver, bone marrow, adrenal glands, smooth and striated muscles, tooth pulp, testes, oral cavity, nose, larynx, and eyes. Involvement of the testes leads first to sterility and then to gynecomastia and impotence. Eye involvement includes corneal anesthesia; early on, this manifestation is due to bacillary infiltration of corneal nerves, while later it arises from damage to the ophthalmic division of the trigeminal nerve. In addition, eye involvement includes episcleritis, iridocyclitis, iris atrophy, cataract and glaucoma, lagophthalmos, corneal ulceration and perforation, and blindness. The nose is the portal of entry for *M. leprae* and is the earliest site of involvement in LL leprosy. Edema and mucosal thickening occur in the inferior turbinate and nasal septum, with crusting and epistaxis. Later, patients develop chronic rhinitis with loss of smell sensation. Septal perforation due to bony destruction, with typical saddle-nose disfigurement, is common in advanced LL disease. In late-stage LL leprosy, ulceration of the tongue, pharynx, hard and soft palates (leading to palate perforation), tonsillar pillars, and uvula occurs. In the hands, slow resorption sets in, starting from the distal end of the terminal phalanx and proceeding proximally to involve the middle and proximal phalanges.

HISTOID LEPROSY Histoid leprosy is a rare form of LL leprosy in which waxy, shiny, firm, symmetrical or asymmetrical nodules and plaques are observed over normal-looking skin. Histologic examination of these lesions shows specific spindle-cell granulomas. Slit-skin smear examination reveals high bacteriologic and microbiologic indices without globi in most cases.

DIFFUSE LEPROSY OF LUCIO AND LATAPÍ This rare form of non-nodular LL leprosy occurring in Mexico and Central America is characterized by diffuse shiny infiltration of the skin and widespread sensory loss. The skin looks waxy and has a shiny appearance ("lepra bonita," or beautiful leprosy), with obvious diffuse induration of the earlobes and forehead as well as loss of eyebrows, sometimes eyelashes, and not infrequently all body hair. This form of leprosy can be complicated by an unusual reaction known as Lucio's phenomenon (see below).

Primary Neuritic Leprosy In some countries, such as India and Nepal, primary neuritic disease is observed in 2–10% of all leprosy cases, with only peripheral nerve involvement and no skin lesions. Nerve thickening and sensory loss occur in the affected area, with or without a motor deficit. Primary neuritic leprosy, even though not described by Ridley and Jopling, can manifest at different points along the disease spectrum. For practical purposes, primary neuritic leprosy is classified as paucibacillary or multibacillary on the basis of the absence or presence of AFB in nerve biopsy sections or the number of thickened nerves (single or multiple).

LEPROSY REACTIONS

Leprosy reactions are immunologic phenomena that occur before, during, or after treatment. They are severe complications that need to be diagnosed and treated early to prevent nerve function impairment and subsequent disfigurement as well as blindness.

Type 1 Leprosy Reaction (T1R) T1R is a delayed hypersensitivity reaction associated with sudden alteration of CMI status and leading to a shift in the patient's position on the leprosy spectrum. This reaction is marked by infiltration of lesions by activated CD4+ T lymphocytes, especially T helper cells. T1R is also called a *reversal reaction* because of the upgrading of CMI status. T1R is usually observed in the borderline portion of the spectrum. Skin lesions are characterized by acute swelling and redness **(Fig. 179-7)**. Nerves may be painful and tender because of neuritis, with consequent nerve damage and disfigurement. In the severe form of T1R, nerve abscesses may be formed. Loss of nerve function can be much less obvious than usual when it occurs without other signs of inflammation. This "silent neuritis" may lead to sensory and motor impairment in the hands, feet, and face. Arthralgia or arthritis sometimes occurs. Rarely, the patient may develop fever and malaise, tenosynovitis, and edema of the feet and hands.

Type 2 Leprosy Reaction (T2R) T2R, also known as ENL (erythema nodosum leprosum), is an immune complex–mediated syndrome (i.e., an antigen–antibody reaction involving complement) that causes inflammation of the skin, nerves, and other organs as well as general malaise. ENL is an example of a type III hypersensitivity reaction (Coombs and Gell classification) or Arthus phenomenon. This reaction occurs mostly during multidrug therapy but can also develop in untreated patients. Evanescent, pink-to-red maculopapular, papular, nodular, or plaque lesions suddenly appear and are usually accompanied by constitutional symptoms like malaise and fever, with or without painful swelling in the joints **(Fig. 179-8)**. These crops of skin lesions present on the outer aspects of the thighs, legs, and face. They are painful or tender and warm, blanch with light finger pressure, and last for a few days. The lesions change in color from pink/red to bluish and brownish after 24–48 h and turn dark in a week. Rarely, ENL lesions become vesicular, pustular, bullous, and necrotic and break down to produce ulceration (erythema nodosum necroticans). The patient may have other associated signs such as lymph node enlargement, myositis, arthritis, synovitis, rhinitis, epistaxis, laryngitis, iridocyclitis, glaucoma, painful dactylitis, acute epididymoorchitis, nephritis and renal failure, hepatosplenomegaly, anemia, and—at a later stage—amyloidosis. Severe T2R may include swollen, painful, and tender nerve trunks with sensory and motor deficits.

FIGURE 179-7 Type 1 leprosy reaction. Increased inflammation of existing lesions. *(From Dr. W. H. van Brakel, with permission from NLR.)*

FIGURE 179-8 Type 2 leprosy reaction. Erythema nodosum leprosum, with pustular lesions. *(From Dr. H. K. Kar, with permission.)*

Lucio's Phenomenon Lucio's phenomenon is observed in diffuse leprosy of Lucio and Latapí and may be a variant of erythema nodosum necroticans. Marked vasculitis and thrombosis of the superficial and deep vessels result in hemorrhage and infarction of the skin. Clinically, the skin reaction begins as slightly indurated, bluish-red, ill-defined, painful, and rarely palpable plaques with an erythematous halo, usually developing on one limb but sometimes on other areas of the body. The lesions are irregular or triangular. After a few days, they become purplish at the center; a central hemorrhagic infarct may develop with or without blister formation, and a necrotic eschar that detaches easily and leaves an ulcer of irregular shape may follow later. The ulcer heals, leaving a superficial scar. Patients remain afebrile throughout.

Nerve Function Impairment, Neuritis, and Disfigurement The terms *nerve function impairment*, *nerve damage*, *neuropathy*, and *neuritis* are often used interchangeably for the sensory, motor, and/or autonomic nerve deficits that occur because of the pathologic processes resulting from *M. leprae* infection of the nerve. Neuritis (nerve inflammation) in leprosy is usually a subacute, demyelinating, and unremitting event involving cutaneous nerves and larger peripheral nerves. "Silent neuritis" or "quiet nerve paralysis" is defined as progressive sensory or motor impairment in the absence of symptoms such as pain, paresthesia, or tenderness of the nerve and with no obvious signs of leprosy reactions. Neuritis can occur at any time during leprosy but is more common and severe during leprosy reactions, mainly in T1R. Sensory and motor neuropathy can lead to secondary impairments in the upper and lower extremities, such as muscle atrophy, mobile- and fixed-joint contractures, bone absorption of digits, and cracks and wounds.

Clinical Diagnosis Three cardinal signs indicate a diagnosis of leprosy. The diagnosis can be established when two of these three signs are present:

1. Hypopigmented or erythematous skin lesion(s) with definite loss or impairment of sensation: The clinical presentation of skin patches or plaques is diagnostic when it is associated with a definite loss or impairment of sensation (light touch, pain, and/or temperature). Diagnostic dilemmas arise in the indeterminate stage of leprosy because of variable loss of sensation and the presence of facial lesions (i.e., because the density of innervation in the face can compensate for damage to certain nerve branches).
2. Involvement of the peripheral nerves, as demonstrated by definite thickening with sensory impairment: Thickening of a peripheral nerve should be assessed by palpation of the affected nerve and comparison with the corresponding contralateral nerve. In multibacillary leprosy, thickening of nerves is often bilateral. Nerve tenderness is established by the application of mild pressure on the nerve during palpation with the fingertips. The peripheral nerves commonly palpated in a leprosy patient are the greater auricular, ulnar, radial, radial cutaneous, median, lateral popliteal, posterior tibial, sural, and superficial peroneal nerves.
3. A positive result for AFB in slit-skin smears, establishment of the presence of AFB in a skin smear or biopsy sample, or a positive result in a biopsy PCR.

Diagnostic Tools • ***TESTING OF SKIN SENSATION*** Light-touch sensation is tested with cotton wool or a feather. Pain is assessed as the patient's ability to distinguish between the sharp and blunt ends of a wooden or bamboo toothpick. Thermal sensation thresholds are assessed with computer-assisted sensory testing equipment.

SLIT-SKIN SMEAR Normally a slit-skin smear is taken from four sites: the right earlobe, the forehead above the eyebrows, the chin, and the left buttock in men or the left upper thigh in women. The material is stained with Ziehl-Neelsen reagent and examined with a light microscope. The bacteriologic index is determined with a standard logarithmic scale and graded from 0 to 6. The microbiologic index is determined as the percentage of solid, stained AFB.

SKIN BIOPSY A skin biopsy is done to confirm the diagnosis of leprosy, to classify the disease, to support the diagnosis of reactions, and to determine cure after the completion of multidrug therapy. When macular lesions are suspected of reflecting IL, a biopsy sample should be taken from the middle of a lesion; with plaques, a sample should be obtained from the active indurated edge. When there are numerous skin lesions with different morphologies, more than one biopsy sample is required for proper evaluation of the disease spectrum. Identification of early lesions of leprosy by histopathologic techniques is enhanced by immunochemical staining, which reveals the presence of *M. leprae* antigens.

PGL-1 ANTIBODY TEST PGL-1 is a specific lipid on the *M. leprae* cell wall. A PGL-1 ELISA has been used for serologic diagnosis of leprosy, yielding positive results in 90–95% of multibacillary cases and in 25–60% of paucibacillary cases. Using PGL-1 antigen and adopting an immunochromatographic technique, a rapid lateral-flow assay—the ML flow test—has been developed for detection of antibody to PGL-1. This assay gives positive results in 92–97% of patients with multibacillary leprosy and in 32–40% of patients with paucibacillary disease.

LEPROMIN TEST The lepromin (or Mitsuda) skin test measures cellular immunity against lepromin. A bacillary suspension standardized by the number of inactivated *M. leprae* it contains is injected just under the skin. The reaction to lepromin is measured as induration in millimeters 3–4 weeks after intradermal inoculation. The result provides information about the ability of an individual's T cells to respond to *M. leprae* and the likelihood of granuloma formation in that individual. A negative lepromin test is generally seen in patients with LL or BL leprosy, indicating the lack of a protective cellular response.

GENE AMPLIFICATION (PCR) TECHNIQUE Gene amplification significantly enhances the detection of *M. leprae*, especially in bacteriologic index–negative leprosy and cases that do not fulfill the criteria for the cardinal signs of leprosy. The several PCR methods developed to amplify different gene stretches in *M. leprae* include conventional DNA-based PCR, reverse-transcription PCR, and multiplex PCR. As major genes for detection of disease targets, PCR uses *M. leprae*–specific genes encoding 36-kDa antigen, 18-kDa antigen, 65-kDa antigen complex 85, 16S ribosomal RNA (rRNA), and repetitive sequences. These assays are sensitive to as few as 1–10 bacilli and yield positive results in 60–75% of smear-negative cases. Multiplex PCR employing the genes encoding the repetitive element RLEP, SodA, and 16S rRNA can be used for early diagnosis and for the diagnosis of subclinical infection among household contacts.

Differential Diagnosis Leprosy is often diagnosed late, with a consequent increase in the risk of nerve damage and its ensuing disabilities. The hypopigmented macules of leprosy must be differentiated from a variety of conditions, including pityriasis alba, vitiligo, progressive macular hypomelanosis, pityriasis versicolor, pityriasis rosea, postinflammatory hypopigmentation, sarcoidosis, post–kala-azar dermal leishmaniasis, and morphea. In the analysis of plaques and nodular lesions, conditions such as granuloma annulare, cutaneous sarcoidosis, cutaneous leishmaniasis, lupus miliaris disseminatus faciei, nodular histiocytosis, lupus erythematosus, cutaneous T–cell lymphomas (especially mycosis fungoides), and secondary syphilis should be kept in mind. ENL lesions must be differentiated from erythema nodosum of other etiologies, nodular vasculitis, and cutaneous polyarteritis nodosa. In the case of mononeuropathy lesions, diabetes, amyloidosis, and myxedema must be considered. With polyneuropathy lesions of acute onset, Guillain-Barré syndrome and toxic polyneuropathy must be given consideration.

Diagnostic Tools for Nerve Function Impairment All sensory modalities, autonomic function, and motor function of motor nerves may be affected in leprosy to varying degrees. The modalities mediated by small unmyelinated fibers, such as pain and warm temperature sensation and autonomic function, are often affected first. Clinically detectable impairment of touch sensation and motor function frequently follows after several months. Unfortunately, tools that allow reliable and safe testing of pain and temperature sensation and autonomic function often are not available at peripheral health facilities, but simple and reliable tests of touch sensation and motor function do provide a reflection of the underlying neuropathy.

TOUCH SENSATION TESTING The ulnar and median nerves and the posterior tibial nerve are usually tested for touch sensation. The most reliable test is the Semmes-Weinstein monofilament (SWM) test. If the impairment is of <6 months' duration and/or new nerve function impairment is diagnosed, glucocorticoid treatment should be given. Because filaments are not available in most peripheral health centers, the WHO recommends that a ballpoint pen be used instead. The testing protocol is the same as in the SWM test: the stimulus is delivered by touching the test sites with the tip of a ballpoint pen held at an angle of ~45° relative to the skin.

VOLUNTARY MUSCLE TESTING Motor function of the hands and feet should be evaluated by voluntary muscle testing. The muscle functions most affected in leprosy are eye closure (facial nerve), finger abduction (ulnar nerve), thumb opposition (median nerve), wrist extension (radial nerve), and ankle extension (common peroneal nerve). Strength is assessed with a WHO-recommended system as strong, weak, or paralyzed.

NERVE CONDUCTION TESTS Testing of nerve conduction parameters is sensitive in detecting early signs of peripheral neuropathy in leprosy. Sensory nerve conduction parameters are often affected several months ahead of clinical tests (e.g., the SWM test). However, a trial of glucocorticoid treatment of such early changes did not show improved long-term outcomes, perhaps suggesting that the glucocorticoids are unable to switch off or reverse the pathologic process.

ULTRASOUND TESTING OF NERVES Palpable enlargement of certain peripheral nerves is one of the cardinal signs of leprosy. Definite enlargement is easy to establish, but milder degrees are much harder to diagnose by palpation. Ultrasound imaging and measurement of nerve diameters—even with portable equipment—can detect nerve enlargement accurately. This technique may be used to support the diagnosis of leprosy and may indicate the onset of neuropathy that warrants anti-inflammatory treatment.

OTHER TESTS OF PERIPHERAL NERVE FUNCTION Pain and temperature sensation are commonly affected in leprosy neuropathy. However, these sensations are difficult to test safely and reliably under field conditions. Studies have shown that heat detection thresholds are often affected several months before touch sensation is impaired. Laser Doppler measurement of autonomic vasomotor reflexes is a sensitive method for detection of peripheral autonomic nerve damage in leprosy patients.

TREATMENT

Leprosy, Leprosy Reactions, And Other Major Manifestations

TREATMENT OF LEPROSY

Multidrug Therapy Only one multidrug regimen is recommended by the WHO for the treatment of leprosy. This regimen consists of a combination of two or three of the following drugs: rifampin, dapsone, and clofazimine **(Table 179-1)**. The keystone of WHO-recommended multidrug therapy for multibacillary leprosy is a monthly dose of rifampin together with daily doses of dapsone and daily and monthly doses of clofazimine. Patients with paucibacillary leprosy are treated with two drugs, receiving monthly doses of rifampin and daily doses of dapsone. The treatment duration is 12 months for multibacillary disease and 6 months for paucibacillary disease. Provided that patients complete therapy, treatment failure rates are very low.

Some studies have investigated a uniform regimen of three drugs for 6 months. In a recent systematic review of evidence on the potential benefits and risks of this shorter regimen, the WHO concluded that relevant evidence is limited and inconclusive, with a potential increase in the risk of relapse. Therefore, the WHO does not recommend a shortened treatment duration for multibacillary leprosy.

The WHO further recommends supervised intake, but actual practice varies among countries. Through the WHO, multidrug therapy is provided free of charge as blister packs for adults to all countries reporting leprosy. Blister packs are also provided for 10- to 14-year-olds, while younger children are given doses adjusted according to body weight (Table 179-1).

TABLE 179-1 WHO-Recommended Multidrug Treatment for Leprosy

DRUG, AGE GROUP	PAUCIBACILLARY LEPROSY[a]	MULTIBACILLARY LEPROSY[b]
Dapsone		
Adult	100 mg/d	100 mg/d
Child age 10–14 years	50 mg/d	50 mg/d
Child <10 years	Dose adjusted to body weight	Dose adjusted to body weight
Rifampin		
Adult	600 mg monthly	600 mg monthly
Child 10–14 years	450 mg monthly	450 mg monthly
Child <10 years	Dose adjusted to body weight	Dose adjusted to body weight
Clofazimine[c]		
Adult	—	50 mg/d plus 300 mg monthly
Child 10–14 years	—	50 mg/d plus 150 mg monthly
Child <10 years	—	Dose adjusted to body weight

[a]Duration: 6 doses (6 blister packs). [b]Duration: 12 doses (12 blister packs). [c]In 2018, the World Health Organization (WHO) suggested including clofazimine in the multidrug therapy regimen for paucibacillary leprosy as well, but it is questionable whether this suggestion will be implemented because of the possibility that skin discoloration might compromise compliance. In addition, this alteration would involve a major change in the production of blister packs, which currently do not include clofazimine for paucibacillary leprosy patients (in line with the original WHO recommendation).

Adverse Events • **Rifampin** Rifampin acts by inhibiting DNA-dependent RNA polymerase, thereby interfering with bacterial RNA synthesis. Rifampin is well absorbed orally. Hepatotoxicity may occur with a mild transient elevation of hepatic aminotransferases, but this reaction is rare at the dosages and intervals recommended for leprosy and is not an indication for discontinuation of treatment. Because rifampin is given only monthly in WHO-recommended multidrug therapy regimens, the adverse effects recognized from its use in tuberculosis probably do not occur. A monthly dose of rifampin probably does not cause induction of hepatic cytochrome p450, but this outcome has not been formally assessed. Urine discoloration occurs but is harmless.

Dapsone Dapsone (4,4-diaminodiphenyl sulfone [DDS]) acts by blocking folic acid synthesis and is only weakly bactericidal. Oral absorption is good, and the drug has a long half-life averaging 28 h. Dapsone has a poor safety profile, and its use should be monitored carefully. In the doses recommended for leprosy, it can cause mild hemolysis and may cause anemia or, rarely, psychosis. Glucose-6-phosphate dehydrogenase deficiency seldom causes a problem, and enzyme levels are not routinely tested before the start of multidrug treatment. On the other hand, the "DDS syndrome" (also called the *dapsone hypersensitivity syndrome*) is a severe adverse event that is not uncommon in some countries. It usually develops 6 weeks after the commencement of dapsone administration and manifests as fever, skin rash, eosinophilia, lymphadenopathy, hepatitis, and encephalopathy. Other rare but severe cutaneous adverse reactions are erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, and exfoliative dermatitis. The fatality rate for DDS syndrome is 10%, with death occurring from liver failure, sepsis, and bone marrow failure. Most patients require treatment with systemic glucocorticoids. In all cases, dapsone treatment must be stopped. Agranulocytosis, hepatitis, and cholestatic jaundice occur rarely with dapsone therapy.

Clofazimine Clofazimine is a brick-red, fat-soluble crystalline dye. The mechanism of its weakly bactericidal action against *M. leprae* is not known. High drug concentrations are found in the intestinal mucosa, mesenteric lymph nodes, and body fat. The most noticeable adverse event is skin discoloration ranging from red to purple or black, with the degree of discoloration depending on the dosage. Clofazimine can accumulate in active leprosy skin lesions, thus making them more prominent. The abnormal pigmentation usually fades within 6–12 months of clofazimine discontinuation, although traces of discoloration may remain for up to 4 years. The skin discoloration associated with clofazimine is psychologically distressing for many people. Patients often stop taking the drug because the discoloration is socially disabling for them, alerting their social environment to the fact that they are taking anti-leprosy medication and thus breaking confidentiality about treatment. Urine, sputum, and sweat may become pink during clofazimine administration. Clofazimine also produces a characteristic ichthyosis on the shins and forearms. Adverse gastrointestinal events ranging from mild cramps to diarrhea and weight loss may result from clofazimine crystal deposition in the wall of the small bowel.

Relapse The cure rate for leprosy with multidrug therapy is 99%, but relapse is possible. In multibacillary leprosy, relapse is defined as the multiplication of *M. leprae*, with an increase of at least 2+ over the previous value in the bacteriologic index at any single site;

this change usually occurs in conjunction with evidence of clinical deterioration (e.g., new skin patches or nodules and/or new nerve damage). Relapse rates are well below 1% except among a small proportion of patients who have a very high bacillary load at the start of treatment (bacteriologic index ≥4). In different studies, four to seven relapses were recorded per 100 person-years. These relapses usually occurred <5 years after the end of multidrug therapy. Since antimicrobial resistance to the combination of drugs used in multidrug treatment is rare, patients with relapse can be re-treated with the same multibacillary regimen.

Recognizing a relapse in paucibacillary leprosy can be difficult, as symptoms may resemble T1R. However, relapse of paucibacillary disease is very rare. Administration of a therapeutic trial with glucocorticoids to patients with new lesions may help distinguish between these two phenomena: a definite improvement within 4 weeks of initiation of glucocorticoid therapy indicates T1R, whereas a lack of response favors the diagnosis of a clinical relapse. Patients with multibacillary disease who present with a relapse are re-treated with the multidrug regimen regardless of any change in classification. Patients with paucibacillary disease require 2 years of monitoring after treatment and patients with multibacillary disease at least 5 years. Re-infection by different strains of *M. leprae* is possible and can be confused with relapse.

Rifampin Resistance and Second-Line Drugs Resistance to rifampin has been reported from several countries, although the number of patients involved is small. Evidence on the potential benefits and risks of using alternative regimens for drug-resistant leprosy is not available. Therefore, recommendations provided by the WHO for second-line regimens are based on expert opinion and the known activity of alternative drugs, including the likelihood of cross-resistance. For rifampin-resistant leprosy, the WHO guidelines recommend daily treatment with at least two second-line drugs—clarithromycin, minocycline, or a quinolone (ofloxacin, levofloxacin, or moxifloxacin)—plus clofazimine for 6 months, followed by clofazimine plus one of the second-line drugs daily for an additional 18 months. Leprosy patients infected with *M. leprae* resistant to both rifampin and ofloxacin may be treated daily with the following regimen: clarithromycin, minocycline, and clofazimine for 6 months, followed by clarithromycin or minocycline plus clofazimine for an additional 18 months.

TREATMENT OF LEPROSY REACTIONS

Type 1 Reactions Oral, short-acting glucocorticoids are the treatment of choice for T1R. Prednisolone is used most often in an initial dose of 1 mg/kg of body weight once a day, usually with a maximum of 60–80 mg. If standard treatment protocols are followed, as they are in most leprosy programs in endemic countries, an initial dose of 40 mg of prednisolone is recommended by the WHO. The dose is tapered slowly, usually by 5 mg every 2 weeks over a period of 20 weeks—a schedule that results in better outcomes and lower reaction relapse rates than the previously recommended 12-week glucocorticoid regimen. However, the clinical response should guide treatment. Patients should be examined every 2 weeks, and the examination should include a quick nerve function assessment. Not infrequently, the reaction flares up again once the daily glucocorticoid dose is tapered to <10–20 mg. The potential benefits of longer treatment should be balanced against the risks of prolonged glucocorticoid use, especially at higher doses.

Type 2 Reactions Mild first-time T2R (or ENL) reactions with localized skin nodules may be treated with aspirin and pentoxifylline. If a rapid effect is needed, the most effective drug to date is thalidomide, which rapidly suppresses clinical signs, including nerve impairment and iritis. However, the drug is blacklisted in many countries because of its teratogenicity. If available, it should be given with great caution to women of childbearing age—only after careful counseling and a negative pregnancy test and with strict adherence to contraception. A dose of 100–200 mg is given either once or twice daily. In acute first episodes, thalidomide treatment should be tapered down and stopped after 1–2 weeks. If tissues other than the skin are affected—e.g., the eyes (iritis/uveitis), testes (orchitis), kidneys (nephritis), or joints (arthritis)—longer treatment may be needed until signs and symptoms have resolved. In patients with severe recurrent ENL, a daily thalidomide maintenance dose of 50 mg may be effective in suppressing new episodes. Because of the restricted availability and use of thalidomide, patients with acute ENL are usually treated with glucocorticoids. T2R tends to be transient, often resolving in ~2 weeks. The treatment strategy is therefore to suppress the acute signs and symptoms with high-dose oral prednisolone, quickly tapering treatment in 2–3 weeks either to zero or to a low maintenance dose if the patient has had previous attacks. High-dose clofazimine also is effective in preventing recurrent ENL, but attainment of a maximal effect takes several weeks. The usual regimen is 300 mg daily for 1 month, followed by 200 mg daily for 1 month and, subsequently, 100 mg daily as a maintenance dose for as long as necessary. Prolonged use of high-dose clofazimine may cause significant adverse gastrointestinal effects. An important side effect of clofazimine is a dark discoloration of the skin. While discoloration resolves gradually after the drug is discontinued, it is one main reason that patients dislike or even refuse to take clofazimine.

TREATMENT AND PROGNOSIS OF NERVE FUNCTION IMPAIRMENT

Episodes of sensory or motor nerve function impairment without skin signs are common. Neuropathy may occur without obvious neuritis. Still, the treatment of such "silent neuropathy" is the same as that for T1R. High-dose prednisolone is the drug of choice. Some experts think that patients will benefit from nerve decompression surgery, but evidence from randomized controlled trials is lacking.

If glucocorticoid treatment is started shortly after the development of nerve function impairment, the prognosis for full recovery is good. Generally, some recovery can still be expected up to 6 months after onset, but the likelihood of recovery diminishes with every new episode. Generally, nerve function impairment that has persisted for >6 months does not benefit from glucocorticoid treatment.

TREATMENT OF (NEUROPATHIC) PAIN

Pain is common in people affected by leprosy and is often of neuropathic origin. Little evidence-based information is currently available on the origin and treatment of pain in leprosy. Generally, for the treatment of neuropathic pain, three classes of medication are available: tricyclic antidepressants, phenothiazines, and anticonvulsants (carbamazepine, oxcarbazepine, gabapentin, and pregabalin). These agents can be combined with analgesics and anti-inflammatory drugs according to the patient's needs.

DISEASE MANAGEMENT DURING TREATMENT

Leprosy can be cured effectively, but the long duration of multidrug therapy means that careful management is needed to help the patient complete treatment. Regular visits to a health center may invoke questions from community members that may threaten the patient's privacy, thus causing the patient mental distress and jeopardizing treatment adherence. Counseling is essential, as are patient-friendly arrangements for collecting treatment drugs. The disease, its treatment, and its possible complications should be discussed, including a consideration of disease prognosis, the resolution of skin patches, skin discoloration by clofazimine, the lack of contagiousness during multidrug therapy, and the capacity for unrestricted family relations, including marital life and sexual activity. Possible stigmatization, including self-stigmatization, also should be discussed.

Because of the diverse complications that are possible, especially in patients with multibacillary leprosy, a multidisciplinary approach to patient management is required. In low-income countries, the responsibility for treatment usually lies with a leprosy control officer or a general medical practitioner. In middle- and high-income countries, the main treatment responsibility usually falls to a dermatologist. Additional support should come from a neurologist or

neurophysiologist for the diagnosis of nerve function impairment, and a rehabilitation physician, physiotherapist, infectious disease specialist, and/or psychologist may be needed. Occasionally, specialist support with regard to orthotics as well as in ophthalmology, occupational therapy, reconstructive surgery, and/or community-based rehabilitation is indicated.

Supervised Multidrug Therapy Regular treatment is important, especially the supervised 4-weekly dose of rifampin and clofazimine. However, treatment adherence can be facilitated by flexible arrangements; for example, patients can be allowed to take home more than one 4-week blister pack if they will be away for travel or seasonal labor. In such cases, a family member or another responsible person can be asked to supervise the monthly dose.

Monthly Nerve Function Assessment Since nerve damage can be insidious and silent, it is important to conduct a brief nerve function assessment at each clinic visit during multidrug therapy. This regular assessment is especially important in patients with known risk factors for nerve function impairment. At highest risk are patients with multibacillary disease, who already have nerve damage at the start of treatment. Their risk of additional nerve damage is as high as 65%. Multibacillary leprosy patients without nerve function impairment at diagnosis and paucibacillary leprosy patients *with* such impairment at diagnosis have a 16% chance of developing damage and additional damage, respectively. Patients with paucibacillary disease who do not have nerve function impairment at diagnosis are at lowest risk (3%); for them, an assessment at the start and completion of multidrug therapy can be sufficient. Leprosy reactions and new nerve damage may also occur after completion of multidrug treatment. While the risk diminishes with time, these manifestations can occur up to 3 years after the conclusion of therapy.

Health Education During treatment, patients will have questions that need to be addressed in order to ensure their treatment adherence. Sensitive questions may arise regarding everyday life within the family and at work that, if not addressed properly, could lead to social withdrawal and mental health issues. Crucial points for health education are at diagnosis and at completion of treatment. When communicating the diagnosis, the physician must explain that the disease is caused by a curable microbial infection and must cover the possible discomforts of drug intake, the interruption of disease transmission through drug intake, and the importance of adhering to treatment to achieve a cure. At the completion of multidrug therapy, the emphasis should be on separating the concept of cure (bacterial activity) from the sequelae of the disease (nerve function impairment, leprosy reactions, and disabilities) and explaining that the patient may need to continue receiving health care, including reconstructive surgery, for the sequelae. Patients often associate cure with the absence of symptoms, which is not accurate in leprosy. Some patients will experience discomfort during bacterial activity but will have no sequelae after treatment. In others, nerve function impairment or leprosy reactions may cause disfigurement with physical discomfort after cure; these sequelae will need further management. Disabilities such as claw hand or neuropathic foot require chronic care.

Guidelines after the Completion of Multidrug Therapy Patients should receive counseling at release from treatment. The topics covered should include reassurance that the person is no longer contagious, that in some patients hypopigmentation in skin lesions may not resolve for a long time, and that skin discoloration due to clofazimine will gradually disappear in the following months. Nerve impairment may continue to improve after release from treatment, but this is by no means certain. Most important, patients should be instructed to return to the clinic if any new skin signs or fresh nerve damage occurs. This situation is not uncommon, is usually due to a leprosy reaction, and should be managed carefully from both a medical and a social perspective, since patients and persons in their environment will interpret this development as "leprosy coming back." Patients at risk of further episodes of reaction and/or additional nerve function impairment (e.g., patients with preexisting nerve function impairment and multibacillary infection or patients who have experienced a reactional episode during therapy) should be asked to return for a check-up every 6 months for at least 3 years after being released from treatment.

REHABILITATION AND SOCIAL ASPECTS

Physical Rehabilitation Peripheral neuropathy and its secondary disabling consequences often require physical rehabilitation. This effort may include reconstructive surgery in the case of facial, ulnar, median, or posterior tibial paralysis. In this case, pre- and postoperative physical therapy is of crucial importance. Physical therapy is also indicated when muscles are not completely paralyzed or when contractures are too stiff to allow surgery. Since paralysis is usually accompanied by sensory and autonomic neuropathy, occupational therapy also is helpful; therapists teach patients how to minimize the risk of further injury and other techniques for prevention of disabilities. The key principle is teaching patients and former patients to self-manage their disabilities. In many programs, this teaching occurs in the setting of self-care groups. A well-tested and evidence-based self-care routine for hands and feet consists of inspection, soaking, scraping, and oiling (ISSO). Specifically, in ISSO, the person inspects the affected limbs for hotspots (evidence of too much stress on an area of skin): wounds, cracks, and calluses. Next the affected limb(s) are soaked in plain water for 15 minutes. While the skin is wet, areas with excess calluses are scraped with a rough stone or another rough object. The skin is then rubbed with petroleum jelly or another nonfragrant oil in order to trap moisture in the skin. If this routine is performed daily, the skin can be kept supple and in good condition, despite sensory and autonomic damage. If sensation on the soles of the feet is impaired, the person must wear protective footwear. Simple footwear (e.g., sandals or sneakers) available at the local market is adequate as long as it has a strong sole and a soft insole of ethylene-vinyl acetate or microcellular rubber that distributes pressure—an especially important feature when foot muscles are weak or paralyzed or the architecture of the foot is damaged, as is often the case with neuropathy. In high-resource settings, tailor-made orthopedic shoes can be provided.

Mental and Social Support Like other chronic health conditions, leprosy requires patients to cope with the burden of new routines in everyday life. In addition to coping with stigma, they must organize themselves for prolonged treatment, prevention of disabilities, and rehabilitation activities. Moreover, like other neglected tropical diseases (see "Neglected Tropical Diseases," below), leprosy may lead to poor mental health. Such diseases are accompanied by social exclusion in the form of poor access to services such as health care, education, employment, and housing. This exclusion accounts for common mental health comorbidities in leprosy patients and their family members, including depression, anxiety, and suicidal thoughts. Leprosy is probably the most notorious of all stigmatized health conditions, and social stigmatization is the most common issue that triggers mental suffering. Other infectious diseases that raise this issue include HIV infection, tuberculosis, and neglected tropical diseases like lymphatic filariasis, Buruli ulcer, and dermal leishmaniasis. Although the reasons for stigmatization vary, the manifestations and interventions that effectively reduce stigma are similar across conditions and countries. Therefore, joint interventions addressing health-related stigmas for multiple conditions would be strategically and financially attractive. The need to introduce mental health care in leprosy services is pressing. Therapeutic group meetings among institutionalized patients and self-care groups at the community level, with a focus on prevention of disabilities and mental well-being, are known to ameliorate depression, encourage self-acceptance, and promote confidence.

NEGLECTED TROPICAL DISEASES Leprosy is one of a medically diverse group of 20 neglected tropical diseases (NTDs). This group includes infectious diseases caused by bacteria, viruses, fungi, and parasites as well as some noninfectious conditions, such as podoconiosis and snakebite. NTDs have been grouped together because they affect

1.5 billion of the poorest people on Earth and have been widely neglected in domains such as public policy, funding, and the development of diagnostics and treatments. Leprosy is the archetypical NTD, featuring all of the common characteristics: a treatable infectious disease, a known population at risk, available preventive chemotherapy, disease complications that may lead to severe disabilities, and a pervasive social stigma that leads to discrimination, social exclusion, and severe mental health consequences. Nevertheless, the priority accorded to leprosy on the public health agenda of most endemic countries is very low. By joining hands in advocacy, fundraising, and development of joint control strategies, health care organizations can substantially raise the priority profile of NTDs, benefiting each of the individual disease control programs. Such a joint approach serves the goal of universal health coverage and helps to strengthen health services more effectively than vertical programs are ever able to do on their own.

PREVENTION AND CONTROL

Interruption of Transmission and Novel Preventive Strategies Leprosy control was traditionally based on early case detection and multidrug treatment. Apart from health education and leprosy awareness campaigns, no preventive measures were available. In the 1990s, authorities hoped that the transmission of *M. leprae* in the community could be interrupted through timely detection of cases and provision of multidrug therapy, leading to a decline in leprosy incidence. Unfortunately, this has not been the case (Fig. 179-1). The inability to reduce leprosy incidence in many countries and the heightened interest in neglected tropical diseases have invigorated research into new techniques for the diagnosis of disease and infection, leprosy vaccines, enhanced postexposure chemoprophylaxis regimens, epidemiologic tools (e.g., geographic information systems for identifying leprosy hotspots), surveillance of antimicrobial resistance, and alternative drugs and drug treatment regimens.

Vaccines against Leprosy The bacille Calmette-Guérin (BCG) vaccine used against tuberculosis provides varying degrees of protection against leprosy and is used routinely as postexposure immunoprophylaxis for contacts of leprosy patients in Brazil. Two promising vaccine candidates are in the pipeline: the MIP vaccine from India, which is based on killed *Mycobacterium indicus pranii,* and the synthetic LepVax vaccine developed by the University of Washington's Infectious Disease Research Institute in the United States. If proven effective, these vaccines, like the BCG vaccine, will be used as postexposure prophylaxis for contacts of leprosy patients. Trials are in early stages, and sufficient proof of efficacy will take years.

Postexposure Chemoprophylaxis The introduction of postexposure chemoprophylaxis (PEP) for household and other close contacts of leprosy patients is an important innovation. A large randomized controlled trial has shown that single-dose rifampin, given once to household contacts, neighbors, and social contacts, reduces the recipients' risk of leprosy by ~60%. Implementation studies have shown that PEP with single-dose rifampin is feasible and well accepted by patients, contacts, and health workers in a variety of health care settings. Furthermore, modeling studies have indicated the potential impact of PEP on transmission of *M. leprae* in endemic populations. This intervention was included in the 2018 WHO Guidelines for the Diagnosis, Treatment, and Prevention of Leprosy and is currently being introduced in many countries. Research is ongoing into enhanced PEP regimens for those close contacts who are at increased risk of leprosy (e.g., blood-related household contacts and close contacts of multibacillary leprosy patients).

"Zero Leprosy" The WHO has formulated its new Global Leprosy Strategy 2021–2030. As in the organization's previous strategy, a holistic approach to leprosy control is advocated, focusing on zero infection and disease, zero disability, and zero stigma and discrimination. For 2030, the WHO is setting ambitious targets of achieving 120 countries with zero new autochthonous leprosy cases, reducing the annual number of new cases detected by 70%, reducing the rate of new cases with grade 2 disability per million population (as a proxy for detection delay) by 90%, and reducing the rate of new child cases with leprosy per million children (as a proxy for recent transmission) by 90%. Widespread implementation of PEP with single-dose rifampin is one of the key strategies to achieve these goals. The "Triple Zero Strategy" (*zeroleprosy.org*) has also been embraced by the partners united in the Global Partnership for Zero Leprosy, the International Federation of Anti-Leprosy Associations, the Novartis Foundation, the Sasakawa Health Foundation, and the International Association for Integration, Dignity, and Economic Advancement.

The outlook for achieving "zero leprosy" in the coming decades is better than ever before, but this goal is admittedly very ambitious. It can be reached only when all leprosy-endemic countries enhance their leprosy control activities to include (1) active case-finding strategies, including improved diagnosis; (2) contact screening; (3) implementation of PEP; (4) improved prevention of disability services; and (5) activities to reduce stigma and discrimination and to promote the social inclusion and mental well-being of affected patients and their families. Coincident with these efforts, an important threat must be confronted. With the waning of interest in leprosy and the integration of management of the disease into nonspecialized health systems, the number of medical doctors and health workers at the primary care level who have experience in diagnosing and treating leprosy has decreased substantially all over the world. Once lost, expertise is difficult to regain. Therefore, new energy and resources need to be invested in bolstering technical capacity for all aspects of leprosy services, with a view to strengthening the health system in an integrated way and leaving no one behind.

180 Nontuberculous Mycobacterial Infections

Steven M. Holland

Several terms—nontuberculous mycobacteria (NTM), atypical mycobacteria, mycobacteria other than tuberculosis, and environmental mycobacteria—all refer to mycobacteria other than *Mycobacterium tuberculosis*, its close relatives (*M. bovis*, *M. caprae*, *M. africanum*, *M. pinnipedii*, *M. canetti*), and *M. leprae*. The number of identified species of NTM is growing and will continue to do so because of the use of DNA sequence typing for speciation. The number of known species currently exceeds 199. NTM are highly adaptable and can inhabit hostile environments, including industrial solvents.

EPIDEMIOLOGY

NTM are ubiquitous in soil and water. Specific organisms have recurring niches, such as *M. simiae* in certain aquifers, *M. fortuitum*

in pedicure baths, and *M. immunogenum* in metalworking fluids. Most NTM cause disease in humans only rarely unless some aspect of host defense is impaired, as in bronchiectasis, or breached, as by inoculation (e.g., liposuction, trauma, cardiac surgery). There are few instances of human-to-human transmission of NTM, which occurs almost exclusively in cystic fibrosis. Because infections due to NTM are rarely reported to health agencies and because their identification is sometimes problematic, reliable data on incidence and prevalence are lacking. Disseminated disease denotes significant immune dysfunction (e.g., advanced HIV infection), whereas pulmonary disease, which is much more common, is highly associated with pulmonary epithelial defects but not with systemic immunodeficiency.

In the United States, the incidence and prevalence of pulmonary infection with NTM, mostly in association with bronchiectasis **(Chap. 290)**, have for many years been several-fold higher than the corresponding figures for tuberculosis, and rates of the former are increasing among the elderly as rates of tuberculosis continue to fall. Among patients with cystic fibrosis, who often have bronchiectasis, rates of clinical infection with NTM range from 3% to 15%, with even higher rates among older patients. Although NTM may be recovered from the sputa of many individuals, it is critical to differentiate active disease from commensal harboring of the organisms. A scheme to help with the proper diagnosis of pulmonary infection caused by NTM has been developed by the American Thoracic Society and is widely used. The bulk of nontuberculous mycobacterial disease in North America is due to *M. kansasii*, organisms of the *M. avium* complex (MAC), and *M. abscessus*.

In Europe, Asia, and Australia, the distribution of NTM in clinical specimens is roughly similar to that in North America, with MAC species and rapidly growing organisms such as *M. abscessus* encountered frequently. *M. xenopi* and *M. malmoense* are especially prominent in northern Europe. *M. ulcerans* causes the distinct clinical entity Buruli ulcer, which occurs throughout tropical zones, especially in western Africa. *M. marinum* is a common cause of cutaneous and tendon infections in coastal regions and among individuals exposed to fish tanks or swimming pools.

The true international epidemiology of infections due to NTM is hard to determine because the isolation of these organisms often is not reported and speciation often is not performed for *M. tuberculosis* or NTM. The latter issue poses an especially important problem during therapy for tuberculosis when smears positive for acid-fast bacilli are considered evidence of treatment failure. The increasing ease of identification and speciation of these organisms is already having a major impact on the description of the dynamic international epidemiology of tuberculosis and NTM infections.

PATHOBIOLOGY

Because exposure to NTM is essentially universal and disease is rare, it can be assumed that normal host defenses against these organisms must be strong and that otherwise healthy individuals in whom significant disease develops are highly likely to have specific susceptibility factors that permit NTM to become established, multiply, and cause disease. At the advent of HIV infection, CD4+ T lymphocytes were recognized as key effector cells against NTM; the development of disseminated MAC disease was highly correlated with a decline in CD4+ T lymphocyte numbers. Such a decrease has also been implicated in disseminated MAC infection in patients with idiopathic CD4+ T lymphocytopenia. Potent inhibitors of tumor necrosis factor α (TNF-α), such as infliximab, adalimumab, certolizumab, golimumab, and etanercept, neutralize this critical cytokine, with consequent inhibition of granuloma formation. The occasional result is severe mycobacterial or fungal infection; these associations indicate that TNF-α is a crucial element in mycobacterial control. However, in cases without the above risk factors, much of the genetic basis of susceptibility to disseminated infection with NTM is accounted for by specific mutations in the interferon γ (IFN-γ)/interleukin 12 (IL-12) synthesis and response pathways.

Mycobacteria are typically phagocytosed by macrophages, which respond with the production of IL-12, a heterodimer composed of IL-12p35 and IL-12p40 moieties that together make up IL-12p70. IL-12 activates T lymphocytes and natural killer cells through binding to its receptor (composed of IL-12Rβ1 and IL-12Rβ2/IL-23R), with consequent phosphorylation of STAT4. IL-12 stimulation of STAT4 leads to secretion of IFN-γ, which activates neutrophils and macrophages to produce reactive oxidants, to increase expression of the major histocompatibility complex and Fc receptors, and to concentrate certain antibiotics intracellularly. Signaling by IFN-γ through its receptor (composed of IFN-γR1 and IFN-γR2) leads to phosphorylation of STAT1, which in turn regulates IFN-γ-responsive genes, such as those coding for IL-12 and TNF-α. TNF-α signals through its own receptor via a downstream complex containing the nuclear factor κB (NF-κB) essential modulator (NEMO). Therefore, the positive feedback loop between IFN-γ and IL-12/IL-23 drives the immune response to mycobacteria and other intracellular infections. These genes are known to be the critical ones in the pathway of mycobacterial control: specific Mendelian mutations have been identified in *IFNGR1*, *IFNGR2*, *STAT1*, *GATA2*, *ISG15*, *IRF8*, *IL-12A*, *IL-12RB1*, *IL-12RB2*, *CYBB* (which encodes the gp91*phox* protein of the NADPH oxidase), *SPP2A*, and *IKBKG* (which encodes NEMO) **(Fig. 180-1)**. Despite the identification of genes associated with disseminated disease, only ~70% of cases of disseminated nontuberculous mycobacterial infections that are not associated with HIV infection have a genetic diagnosis; the implication is that more mycobacterial susceptibility genes and pathways remain to be identified.

In contrast to the recognized genes and mechanisms associated with disseminated nontuberculous mycobacterial infection, the best-recognized underlying condition for pulmonary infection with NTM is bronchiectasis **(Chap. 290)**. Most of the well-characterized forms of bronchiectasis, including cystic fibrosis, primary ciliary dyskinesia, STAT3-deficient hyper-IgE syndrome, and idiopathic bronchiectasis, have high rates of association with nontuberculous mycobacterial infection. The precise mechanism by which bronchiectasis predisposes to locally destructive but not systemic involvement is unknown.
